Before the decision was announced, concern had been freely expressed within and outside the universities as to the adequacy of the support provided for academic research, and some fear expressed that the coming quinquennium might be unduly stringent. In the debate on April 5, the Government was taxed with unloading research on the universities from the Department of Scientific and Industrial Research, the Agricultural Research Council and the Medical Research Council. Neither Mr. Brooke nor Sir Edward Boyle replied to this charge, which can perhaps well await the report of the inquiry into the organization of civil research which the Minister for Science has already implemented. Meanwhile, however, the need for the universities to have available adequate funds for research in their own right cannot be too strongly emphasized, and this is a vital factor in their ability to recruit and attract staff of the highest quality.

The scale and quality of the research facilities available are a dominant factor in building up a university science department of high quality as is well brought out by the Institute of Physics and the Physical Society in their evidence to the Robbins Committee, and it would be foolish to deny that it affects the migration to the United States of leading scientists. None the less, it is difficult to assess how serious is such migration. Probably no salary scale that is practicable in British universities can have much effect provided the scale does not compare too unfavourably with those existing in comparable professions in Britain. The nature of the facilities available and the scale of financial support are far more likely to be determinants. It would appear that the Government has given far too little weight to the need for the universities to increase the scale of their research effort in asking them to attempt to increase the number of students by 35 per cent with the recurrent grants now announced.

While there is substance in the charge that the Government in willing the end has failed to will the means, there is rather more to be said for the Government than many of its critics have conceded, and probably the most serious charge to be brought against the Government is that it has not been entirely honest. As Mr. Brooke quite rightly emphasized, the final responsibility for deciding how much Britain can spend on university education and on higher education generally must rest with the Government: it cannot be bound to accept the advice of the University Grants Committee in that respect. It is bound, however, to ensure that the Committee does not spend its time unprofitably, and when for good and convincing reasons the Government believes that economic circumstances put a strict limit on the nation's expenditure in that direction, good management would have suggested that the University Grants Committee should have been advised before and not after they formulated their quinquennial proposals.

It was also appropriate that both Sir Edward Boyle and Mr. Brooke should point out that university expansion does not provide the only means of providing increased opportunities in higher education. It is too readily assumed that a university education is necessarily the best means of developing the talents of the gifted adolescent. Quite apart from the 22,000 places which will be available in the colleges of technology, other institutions of higher education have an important contribution to make, and the Robbins Committee is at present endeavouring to assess the relative significance of the various alternatives. Nor is the present structure of university education to be taken as sacrosant. Even without sacrifice of academic standards, it is possible that substantial economies in the cost per student could be achieved, quite apart from the use of new methods of teaching on which research is only now being prosecuted.

All this comes within the purview of the Robbins Committee, but in the meantime it is probable that, with the development of the new universities, the cost per student may rise appreciably in the near future. It is only right that the Government should have clearly in mind the possibility of the present expenditure on education rising to more than £1,000 million a year in a few years time and that university education should not be treated as something apart. What is not reasonable is that while these questions are being explored with what can only be assumed to be the fullest possible expedition, the Government should take action which not only threatens to prejudice the work of the Robbins Committee but also to cause frustrations and waste that endanger the effectiveness of expansion in any way.

This, however, is exactly what it is manifest that the Government's handling of the whole situation has done. They have failed either to take the University Grants Committee into their confidence or, noting an unequivocal warning which the Zuckerman Report addressed to them only last August, to hold their hand and take decisions on the basis of the Robbins report when it is received. In consequence, they have brought into question the adequacy of the administrative arrangements through the University Grants Committee which they profess to respect and have created feelings of anxiety and frustration among its members and the responsible authorities in the universities which can scarcely conduce to efficiency. Thus, there are grounds for asking whether the Government really believes that the universities and the colleges of technology, for example, are a real factor in industrial and economic development.

Nor is this all. However reasonable in theory the Government's objectives, the execution of that policy in practice could scarcely have been more inept. Besides bringing organization into disrepute, it has contrived to create feelings of frustration and exasperation among a body of responsible men and women whose whole attitude to questions of salary has been marked by restraint and patience. If this were not enough, it also threatens to cause further deterioration in the conditions of service and general attractiveness of academic life, which to many of them are far more determinant than salary. There is no sign that the Government even yet appreciates the seriousness of the situation or the urgency of, at the least, being ready to overhaul the scales of salary at an appropriate moment by the proper means with the utmost despatch. On the contrary, it appears all too likely that the situation is being allowed to drift while tendencies develop which it will be far from easy to dispel and which may prevent all hope of achieving anything like the target of university expansion which even the Government has set within the next decade. Plausible as were some, even most, of the arguments presented for the Government in the debate on April 5, they fail altogether to take account of the mischief wrought by the Government's own handling of the whole question—its refusal to recognize that it is the putting of pressure on the universities which limit their ability to deal according to their own judgment with the problems that confront them, its unwillingness to face the existing situation and provide what is required while the Robbins Committee provides the facts on which a long-term policy can be based, or to say honestly that it believes Britain to be too poor to provide for university expansion to meet the needs of an expanding population except by a drastic cut in standards both in the universities themselves and those who teach and work in them.

FABRICATION OF REACTOR FUELS

Fuel Element Fabrication with Special Emphasis on Cladding Materials

(Proceedings of a Symposium held in Vienna, May 10–13, 1960.) Vol. 1. Pp. xi + 538. 100*s*. Vol. 2. Pp. xii + 384. 71*s*. 6*d*.; 10 dollars; 260 Austrian schillings (London: Academic Press, Inc. (London), Ltd.; New York: Academic Press, Inc., 1961. Published for the International Atomic Energy Agency.)

THE primary functions of the cladding on a fuel element are to prevent (*a*) the escape of fission products into the coolant, and (*b*) attack of the fuel by the coolant. A most important factor, however, is to keep the ratio of the volume of canning material to that of the fuel as low as possible, and hence to reduce the parasitic loss of neutrons to a minimum while ensuring complete integrity of the can throughout the life of the fuel element. The object of the symposium, arranged by the International Atomic Energy Agency, was to review the work being undertaken at present on fuel elements and cladding materials in particular, to reduce costs in fuel-cycle and to improve the economics of atomic power.

Volume 1 of the proceedings contains twenty-eight papers from nine countries collected under two general headings "Characteristics of Cladding Materials" and "Fuel Element Fabrication". The subject-matter ranges over problems associated with the more popular canning materials, including stainless steel and alloys based on zirconium, aluminium, magnesium and beryllium, with the greatest accent on zirconium cans for steam and water-cooled reactors.

Canadian experience of the behaviour of zirconium alloys is described in two papers which discuss the pick-up of hydrogen during corrosion and its effect on the mechanical properties, the advantages of Zr–Nb–Sn alloys over zircaloy-2, the consequence of neutron irradiation and the possible economical advantages of modifying the design and methods of fabrication of zirconium-clad uranium dioxide fuel elements. The development of zircaloy-4 in the United States to decrease the hydrogen pick-up on corrosion in water and steam up to 400° C. is described, and a Swedish paper outlines the possible improvement in the mechanical properties of zircaloy-2 by suitable heat-treatment. Another Swedish author details pickling treatments for zirconium components and two German papers survey the production and welding of zircaloy tubes. Workers from the United States describe the fabrication of flat-plate elements of uranium dioxide clad in zircaloy which are pressure-bonded and include chromium or graphite diffusion barriers to prevent interaction between fuel and can.

Swedish tests on various aluminium alloys indicate that Al–Mg–Si alloys may be suitable for application in water-cooled reactors at 160° C., whereas Al–Mg and Al–Mg–Ni alloys are susceptible to intercrystalline corrosion under these conditions. The fabrication and testing carried out in the United Kingdom of material testing reactor fuel elements are described both for standard components and for hollow elements which can be used for irradiation esperiments in a fast neutron flux. As an alternative to the standard "picture frame" technique described by the British, Belgian authors give details of the rolling of material testing reactor fuel elements from Al–U billets around which the aluminium sheath has been cast. The present state of knowledge on the suitability of sintered aluminium powder as a canning material is summarized by European authors, including its formability, mechanical properties and compatibility with both uranium and uranium dioxide fuels and with steam at 500° C.

Several papers deal with the production and impregnation of graphite for high-temperature gas-cooled reactors, including one on the German manufacture of spherical graphite elements. A Belgian paper describes the fabrication of elements for an experimental swimming pool reactor which consist of uranium dioxide particles dispersed in impregnated graphite. The varied applications of austenitic steels are well illustrated by papers dealing with elements for helium-cooled reactors (with can temperatures up to 700° C.), organic liquid moderated reactors and liquid sodium cooled reactors. Workers in the United States describe the hot extrusion of stainless steel clad elements in which from 91·3 to 100 per cent theoretical density of the uranium dioxide fuel has been obtained. Other papers include details of French fabrication of elements canned in magnesium *ZA* alloy (containing 0·6 per cent zirconium), of British facilities for fabrication of beryllium components, including the precautions necessary to shield the operators from hazards arising from the toxicity of the metal, and of the plant available in Trombay, India, for manufacturing various types of fuel elements.

With such a miscellany of topics as those covered by the papers, a subject-index is essential and this, along with an author-index, is provided at the end of the volume. As is usual for a symposium of this kind, there is a wide variation in the quality of the papers presented, but nevertheless there is a wealth of new data on many of the materials and processes discussed. The full text of most of the papers is in English with a few others in French, but abstracts are provided in each case in English, French, Russian and Spanish.

Volume 2 includes the remaining twenty-two papers presented at the symposium by authors from nine countries under three main headings, "Quality Control and Inspection", "Corrosion and Radiation Damage" and "Economics and General Trends in Development". The most interesting and novel inspection technique described is in a British paper which details work on microradiography of a variety of components both before and after irradiation. Other papers deal with the inspection of zircaloy tubes for the Swedish heavy-water-cooled reactor, helium leak-testing of elements for the French *G*2 reactor and the types of defect observed in swaged stainless-steel-clad uranium dioxide elements by Japanese workers.

On compatibility problems, Australian authors describe tests on stainless steel in carbon dioxide, and discuss the mechanism of the oxidation of beryllium in wet carbon dioxide and the factors that affect breakaway oxidation, while a French paper deals with the oxidation of magnesium alloys in carbon dioxide. A German paper reports on an investigation of the diffusion-rate of certain metallic fission products through sintered aluminium products, and the effect of various alloying additions on the creep properties of this cladding material at 350° C. and its corrosion behaviour in water at 300° C. and in steam at 400° C. The general effects of radiation on various metals and alloys are summarized by a British author; these include the formation of dislocation loops in aluminium and copper and of helium gas bubbles in beryllium, copper and aluminium as identified by electron microscopy of both replicas and thin sections. American experience is given of the irradiation behaviour of various canning materials with special reference to the variability of the effect of irradiation on the pick-up of hydrogen in zirconium alloys. The examination of irradiated Calder-type fuel elements at Windscale has made a big contribution to the improvement of the design of fuel elements for British civil power stations and the facilities for doing this tedious work are described.

In a paper from the United States on the economic factors associated with design variations in fuel elements for water reactors, it is concluded that there is little advantage in using annular uranium dioxide pellets with stainless steel as the cladding material. A development gained in the United States is described for coating uranium dioxide particles with metals prior to compacting to increase thermal conductivity and retention of fission product gases. Descriptions of other bonding techniques for improved performance are given by the Belgians (bonding uranium fuel to an aluminium can with nickel) and the Italians (uranium dioxide particles dispersed in liquid lead in a sintered aluminium product canned fuel element for organic liquid-cooled reactors). The French detail the fabrication on fuel elements for gas-cooled reactors and discuss the problems associated with the manufacture of their 'snow crystal' elements, which consist of clusters of aluminium tubes containing uranium dioxide. Two papers illustrate the considerable effort being directed in the United States towards improved methods of fabricating fuel elements containing uranium dioxide, of which the most promising technique appears to be the vibration compacting of uranium dioxide powder followed by swaging; the novel use of yttrium as a can for liquid fuels is also mentioned. A historical description of fuel element research and fabrication in the United Kingdom includes cost estimates of the various phases of the development work required.

As with Volume 1, the papers vary in quality and detail and include data which have been published previously. However, taken as a whole, they give a reasonably clear picture of the effort required to ensure the highest integrity in fuel elements and to develop a real measure of improvement in the processes used for their manufacture. Both author- and subject-indexes are provided.

B. W. Mott

IONIZATION PHYSICS

Ionization Phenomena in Gases

By Dr. Gordon Francis. Pp. vii+300. (London: Butterworths Scientific Publications, 1960.) 60*s*.

Dr. Francis has excellent qualifications for writing a book on ionization phenomena in gases and has made good use of them. His book is written mainly for those finishing their degrees and those beginning research but will in fact, by virtue of the choice of material and breadth of treatment, be eagerly read by a much wider public with an interest in the behaviour of ionized media. Throughout the book the emphasis is on the understanding of the physical principles of ionization processes and the linking together of a wide range of physical phenomena involving ionization.

The first chapter is a brief one devoted to the nuclear atom, spectra, spectroscopic notation and the concepts of excitation, ionization and the conduction of electricity in a gas. Chapter 2 gives an account of fundamental collisional, excitation, ionization and deionization processes in gases and at electrode surfaces and treats the behaviour of swarms of charged particles in gases. The succeeding chapters are devoted to detailed accounts of several special and important subjects in ionization physics and their applications. Thus, in the third chapter the similarity principle in discharges is dealt with at length and some applications to a number of types of discharge are examined. Alternating and high-frequency discharges at low and high gas pressures in various electric field configurations are treated extensively in the succeeding chapter and applications considered include nuclear particle detection, high-temperature welding and plasma diagnostics. Excitation and ionization in the upper atmosphere, the reflexion, scattering and absorption of radio waves and the physical processes responsible for these phenomena are examined in Chapter 5, which also includes a short account of aurora. The sixth chapter deals with some selected topics of very recent investigations in thermonuclear and plasma physics. The theory of the high-current pinched discharge, the phenomena of the collapse of the pinched discharge, skin effect and instabilities are developed in a clear manner. Some of the practical devices aimed at producing high-temperature gas discharges and controlled fusion reactions are described. The final chapter is a highly concentrated treatment of oscillations and waves in ionized media. Six very useful appendixes are included in the book; these give the Periodic Table and electron configuration of the elements, critical potentials of elements and compounds, some physical constants, a neat derivation of the Boltzmann transfer equation and finally, specialized references to very recent developments in branches which could not be treated at length in the book.

Dr. Francis's book is well written in a refreshing and stimulating manner. It contains a wealth of information which will not be found in many other books and which can otherwise be obtained only by extensive literary research. The book can be highly recommended to anyone with an interest in ionization physics.

C. GREY MORGAN

BILIARY CIRRHOSIS OF THE LIVER

Biliary Cirrhosis

By Sir Roy Cameron and P. C. Hou. (Pathological Monographs, No. 1). Pp. x+214. (Edinburgh and London : Oliver and Boyd, Ltd., 1962.) 63*s*. net.

THIS volume is the first of a series of monographs on clearly defined pathological subjects under the general editorship of Sir Roy Cameron and Prof. G. Payling Wright. In their general introduction to the series, they stress the indebtedness of pathology to the 'basic' sciences of biochemistry, biophysics and genetics. Both the editors are eminent pathologists, and it is doubtless due to their innate modesty that they refrain from pointing out that this intellectual traffic has not been entirely one way; pathology and medicine in general have provided fruitful stimuli to research in the more basic sciences in the past, as it is to be hoped they will continue to do in the future.

Sir Roy himself is joined by Prof. Hou Pao-chang, until recently professor of pathology in the University of Hong Kong, in the authorship of this excellent first monograph. Biliary cirrhosis is a term covering many pathological pictures in the liver which are by no means obviously interrelated. Nevertheless, the title gives to pathologists a clear idea of the ground to be covered, and it will be invaluable to have available in this convenient form the history of clinical, morphological, physiological and experimental research into this complex subject, and the present status of knowledge about it. The authors make clear where the gaps in knowledge lie, and this book will be essential reading for future investigators in this field of study.

Part 1, consisting of five chapters, gives a full but succinct account of the anatomy, embryology and physiology of .the biliary apparatus ; a particularly useful section is devoted to the experimental work which has been done on bile-duct regeneration, and in which Sir Roy Cameron himself has played a distinguished part over the past thirty years.

Part 2 is concerned with the pathology of human biliary cirrhosis. It recapitulates (Chapter 6) earlier classifications, and gives sound reasons for not adding to their number. Chapters 7 and 8 deal with secondary (obstruction of extra-hepatic ducts) cirrhosis and with congenital types. Chapters 9–12 are concerned with the various forms of primary biliary cirrhosis, that is, those where extra-hepatic biliary obstruction is absent. One wonders if 'primary' is really the best adjective available for this group, but it has become hallowed by convention. The possible part played by virus hepatitis is discussed on pp. 158–163. Rather surprisingly, a whole chapter is devoted to the somewhat mysterious entity described by Hanot more than 80 years ago. The closing chapter deals with parasitic cirrhosis, a subject to which Prof. Hou himself has made important contributions.

The book is beautifully produced, the bibliographies comprehensive, and the illustrations clear. Only one misprint has been detected. The price, as usual nowadays, is too high.

J. W. ORR

ESSAYS ON EVOLUTION

Evolution und Hominisation

Festschrift zum 60. Geburtstag von Gerhard Heberer. Herausgegeben von Gottfried Kurth. Pp. x+228. (Stuttgart: Gustav Fischer Verlag, 1962.) 48.50 D.M.

A *FESTSCHRIFT* dedicated to a distinguished scientist when he retires, or when he reaches the age of seventy or eighty, or on his death, has not been uncommon in the past. But here we have a *Festschrift* to celebrate the sixtieth birthday of a palæontologist. Dr. Gerhard Heberer. All honour to him that his work should thus be recognized at such an early age; clearly his colleagues at the University of Göttingen and elsewhere hold him in high esteem and affection. But it is not easy to review a mixed collection of essays such as the present volume offers for the reason that they are so various in their themes, though broadly speaking their content is covered by the title "Evolution and Hominization". (Parenthetically, it is to be hoped the term "Hominization" has not come to stay—it was originated by Teilhard de Chardin and inevitably tends to convey an element of the mysticism that is so apparent in the posthumous publications of this Jesuit Father—himself also a distinguished palæontologist.)

Dr. G. G. Simpson writes on "Some Cosmic Aspects of Evolution" and extends his thesis of the opportunistic factor in the evolutionary process to a surmise on the possibility of life in other worlds than our own. Ernst Mayr discusses the problem of chance and plan in evolution, Dobzhansky and Drescher write on the genetic basis of 'quantum evolution' with particular reference to the evolutionary potentialities of modern man (der Mensch passt öfter die Umwelt seinen Genen an, als dass er seine gene der Umwelt anpasst), varying opinions are expressed by other authors on the antiquity of early man, but in some cases these are already out of date (an exception is the important paper by von Koenigswald on the absolute age of *Pithecanthropus*), while other essays deal with the australopithecines, early members of the genus *Homo* in Africa, and so forth.

But it has to be admitted that much that this volume contains is not new—some of the essays are but little modified versions of publications that have already appeared in the last few years. This raises the question whether the days of *Festschriften* are not passing, for with so many publications of carefully co-ordinated symposia on so many different subjects, disjointed mixtures of essays no longer serve so useful a purpose in scientific literature. Observations of importance included in such essays are likely to be overlooked unless they are also published in recognized scientific journals (as, in fact, they almost always are). The eagerness to honour a distinguished scientist which his friends and colleagues show is, of course, easy to understand. But with the already voluminous and unwieldy profusion of scientific literature, the growing custom of honouring an eminent scientist by, say, dedicating a volume of a scientific journal to his name, has much to commend it.

Progress in Non-Destructive Testing

Vol. 3. Edited by Dr. E. G. Stanford and J. H. Fearon. Pp. vii + 227 + 15 plates. (London: Heywood and Co., Ltd., 1961.) 55*s*. net.

THIS volume contains articles on seven topics, three of which are concerned with X-rays. Recent developments in X-ray spectrochemical analysis have been concentrated on finding the most efficient and speedy detectors. The article includes a discussion of the accuracy now obtainable and also a description of the X-ray microanalyser, which will show, by simultaneous display on two oscilloscopes, an optical image of a small area and the distribution of various chosen elements.

X-ray microscopy has developed to the stage where sub-microscopic flaws, inclusions and lattice defects, including dislocations, may be located and identified. The use of the xerographic process, associated with X-rays, can save time compared with the standard radiographic process. The nature and preparation of the semiconductor plates and their response to X-rays are discussed at some length.

The visco-elastic properties of plastics under dynamic loading can be interpreted in terms of storage and loss moduli—the latter giving the "mechanical internal energy loss". These moduli are functions of frequency and of temperature. Their relationship to molecular structure and their measurement are discussed in an article.

Optical methods can be used for testing flatness, surface layer strains, homogeneity of thickness or refractive index and for revealing atomic lattice defects. While on the other hand magnetic hysteresis methods can give results which correlate with various other properties, such as composition or mechanical strength. The two methods are dealt with in separate chapters.

The use of electromagnetic testing for such purposes as the detection of local defects, cracks, flaws, inclusions, etc., has required a different theoretical approach from that given by Maxwell's equations.

K. J. PASCOE

Astronomical Dictionary in Six Languages

English/Russian/German/French/Italian/Czech. By Josip Kleczek. Pp. 972. (New York and London: Academic Press, Inc.; Prague: Publishing House of the Czechoslovak Academy of Sciences, 1961.) 25 dollars.

THIS volume, the first of its kind, will be of great use for two categories of persons; for trained translators who are not acquainted with astronomical terms and also for astronomers with a slight knowledge of one of these languages. The author and his co-workers are to be congratulated on the completion of this book which has been prepared with great care. On the pages 16–575 the words and terms are given in six languages. They have been subdivided into 34 sections, the first of these being "General", the last "Astronautics". Within each section the words have been numbered. The choice of the sections is somewhat arbitrary, but this has no influence on the usefulness of the dictionary.

The last 400 pages of the book consist namely of six parts in which all the words have been arranged alphabetically in each language with references to the section and number in the first part. This makes the book equivalent to thirty bilingual dictionaries. It is a handsome volume, and the paper and printing are excellent.

P. TH OOSTERHOFF

The Economics of Education

By John Vaizey. Pp. 165. (London: Faber and Faber, Ltd., 1962.) 21*s*. net.

IN this book Mr. Vaizey follows his survey of *The Costs of Education* with a lively survey of existing economic thought about education. Beginning with a brief review of what leading economists from Adam Smith and David Hume to Marshall have written about education in general, he surveys in successive chapters comments made on specific aspects, such as education as consumption or investment, the returns to education, expenditure on education, the finance of education, the productivity of education, man-power, teachers and their salaries, and the comments of economists on the schools. Two chapters on education in economic growth extend the survey to the under-developed countries, particularly Nigeria and Pakistan, in which he comments on the appalling waste of talent caused in Britain by the desire of successive Governments to keep down taxes, lead him to a very brief concluding chapter on the role of education in a modern economy. The value of this brief but comprehensive survey is enhanced by an excellent select bibliography, which, however, omits Joyce Alexander's *Scientific Manpower*. For its chapter on "Scientific Womenpower" this little book is more relevant to the British context than the American publication entitled *Womenpower* listed by Mr. Vaizey.

R. BRIGHTMAN

Religion, Art, and Science

A Study of the Reflective Activities in Man. By Prof. John Macmurray. (The Forwood Lectures, 1960.) Pp. 78. (Liverpool: Liverpool University Press, 1961.) 12*s*. 6*d*. net.

THIS little volume consists of four lectures given before the University of Liverpool in 1960. The titles are: (1) "Science Out of Bounds"; (2) "Contemplation and Communion"; (3) "Religious Reference"; (4) "Christianity for the Future". The author stresses in particular the part played by action; it is what people do that is important. There is an excellent discussion of self-transcendence (as opposed to ego-centricity) which derives, one suspects, from the writer's study—as far back as 1927—of the relation of this quality to genius. Religion must incorporate both science and art into a universal fellowship.

There are two matters on which comment may be admissible. The first is that dogma seems to be judged a trifle harshly. After all, it means an opinion, which may harden into a tenet or even into an assertion. Science, like other intellectual activities, has its dogmas, and it is difficult to see how religion can get on without at least some of them, if it is to supply mankind's innermost needs.

The other point is that science appears to be taken almost entirely in the Baconian sense of man's conquest of Nature for material ends, including the acquisition of power. (It is true that much of the early history of the Royal Society would support this view.) But it is simply not the case for the highest achievements of pure science, for example, the works of Eddington and Heisenberg, which approximate more to poetry than to anything else, and have nothing in common with technological triumphs.

Nevertheless, these addresses are fascinating, and most timely: scholars will welcome their advent in print.

F. I. G. RAWLINS

FATE OF DIETARY FAT IN THE BODY*

By PROF. A. C. FRAZER
Department of Medical Biochemistry and Pharmacology,
University of Birmingham

THE first Lord Leverhulme pioneered the supply of fats for human consumption on a large scale. The object of this article is to consider what happens to these fats in the body after they are eaten, what effect different dietary fats may have on the body and what the important properties of a food fat may be from the health point of view.

Fats with differing properties are assimilated to a different extent. Short-chain fats tend to be absorbed better than long-chain compounds. This has been ascribed to their melting-points being higher than body temperature, so that crystallization occurs. This is not the whole explanation, however, since erucic acid with a melting-point below body temperature is also selectively rejected. Degree of saturation is also important. Progressive hydrogenation of a fat leads to a corresponding decrease in assimilability, unless a sufficient amount of a carrier oil vehicle is also provided. In patients with defective absorption there is a much greater increase of saturated fats in the stools when the steatorrhœa is aggravated and the administration of more unsaturated dietary fat results in improvement in the steatorrhœa. These points may be related to the peculiar properties of stool fats. They commonly contain 30–40 per cent of stearic acid, which is a higher proportion of this fatty acid than is found in any other natural animal fat. A significant amount of this stearic acid may be formed by hydrogenation, some may be accounted for by selective rejection; possibilities of synthesis and excretion must also be considered. A large amount of hydroxy-fatty acids, such as occurs in castor oil, may interfere with absorption owing to poor emulsification; if a suitable oil vehicle is provided to ensure fine dispersion, good absorption occurs and the cathartic effect of the castor oil is abolished.

Dietary fats are partially hydrolysed by pancreatic lipase. Selective action on the fatty acids in the 1 and 3 position occurs. Thus, the nature of the dietary fat may affect the nature of the monoglyceride formed. In *in vitro* investigations different monoglycerides have different activities in micelle formation and glyceride resynthesis; it is not known, however, whether this has any significance *in vivo*. The fatty material is finely dispersed in the intestinal lumen by means of a triple system consisting of fatty acids, monoglycerides and bile salts. This system is an effective emulsifying system under intestinal conditions; it is also able to form micelles. The particulate fatty material in the lumen ranges from large droplets down to invisible micellar particles. It is not known at what point the particles become absorbable. For a long time the critical diameter has been considered to be less than 0·5μ; recent investigations suggest that it may be in the region of 0·1μ.

The finely dispersed fatty material enters the intestinal cell by passing down the intermicrovillous crypts, as revealed by electron microscope studies. Many invaginations may be seen at the bottom of these crypts; but the precise mechanism of absorption is still under discussion. Visible particulate fat does not appear to enter the substance of the microvilli. During its passage through the intestinal wall the fatty material is changed. Mono- and di-glycerides are converted back to triglycerides, and phosphatides are formed in significant quantities; short-chain fatty acids and glycerol are not re-incorporated into triglycerides and pass into the body in the portal vein.

Two pathways of glyceride biosynthesis have been demonstrated in the intestinal cell. One involves phosphatidic acid as an intermediate; but the other does not. This second pathway may be important, since present evidence still suggests that every molecule of fat absorbed does not pass through a phosphatide stage. Nevertheless, the addition of glycerophosphate, choline, or phosphatidyl choline does increase the amount of glyceride fat absorbed in 3 hr. The precise significance of phosphatides in the fat-absorption mechanism is still obscure. In addition to changes in composition, the fat particles also change their surface properties during absorption. The fat in the chyle after absorption is stabilized with lipoprotein. If treated with phosphatidase D, the chylomicrons flocculate and coalesce. Phosphatidyl choline appears to be essential for their stability in the presence of plasma proteins. Thus, one important function of the phosphatide formed in the intestinal cells may be the provision of the lipoprotein stabilizing film.

The blood fat is carried as lipoproteins. The greater the amount of glyceride present, the lower the density. These lipoproteins can be characterized in various ways; one method extensively used is ultracentrifugation. The glycerides in the lipoproteins during absorption closely resemble those fed, except that short-chain fatty acids (less than 10 carbons) have largely disappeared. The alimentary hyperlipidæmia after a moderate fat intake reaches a peak in 3–3½ hr. and returns to normal levels in 5–6 hr. The essential change is in the glyceride-level. The extent and duration of the alimentary hyperlipidæmia is greater in man and the dog than in the rat; almost no significant change occurs in the guinea pig. Unsaturated fats cause a shorter hyperlipidæmia than saturated fats. Old people may have a prolonged hyperlipidæmia. The administration of pancreatic lipase with the fat affects the amplitude of the hyperlipidæmia; it can also be decreased by the administration of heparin and a number of other substances, and enhanced by the administration of protamine. Further information on the effects of different dietary fats on alimentary hyperlipidæmia might be interesting.

The effect of heparin is due to liberation into the blood of a lipase, which hydrolyses chylomicrons Provided that a fatty acid acceptor, such as albumin, is present, this lipase can cause disappearance of the lactescence in hyperlipidæmic blood. This or a similar enzyme is normally present in muscle, adipose

---

[*] Substance of the seventh Leverhulme Memorial Lecture of the Society of Chemical Industry, delivered in Liverpool on April 5. The full Lecture will be published elsewhere.

tissue and other cells; it is, however, absent from liver cells. This lipase acts better on chylomicrons, possibly due to the presence of the lipoprotein stabilizing film; it has therefore been called 'lipoprotein lipase'. It appears to facilitate the removal of glyceride fat from the blood, but hydrolysis is not an obligatory step, since liver and possibly other cells take up glycerides without previous hydrolysis. In essential hyperlipidæmia, a genetically determined inborn error of metabolism, blood glyceride accumulates because of slow clearing. In three patients with this condition, a deficiency of lipoprotein lipase was demonstrated; but this does not seem to be the explanation of all forms of this disease. More resistant fat particles might also be present and these have been shown to occur under certain circumstances.

Dietary fat has been shown to affect the resting blood lipid-level. This is also affected by age, sex and genetic factors. The ingestion of a relatively high proportion of polyunsaturated fatty acids causes a reduction in the level of cholesterol and β-lipoproteins. The body is able to synthesize fatty acids *de novo* from small fragments. In this way the saturated and monoethenoid fatty acids can be formed. There is difficulty, however, in forming such fatty acids as linoleic and linolenic acid. These are important because the nature of the further polyunsaturated fatty acids formed in the body is dependent on the nature of the starting material. Oleic acid when further desaturated gives rise to 5,8,11-eicosatrienoic acid, whereas linoleic acid yields arachidonic acid and linolenic acid gives docosa pentaenoic and hexaenoic acid. Arachidonic acid is an essential constituent of phosphatides in mitochondria and other cell structures. If there is an insufficient amount of arachidonic acid it will be replaced by a trienoic acid, which is an unsatisfactory substitute—a syndrome known as the essential fatty acid deficiency syndrome results. The linoleic acid must be in the *cis cis* form for it to function as an essential fatty acid. The effect of polyunsaturated fatty acids on blood cholesterol and β-lipoproteins is not, however, confined to the linoleic acid family. Many other polyunsaturated fatty acids, including many fish oils, are equally effective.

Glycerides enter liver cells without previous hydrolysis. The liver is well equipped to carry out any modifications in the fatty acids which may be required. Much of the fatty acid may be oxidized; the remainder is converted into various esters or other lipids. The liver endeavours to keep the level of free fatty acids under control, and it maintains a state of equilibrium with the blood lipids. Glyceride may accumulate in the liver under conditions that involve interference with phosphatide formation; these include choline deficiency from any cause, unsaturated fatty acid deficiency and various vitamin deficiencies. The glyceride which accumulates in greatest quantity is dietary fat.

Adipose tissue takes up dietary fat. Its composition closely resembles the dietary fat if the fat intake is high. Adipose tissue cells can also synthesize fatty acids *de novo* from glucose and shorter-chain fatty acids. Fat is continually being mobilized from the fat depots; their half-life in the rat is 10 days, but it differs with different fats. The main form in which fat is mobilized is as fatty acid; this circulates in the body as non-esterified fatty acid Adrenocorticotrophic hormone; adrenaline and growth hormone stimulate mobilization; insulin and glucose inhibit it.

Lipids are deposited in the walls of blood vessels; these deposits increase with age. More lipid may be deposited in people with high blood fat-levels. Since a high intake of polyunsaturated fatty acids reduces blood fat-levels, this is an important dietary consideration. An adequate intake of polyunsaturated fatty acids, a sufficient amount as *cis cis* linoleic acid, should be maintained. The taking of large quantities of polyunsaturated fatty acids may be a useful therapeutic measure in people with raised blood lipid-levels and severe atheromatous changes, but there does not appear to be a good case for excessive intake in normal people. The link between atheroma and coronary thrombosis and myocardial infarction is tenuous. Controlled trials are needed to establish whether patients with these heart diseases derive any benefit from the ingestion of polyunsaturated fatty acids. There is certainly no justification on present evidence for attributing changes in the incidence of these disorders to dietary factors alone, or in proposing any major change in the national diet.

However, it is the duty of all concerned with food supplies to ensure that as much as possible is discovered about the effects of food on the body. The intake of important nutrients, such as *cis cis* linoleic acid, should be safeguarded. The effects of processing or storage on food materials should be studied and kept under close review. Only by this means can the potential benefits resulting from the work of men such as the first Lord Leverhulme be satisfactorily and safely realized.

TRACE CONSTITUENTS OF BUTTERFAT

By Dr. J. BOLDINGH and R. J. TAYLOR

Unilever Research Laboratories, Vlaardingen, The Netherlands,
and Port Sunlight, England

FIFTEEN years of research on flavour in the Unilever laboratories in the Netherlands and in England has brought to light an interesting series of trace constituents in butterfat, knowledge of which, on one hand, throws considerable light on the nature of butter aroma and, on the other, points to unexpected bypaths in biological synthesis or breakdown in the ruminant.

The investigation was commenced at a time when liquid/liquid partition chromatography opened up a new phase in the study of lipids. This was followed, in 1952, by the introduction, by James and Martin[1], of gas/liquid chromatography, which provided very high resolving power and required only micro-amounts of substances for analysis. In the same period, the development of spectroscopic techniques, such as

Table 1. (*a*) SATURATED FATTY ACIDS IN BUTTERFAT

Type		Known up to: 1940	1955	1960
Straight chain	Even	C_4–C_{26}		C_2
	Odd		C_{11}–C_{15}	C_{17}–C_{23}
Branched chain	Even (iso)		C_{14}	C_{16}
	Odd (iso)		C_{13}–C_{17}	
	(ante-iso)		C_{15}–C_{17}	
Poly-branched				C_{20}

(*b*) UNSATURATED FATTY ACIDS IN BUTTERFAT

Type		Known up to: 1940	1955	1960
Mono-	Even	C_{10}–C_{18}*	C_{18} isomers	Geometric C_{12}, C_{14}, C_{16} isomers C_{20}–C_{24}
	Uneven			C_{15}–C_{23}
Di-		C_{18}†	Conjugated	
Tri-		C_{18}	Conjugated	C_{20}

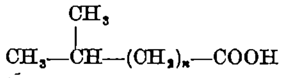
† Linoleic acid containing iso-linoleic acid

infra-red, nuclear magnetic resonance, and mass spectrometry, made it possible in many cases to characterize the molecular structure of compounds when only minute amounts were available.

In Unilever, Schogt and De Bruyn[2] developed a method for the efficient isolation of volatile components from fats and oils, known as the high vacuum degassing method. This technique permits the direct, quantitative transfer of volatile components from oils and fats to the gas-chromatographic column, and from there to the spectroscopic apparatus, without loss or contamination.

Lipid chemistry has greatly profited from these developments. This is illustrated, for example, by the great advances made in the knowledge of the fatty acid composition of butterfat, as shown in Table 1, compiled from literature data.

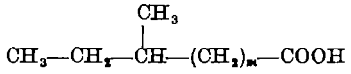
The iso-acids and ante-iso-acids described by Shorland *et al.*[3], namely:



$$CH_3—\overset{CH_3}{\overset{|}{C}H}—(CH_2)_n—COOH$$

iso[C : *13*, 14, *15*, 16, *17*]

and



$$CH_3—CH_2—\overset{CH_3}{\overset{|}{C}H}—(CH_2)_n—COOH$$

ante-iso[C : *13*, *15*, *17*]

are widely represented in butterfat, and we ourselves (Schogt *et al.*) have been able to identify the tetramethyl-palmitic acid with a terpenoid structure[4]. These acids occur in butterfat in concentrations of about 1,000 p.p.m.

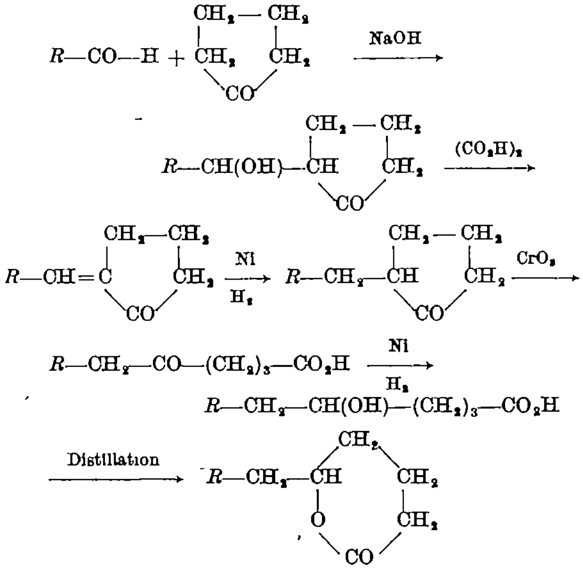
In this article we shall restrict ourselves to trace constituents which have been detected in butterfat either in a free or combined form in concentrations in the order of 10 p.p.m. or less. In particular, the detection and identification of both saturated and unsaturated aliphatic δ-lactones, unsaturated γ-lactones, δ-hydroxy acids, δ-keto acids, β-keto acids and methyl ketones will be described.

δ-lactones. In the course of our investigations we have applied many different methods for the isolation of crude lactone fractions from butterfat, namely: (*A*) methanol extraction; (*B*) molecular distillation; (*C*) steam distillation; (*D*) weak-alkali extraction; (*E*) binding by means of basic ion-exchanger; (*F*) vacuum degassing.

These we have applied singly, or in various combinations, and supplemented them—when the presence of lactones was indicated—by the following operations: (1) saponification; (2) unsaponifiable components extracted; (3) hydroxy-acids lactonized; (4) higher fatty acids removed (urea); (5) lower fatty acids removed (soda).

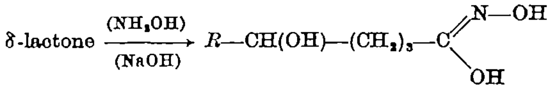
The probability that lactones were present was disclosed initially by repeated titration of a typical concentrate, which exhibited spontaneous partial re-esterification when the soap was split and the acids recovered. Classification as δ-lactone type followed readily when infra-red spectrometry became available. The close resemblance between synthesized δ-dodecalactone, used as model substance and a lactone fraction from butterfat obtained by microdistillation, is shown in Fig. 1. Careful examination of infra-red spectra of various butter lactone preparations, however, revealed that we were dealing with a mixture of lactones of different chain lengths.

A range of δ-lactones was prepared in the laboratory, for use as model substances to aid identification of the butterfat lactones. They could be synthesized in various ways, but we will describe here only the method which proceeds via the δ-keto acid, as this acid has played an important part in further development of the subject.



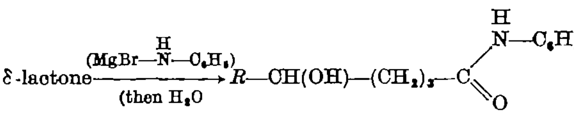
Direct chromatographic separation of the mixture of lactones was not feasible since there was a tendency for the lactone ring to open in solvent systems and for some inter-esterification to take place. To obviate this, and also make chromatographic separation easier to follow, the following derivatives were prepared and examined:

(*a*) hydroxamic acids;
(*b*) anilides.



$$\delta\text{-lactone} \xrightarrow[(NaOH)]{(NH_2OH)} R—CH(OH)—(CH_2)_3—C{\overset{\displaystyle N—OH}{\underset{\displaystyle OH}{\lessgtr}}}$$

hydroxamic acid



$$\delta\text{-lactone} \xrightarrow[(\text{then } H_2O)]{(MgBr—\overset{H}{N}—C_6H_5)} R—CH(OH)—(CH_2)_3—C{\overset{\displaystyle \overset{H}{N}—C_6H_5}{\underset{\displaystyle O}{\lessgtr}}}$$

anilide

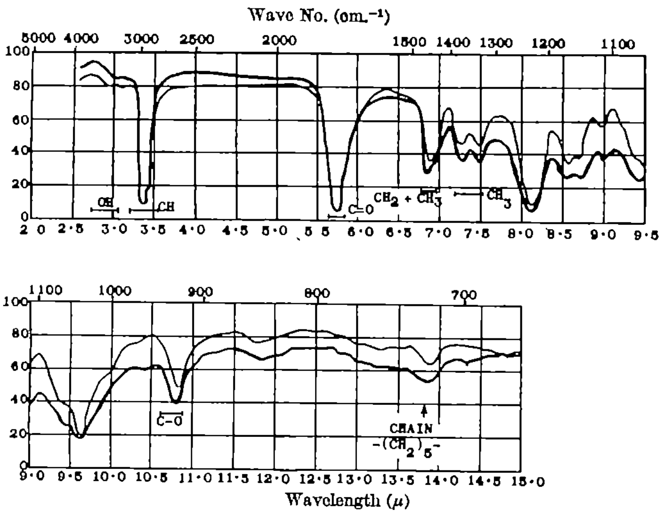


Fig. 1. Infra-red recording of a lactone fraction from butterfat. Thick line, lactone from butterfat; thin line, synthetic δ-dodecalactone

Of the two, the anilides proved to be the more satisfactory, both in the ease and reliability of preparation and in the wealth of information they provided.

The hydroxamic acid mixture, separated by paper chromatography in the solvent system benzene/ethanol and developed by ferric chloride in alcohol, showed only the even series: C$_{10}$, C$_{12}$, C$_{14}$ and possibly C$_{16}$.

The anilides were chromatographed over silica-gel columns in the system cyclohexane/aqueous alcohol and they were more finely resolved than the hydroxamic acids (Fig. 2). Apart from relatively major zones corresponding to lactones with 8, 10, 12, 14 and 16 carbon atoms, there were also other minor zones which corresponded nominally to lactones with uneven numbers of carbon atoms. The concentrattions of these components were of the order of a few per cent of those of the main components. Further investigation brought to light a number of interesting lactones; for example, fraction No. 4 was found to contain, *inter alia*, saturated δ-undecalactone, and fraction No. 3, an unsaturated δ-dodecene-9-lactone, which was found later to be identical with a lactone synthesized by Haverkamp Begemann. In subsequent work, a lactone mixture obtained by vacuum degassing of butter, was separated directly by gas chromatography (Fig. 3). This has also led to the isolation and identification of the unsaturated γ-dodecene-6-lactone.

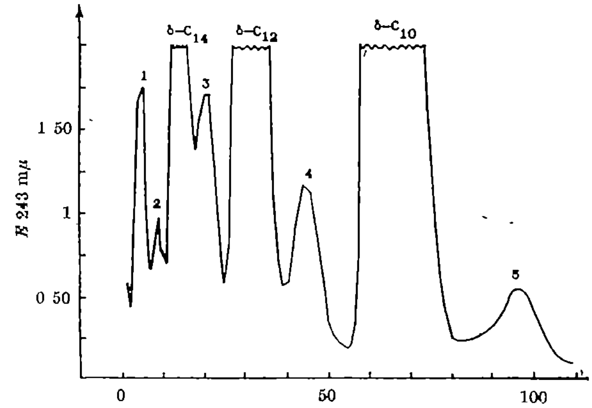

Fig. 2. Partition chromatogram of hydroxy-acid anilides from heated butterfat

However, no quantitative yardstick could be obtained in this way: the ratio of the amounts in which the various components were obtained was greatly influenced, in high vacuum degassing, by differences in volatility, and, in alkali extraction, by differences in the rates of hydrolysis and differences in solubility.

Furthermore, the method of extraction took no account of the possible natural state of the lactones in the butterfat.

Circumstantial evidence on the natural state of the lactones was obtained by an investigation in which a concentrate (obtained via methanol extraction plus molecular distillation) was subjected to liquid/liquid partition chromatography in the system light petroleum/aqueous methanol. Little free lactone was disclosed. Acid fractions yielded some lactone after ring-closure, but they did not account for the quantity of lactones to be expected. A number of fractions, however, had the infra-red characteristics of hydroxy glycerides and these, on hydrolysis, yielded further quantities of lactones. Analysis of one such fraction gave: total combined fatty acids 57 per cent: combined lactonizable acids 22 per cent.

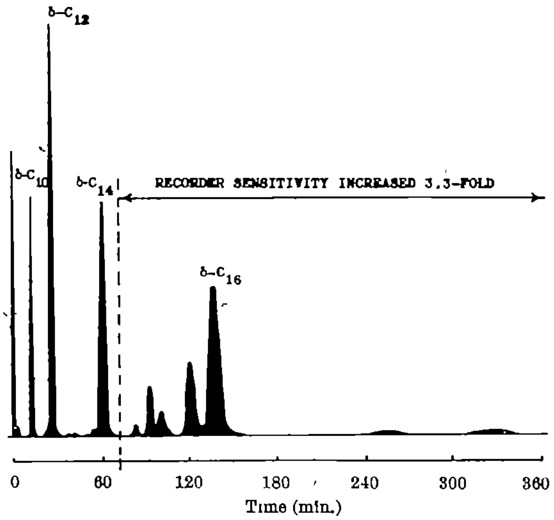

Fig 3. Lactones from butter. Immobile phase, silicone oil; temperature, 185° C.

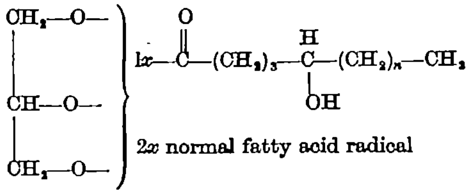
To put the matter on a more quantitative basis the well-known isotope dilution method was applied. A number of lactones, which were labelled with carbon-14 in the carboxyl group, were synthesized.

The interesting fact was then observed that the lactone content of butterfat increased if the fat was heated for some time at 140° C. This is illustrated in Table 2.

We would direct attention to the low free lactone content of fresh cream fat. The conclusion to be drawn again is that δ-hydroxy acid must be present in bound form. The most logical supposition is that the δ-hydroxy acid, in combination with two normal fatty acids, is built into the glycerides, from which lactone can be split off by heating.



We have prepared a number of model glycerides, namely: δ-hydroxy-acid mono- and tri-glycerides, and mixed δ-hydroxy-acid normal tri-glycerides, and studied their breakdown pattern on heating (Fig. 4). They are heat-labile, the mono-glycerides more readily so than the tri-glycerides. (For this reason it is better that the synthesis should proceed via the δ-keto glyceride.)

Table 2. LACTONE CONTENT OF VARIOUS FATS BEFORE AND AFTER HEATING AT 140° C.

Fat phase of	C_{10}	C_{12}
Fresh butter	5 (10)	
	4 (10)	10 (25)
	3 (10)	5 (28)
	9 (14)	16 (30)
Non-pasteurized cream (fresh)	3 (20)	4 (27)
Non-pasteurized cream (soured)	3 (19)	5 (31)
Pasteurized cream (fresh)	6 (19)	11 (38)
Pasteurized cream (soured)	6 (18)	13 (35)
Beef tallow	0·2 (0·5)	0·6 (2·3)

These facts together may not be wholly conclusive, but they provide good circumstantial evidence that glycerides of the structures described are present in butterfat.

We come now to what is perhaps the most important characteristic of the lactones of butterfat—and indeed of milk fat—in so far as it points unequivocably to how they originate. It became evident by observation that the anilides of the naturally occurring lactones deviated, in respect of both melting-point and X-ray diffraction data, from the anilides of synthesized lactones.

From these data we concluded that the lactones represented only one of the two optical antipodes, although measurements of rotation on admittedly minute quantities of anilide gave (α_D) values of the order of only 1°. However, the finding was confirmed by measuring the optical rotation of a more adequate quantity of lactone isolated from butter. (The rotation of the hydroxy acids cannot be measured since spontaneous partial ring closure leads to spurious values. However, for the potassium salt of the decanoic acid we obtained an (α_D) value of $-4°$.) As the highest value for the rotation (α_D) = + 37·8° was found.

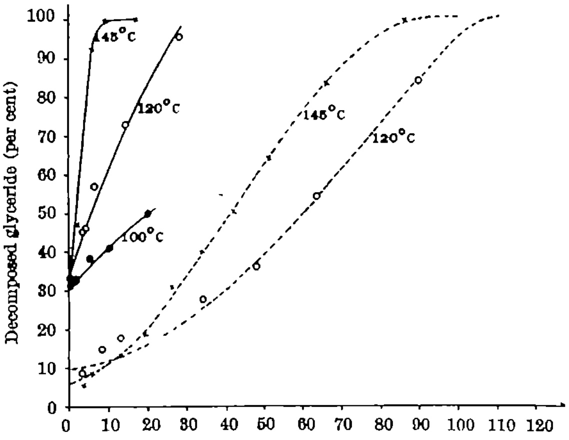


Fig. 4. Decomposition of δ-hydroxydecanoic acid glycerides (measured with the aid of lactone absorption at 926 cm.$^{-1}$) —— monoglyceride; – – – triglyceride

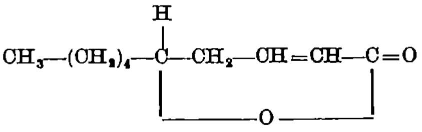
Table 3. MELTING POINTS AND X-RAY DATA OF HYDROXY ACID ANILIDES

		Melting point (°C.)	X-ray analysis Longest observed spacing (Å.)	Chief side spacings (Å.)	
C_{12}	From butter	91–95	21·6	4·63 4·28	4 06 3·66
	Synthesized	104–104 5	15·7	4·50	4·02 3·82
C_{10}	From butter	110–111	18·5	4·71	4·38 4 10
	Synthesized	98 5–99 5	14·2	4·60	4·12

As early as 1940, Th. M. Meyer[5] described the optically active "massoi lactone" and the saturated δ-decalactone obtained from it by hydrogenation.

Massoi lactone occurs in the bark of *Cryptocaria massoia* (Lauraceae), which grows in New Guinea.

Massoi lactone



$$[\alpha_D] = -87{\cdot}6°$$

$$\text{Hydrogenated}: [\alpha_D] = +44{\cdot}6°$$

In our own investigations, slightly deviating values for (α_D), namely, $-$ 84·6° and + 45·5°, were found.

We have also separated the synthetic lactones, by means of cinchonidine, into the optical antipodes. It was then found that the melting-points and X-ray diagrams were in better agreement with the observations made on anilides from butter lactones.

This was also true of the anilide prepared from dihydro-massoi lactone.

If the preponderance of the homologous series with an even number of carbon atoms already indicated the biological formation of the lactones, there was certainly no further room for doubt once their optical activity had been discovered.

At this point mention must be made of a series of articles by Patton, Keeney and Tharp[6], who during the past ten years have published a number of the facts given above. In the course of their work, the compounds originally regarded as off-flavours have been identified as lactones.

The detailed investigation described in the present paper (on the basis of which patents applied for as early as 1952 have been granted), as well as our finding that the lactones are optically active, precludes the possibility of their formation by autoxidation of certain precursors.

It is especially interesting in this connexion to report the discovery by Tuynenburg Muys, De Jonge and Van der Ven[7] that various micro-organisms are capable of converting δ-keto acids into optically active δ-hydroxy fatty acids and lactones. Of these micro-organisms we mention the following:

Moulds, *Cladosporium butyri;* yeasts, *Saccharomyces cerevisiae, S. fragilis, Candida globiformis, C. dattila;* bacteria, *Sarcina lutea.*

Most of these organisms, including *Saccharomyces cerevisiae*, produce lactones which are identical with those occurring in butter; others, including *Clado-*

sporium butyri and *Sarcina lutea*, produce lactones with opposite rotation.

The lactones so prepared have the following optical rotations.

		(α_D)
Lactone mixture from butter :		+37·8°
Homologous series of lactones obtained by micro-biological reduction :	C_8	+58·4°
	C_{10}	+56·0°
	C_{12}	+48·8°

In addition, it has been found that pigeon- and bovine liver can also reduce δ-keto acids. The reducing enzyme present in yeast is located in the mitochondria and it has been found that the reduction proceeds via the coenzyme A ester of the keto-acid. Study of the exact nature of the enzyme is still in progress; it is possibly identical with, or closely related to, enzymes known in the field of biological fatty acid synthesis or breakdown. One might speculate whether, in the biosynthesis, δ-keto acids result from two consecutive additions of acetate, the first of which escapes reduction to β-hydroxy-acid–coenzyme-A. The very interesting and recent discovery of traces of δ-keto acid in the glyceride portion of butterfat (a few p.p.m.) suggests that the lactones are indeed formed via δ-keto acids.

Further evidence, pointing to the presence of other bound keto acids, was obtained during a study of the volatile carbonyls in butterfat.

It was found then that for a certain class, namely, the methyl ketones, precursors must be present in the fat. On complete removal of the volatile carbonyls by high-vacuum degassing, and subsequent steam distillation, at 180° C., of the fat, a homologous series of methyl ketones, with an odd number of carbon atoms, was detected in the distillate.

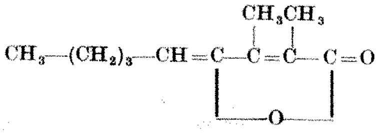
Table 4. METHYL KETONES FROM BUTTERFAT BY STEAM/DISTILLATION AT 180° C. (in p.p.m.)

C_{15}	Methyl-tridecyl ketone	42
C_{13}	Methyl-undecyl ketone	22
C_{11}	Methyl-nonyl ketone	13
C_9	Methyl-heptyl ketone	9
C_7	Methyl-pentyl ketone	12

This evidence suggested that β-keto acids, a normal intermediate in the biological fatty acid cycle, were present in bound form in butter. This was confirmed by isolating pyrazolones, which formed by allowing Girard-*T* reagent to react with butterfat. In addition, synthetically prepared glycerides containing β-keto acids were submitted both to hydrolytic heating and to treatment with Girard-*T* reagent, with similar results to those obtained with butterfat.

γ-Lactones. The presence of minor quantities of normal aliphatic γ-lactones has been detected in butterfat concentrates; isomeric conversion from γ-lactone during isolation is unlikely. But any account of butter lactones would be incomplete without mention of an entirely unique γ-lactone: unique because, in this case, we are not concerned with a homologous series.

The substance in question, to which we have given the name 'bovolide', has the following structure:

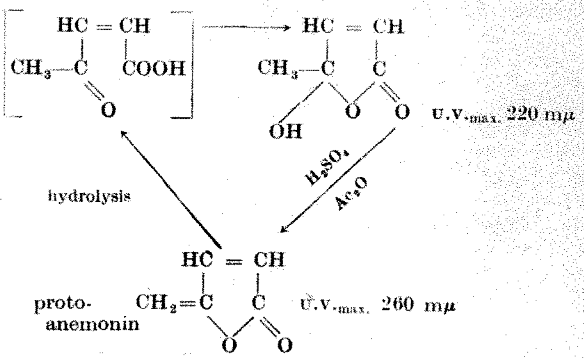


$$\mathrm{CH_3{-}(CH_2)_3{-}CH{=}C{-}\overset{CH_3}{C}{=}\overset{CH_3}{C}{-}C{=}O}$$

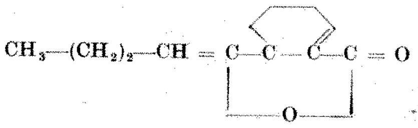
It is the enol lactone of

2,3-dimethyl-4-keto-nonene-2-acid

The compound has a characteristic triene ultraviolet absorption at 270 mμ and occurs in an amount of about 0·5 p.p.m. in butter. It has a strong odour reminiscent of celery. When it is saponified the absorption at 270 mμ disappears and does not return on acidification. The lactone can be regenerated only by the action of a strong dehydrating agent, such as potassium hydrogen-sulphate. The free acid readily converts into a hydroxy-lactone or pseudoacid, analogous with the behaviour of proto-anemonin, as was described by Shaw[8] in 1946.



The analogy with compounds from celery is striking; compare, for example, the lactone of sedanonic acid, in which, however, the double bond is not in the lactone ring.



The origin of this lactone is still not known; we suspect that it comes originally from the fodder and we assume that, in view of the absence of a homologous series, it is not connected with the normal biological fatty acid synthesis.

The work described in this article was a collaborative effort in which the following took part, in addition to the authors: J. C. M. Schogt, Miss P. Haverkamp Begemann, G. Lardelli, G. Tuynenburg Muys, A. P. de Jonge, B. v.d. Ven, A. Francke, G. J. v. Beers, A. S. M. v.d. Zijden, G. Dijkstra, P. Roele, P. D. Harkes, K. de Jong, Miss J. Koster (Vlaardingen, The Netherlands); R. Wellwood, W. T. Weller, J. Clifford, D. Chapman, J. Devine, J. R. Edisbury (Port Sunlight, England); V. Lamberti (Edgewater, New Jersey, United States). Fuller details of the findings will be given in a series of forthcoming publications.

RELATION BETWEEN STRUCTURE AND SEQUENCE OF HÆMOGLOBIN

By DR. M. F. PERUTZ, F.R.S.

Medical Research Council Laboratory for Molecular Biology,
Hills Road, Cambridge

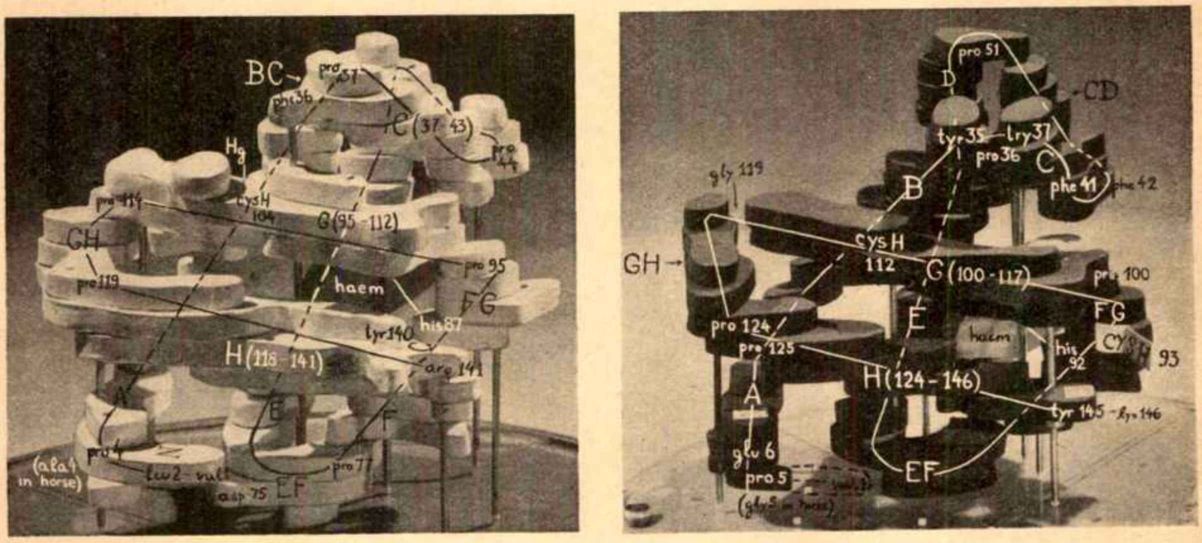
WHEN the tertiary structure of horse hæmoglobin was first published, its amino-acid sequence was still unknown, and the resolution of the X-ray analysis was too low to allow side-chains to be seen[1]. Since then, the amino-acid sequences in the two different chains of human hæmoglobin and in one of the chains of horse hæmoglobin have been elucidated[2-5]. In addition, most of the structure of sperm whale myoglobin is now known in atomic detail[6]. Thanks to the close similarity in tertiary structure between sperm whale myoglobin and horse hæmoglobin the position of almost any residue of a given sequence number can be found by looking up the co-ordinates of the corresponding residue in myoglobin and then transferring those co-ordinates to the model of hæmoglobin. This procedure can be checked, because the positions of certain residues can be found directly in the electron-density maps of hæmoglobin, despite the low resolution, and can then be compared with those inferred by analogy with myoglobin. For example, the cysteines are found by labelling them with mercurials; the indol rings of tryptophan are recognizable as bulges of high electron density protruding from the main chain; by contrast, glycines in non-helical regions sometimes show up by causing a marked constriction in the roughly cylindrical cloud of high electron density which represents the polypeptide chain.

A year ago, Watson and Kendrew published a preliminary comparison of the structure and sequence of hæmoglobin, but at that stage only parts of the chemical sequence were known[7]. In the light of the further knowledge now available, many interesting new features reveal themselves.

In the discussion which follows, the tertiary structures of equine and human hæmoglobin will be assumed to resemble each other closely. This has not yet been proved; but is very probable in view of the similarity in amino-acid sequence of these two hæmoglobins, and in view of the correspondence between the tertiary structures of the different species of myoglobin and hæmoglobin so far examined[9,10].

Chemical Identification of Chains in the Crystallographic Model

The two different chains of horse hæmoglobin have the *N*-terminal sequences valyl-leucyl and valyl-glutaminyl, and are similar in composition to the valyl-leucyl and valyl-histidyl-leucyl chains of human hæmoglobin[4,5], which have become known respectively as the α- and β-chains. Smith and Perutz have shown the valyl-glutaminyl chain to correspond to the black chain of the crystallographic model[8], from which it would follow that the black chain also corresponds to the β-chain of human



a *b*

Fig. 1. *a*, A model of the cloud of high electron density representing the α-chain of horse hæmoglobin. The letters *A*, *C*, *E*, *F*, *G* and *H* refer to various regions of chain identified as right-handed α-helices in myoglobin. The numbers in brackets give the sequential residue numbers associated with them. *EF*, *FG*, *GH* refer to corners or non-helical regions. Except for proline 4_α all the residues marked in this figure occupy the same sequential positions in human and equine hæmoglobin. Note the proximity of aspartic acid 75 to valine 1, the *N*-terminus

b, The β-chain. The residues marked on the model are taken from the sequence of human hæmoglobin. Cysteine 112_β is known to be replaced by another residue in equine hæmoglobin; there may be some other differences between the two hæmoglobins which affect this figure and which are not yet known. Note the position of glutamic acid 6, the residue which is replaced by valine in sickle-cell hæmoglobin; also the bulges marking the positions of tyrosine 35, tryptophan 37 and of phenylalanines 41 and 42, and the gap which marks the position of glycine 119 in the non-helical region *GH*. The hæm group lies at the back of the models

Table 1. ABBREVIATED AMINO-ACID SEQUENCES OF VARIOUS HAEMOGLOBIN CHAINS, ILLUSTRATING POINTS MENTIONED IN THE TEXT
For the α-chain of horse hæmoglobin only those residues are shown which differ from the corresponding ones in human hæmoglobin. In the β-chain of horse hæmoglobin only the *N*-terminal sequence is shown which differs from human hæmoglobin in three places. The vertical lines indicate tryptic peptides the composition of which is either the same as that of the corresponding peptide of human hæmoglobin or differs from it by only one amino-acid residue. In the γ-chain only those residues are shown which differ from the corresponding ones of the β-chain or (bracketed) where only the composition, but not the sequence of the peptide is known

hæmoglobin. We therefore have the following relations:

	N-*Terminal sequences*		*Crystallographic model*
	Horse	*Human*	
α-Chain	valyl-leucyl	valyl-leucyl	white chain
β-Chain	valyl-glutaminyl	valyl-histidyl-leucyl	black chain

Table 1 lists those parts of the sequences of human and equine hæmoglobin which are discussed in this article, while Fig. 1 shows the tertiary structures of the α- and β-chains with the positions of certain residues superimposed. The sequences of the α- and β-chains are similar, but to bring them into register all along their length appropriate gaps have to be left in certain positions. Thus a gap of one, and another of five, residues have to be assumed between residues Nos. 46 and 51 in the α-chain in order to keep its sequence in register with that of the β-chain. These gaps evidently correspond to a shortening of the α-chain which should be noticeable in the model. By looking up the positions of the corresponding residues in myoglobin the shortening can be traced to the non-helical region *CD* and the helical region *D* which lie in the loop at the top of the models in Fig. 1. It will be noted that in the white chain this loop is cut short compared with the black chain, showing that the shortening of the α-sequence has its corollary in the electron density maps.

Co-ordination of Hæm Groups

The hæm-linked residue in myoglobin has been identified as histidine. The α- and β-sequences each show a histidine in the corresponding position (87_α and 92_β), thus confirming that histidine is the hæm-linked residue in hæmoglobin, as had long been predicted from physico-chemical data[12-14]. Watson and Kendrew have pointed out that a second histidine occurs on the distal side of the hæm group in all three chains (62 in myoglobin; 58_α and 63_β); this histidine is not in contact with the iron atom, but is within hydrogen-bonding distance of the hæm-linked water molecule, and is the residue which is replaced by tyrosine in two of the forms of hæmoglobin M (ref. 15). This may be the second histidine in close proximity to the iron atom, but not directly linked to it, the presence of which has long been surmised[11–13,16,17]. It is most satisfactory to find these expectations confirmed by crystallographic analysis.

Position of Cysteines

All vertebrate hæmoglobins appear to contain at least one pair of cysteines the sulphydryl groups of which are reactive in the native protein. Their positions can be determined by X-ray analysis, using mercurials as a label. From the X-ray results, combined with model building, it was possible to show that in horse hæmoglobin the reactive cysteine is the residue immediately following the hæm-linked histidine in the β-chain, and a cysteine in this position has since been found by chemical sequence work in human hæmoglobin (93_β). The histidine and cysteine are part of an α-helix, and the side-chain of cysteine points in the direction away from the iron atom.

Horse hæmoglobin contains one other pair of cysteines which is unreactive in the native protein[18,19], but can be labelled with mercurials under appropriate conditions. This is attached to the helical regions *G* of the α-chains, and lies tucked away in the interior of the molecule, sandwiched between neighbouring sub-units. The position deduced by labelling with mercury corresponds exactly to that inferred for residue No. 104_α, the sequential position of the corresponding cysteine in human hæmoglobin, by analogy with the myoglobin structure.

Adult human hæmoglobin, but not fœtal human or horse hæmoglobin, contains a third pair of cysteines (112_β), the position of which in the model is similar to that of 104_α in that it is part of the helical region *G* and lies in the interior of the molecule. This pair is also unreactive in the native protein[19,20]. Neither of the unreactive pairs has any contact with the hæm group, nor are they in contact with each other or with residues of any chain other than their own. Thus their function is obscure. Their lack of reactivity in the native protein can be attributed to their situation in the interior of the molecule, though covering of the sulphydryl groups by immediate neighbours cannot be excluded at this stage.

Tryptophan

As has already been mentioned, the indol groups of tryptophan are recognizable as marked bulges of high electron density protruding from the main polypeptide chain, even at a resolution of only 5·5 Å. Tryptophan 14_α and 15_β appear in the exact positions occupied by tryptophan 12 in myoglobin and are part of the helical region *A*. The indol ring lies in the interior of the molecule, sandwiched between helices *A* and *E*; it is almost parallel to the plane of the porphyrin ring, but separated from the latter by helix *E*, and lies at a distance of 14 Å. from the iron atom. Since this is the only tryptophan which all chains of hæmoglobin and myoglobin so far analysed have in common, it is probably the residue responsible for the photodissociation observed when carbon monoxyhæmoglobin is illuminated at the ultra-violet absorption band of tryptophan. In this process a quantum must be transferred from the indol ring, across helix *E*, to the porphyrin ring. However, the photodissociation of carbon monoxide is unlikely to be of biological significance, and the common occurrence of tryptophan in this position suggests that it may actually play a part in the oxygen-combining activity in a manner which we cannot yet guess. The β-chain of human hæmoglobin contains another tryptophan in position 38. This is also present in the slow component of horse hæmoglobin, but in the fast component it is replaced by lysine[21]. Myoglobin contains a second tryptophan in position 5 which is absent in hæmoglobin. Evidently these tryptophans are not essential.

Prolines and Corner-turning

The two chains of human hæmoglobin each contain seven prolines which all lie in corners or non-helical regions of the chain, as had been suggested by Watson and Kendrew[7]. However, there are only three positions (the corner *CD*, the *N*-terminal end of helix *G* and the corner *GH*) where prolines occur both in myoglobin and in the α- and β-chains. The fourth proline of myoglobin (98) occurs in a position where the hæmoglobin chains have none, and curiously enough, the prolines which occur in each of the chains of hæmoglobin do not all occur at the same corners. For example, in the neighbourhood of the short helical region *D* the α-chain has no proline and the β-chain has two (51 and 58). On the other hand, the α-chain has a proline near the *C*-terminal end of the region *C* (44) where the β-chain has none. Admittedly, the regions *C*, *CD* and *D* are those where the two chains also differ most markedly in structure, but there is also proline 77_α which occurs in the non-helical region *EF* and has no counterpart in the β-chain. In the γ-chain of human fœtal hæmoglobin, which replaces the β-chain in the adult form, the prolines in positions 5 and 51 are replaced by glutamic acid and alanine respectively[22]. The two chains of horse hæmoglobin contain only six prolines each, and differ from the human chains by the absence of prolines 4_α and 5_β at the *N*-terminal end of helix *A*; these are replaced respectively by alanine and glycine. These results suggest that the corner-turning mechanism which depends on the presence of proline is readily replaced by others, and is therefore not of great evolutionary importance.

The correspondence between structure and sequence found in this work provides an independent check for the interpretation of the X-ray results. If the meaning of the electron density maps of either hæmoglobin or myoglobin had been misinterpreted, the correspondence between the observed and predicted positions of cysteine and other residues could not have been found.

A full account of this work, giving a complete description of the methods and results of the X-ray analysis, has been published by Cullis, Muirhead, North, Perutz and Rossmann[23].

OBITUARIES

Dr. Ernst Schwarz

SYSTEMATIC mammalogy suffered a severe loss with the death on September 23, at Bethesda, Maryland, of Dr. Ernst Schwarz. Although in recent years Schwarz had retired from active work in systematic mammalogy to devote his energies to public health problems his name will long be remembered for his earlier fundamental contributions to the diagnosis of a very wide range of mammalian groups from marsupials to primates.

Schwarz was born at Frankfurt am Main on December 1, 1889. His academic studies (1907-12) were pursued at the Universities of Berlin, London and Munich, and he graduated Ph.D. at the last mentioned in 1912. During 1912–15 he was in charge of the mammal collections at the Senckenbergische Naturforschende Gesellschaft in Frankfurt, thereafter (1915–18) transferring his interests to the clinical laboratory of the University Hospital in the same city. His interest in medical science was continued after the First World War when, in 1919, he became research assistant to the Paul Ehrlich Institute for Experimental Therapy, where his interests were directed towards cancer research. In 1925 he returned to mammalogy, spending the next four years in research at the Zoological Museum of the University of Berlin. During 1929–33 he was custodian of the Natural History Museum of the University of Greifswald, but fled from Germany to London on the advent of the Nazi régime. He spent the next four years attached unofficially to the mammal room of the British Museum, whence many of his best-known papers emanated. In 1937 he transferred to the U.S. National Museum in Washington, where he remained for ten years, with numerous intermediate assignments such as a guest lectureship at the U.S. Navy Medical School at Bethesda (1942–43) and later (1947–53) to the Graduate Medical School, U.S. Naval Hospital, Bethesda. During 1948 he was organizing, planning and participating in the U.S. Navy African Expedition. In 1950 he went on a mission to Venezuela studying bubonic plague, becoming a member of the World Health Organization Commission on this disease. His last years, 1956–59, were spent as a guest research worker at the Armed Forces Research Institute of Pathology at Washington, where he was attached to the Section of Neuropathology.

Schwarz was decorated with the Medal of King Leopold II of Belgium and with the Distinguished Service Medal of the United States.

As a systematic mammalogist, Schwarz is considered a lumper; in fact, he was perhaps overzealous in this direction, as witnessed especially by his treatment of the *Colobus* monkeys—a fact he himself admitted after the publication of his studies. His very last publication dealt with pygmy marmosets, where here too he oversimplified the problems. The position is tersely assessed by Booth, who declared that "Schwarz's descriptions are meticulously careful, but his conception of the species is, in the case of the Primates, often too broad".

Of some sixty-eight scientific papers published by Schwarz, about two thirds were devoted to the systematics of mammals, living and extinct. The remainder deal with problems of applied medicine dating from his early interest in carcinogenesis and some few to general problems of distribution, genetics and evolution.

Deep sympathy goes to his widow, Henrietta E. Schwarz, whom he married during his period in London, and who was a constant help to him in his work.

W. C. OSMAN HILL

Dr. N. K. Sen

DR. N. K. SEN, who died on March 21, was born on February 26, 1917, the eldest son of late Jitendra Prosad Sen, subordinate judge, who was the son of the well-known Dewan Bahadhur Sarada Prosad Sen of Dacca. Dr. Sen graduated with honours in botany from the Presidency College, Calcutta, in 1936, and M.Sc. in 1939.

During 1939–41, he was lecturer in botany, Jagannath College, and during 1942–43 in the Dacca Intermediate College and the Rajsahi College (now in East Pakistan). He joined the Botany Department of Presidency College, Calcutta, as a lecturer in botany in 1943 and stayed there until 1948. For two years (1948–50) he was a graduate student, University of California. In 1951 he was awarded the Ph.D. degree in genetics by that University. In 1951 he was also awarded D.Phil. (Science) degree of the University of Calcutta.

In 1952, Sen joined the Agricultural Engineering Department (Applied Botany Section) of the Indian Institute of Technology as assistant professor of applied botany. He published more than fifty scientific papers on genetics, cytogenetics and breeding of pulses.

He started the first course in India on applied botany. He was the editor of *Bulletin of the Botanical Society of Bengal* (1961–62), and first editor of *Bijnan Parichaya*, a scientific Bengali monthly, published from Dacca and founded by Prof. S. N. Bose, Prof. P. N. Mazumdar, Prof. S. G. Mukherjee, the late S. K. Sen, etc., under the inspiration of the late poet Rabindranath Tagore.

R. M. DATTA

NEWS and VIEWS

The Queen's Birthday Honours List

The following names of scientists and others associated with scientific work appear in the Queen's Birthday Honours List:

K.C.B.: G. E. Godber, chief medical officer, Ministry of Health, Ministry of Education and Home Office.

K.B.E.: Sir Charles Harington, director, National Institute for Medical Research; F. W. G. White, chairman, Australian Commonwealth Scientific and Industrial Research Organization.

Knights: B. de Bunsen, principal, Makerere College, East Africa; T. F. Fox, editor of the *Lancet*; J. F. Lockwood, Master of Birkbeck College, University of London; J. T. Randall, professor of biophysics, King's College, University of London; F. J. Schonell, vice-chancellor, University of Queensland.

C.B.: A. W. Stableforth, director, Veterinary Laboratory, Ministry of Agriculture, Fisheries and Food; R. W. Sutton, superintendent, Services Electronic Research Laboratory, Admiralty.

C.M.G.: J. C. F. Hopkins, director, Commonwealth Mycological Institute; D. Rhind, adviser on agricultural research, Department of Technical Co-operation; P. R. Stephenson, lately director, Desert Locust Survey; L. T. D. Williams, director-general of Atomic Weapons, Ministry of Aviation.

C.B.E.: A. C. Best, chief scientific officer, Meteorological Office; F. C. Fraser, keeper of zoology, British Museum (Natural History); A. C. Frazer, professor of medical biochemistry and pharmacology, University of Birmingham; T. R. R. Mann, director, Agricultural Research Council Unit of Reproductive Physiology and Biochemistry, Cambridge; J. M. Robertson, Gardiner professor of chemistry, University of Glasgow; T. L. Viney, director (works and buildings), engineering group, U.K. Atomic Energy Authority.

Ministry of Aviation Appointments :

Mr. F. H. East

Mr. F. H. East has been appointed head of Weapons Project Group, Weapons Department, Royal Aircraft Establishment, Farnborough. Mr. East was educated at the Skinners' Company's School, Tunbridge Wells, and at University College, Exeter. After taking a University of London degree in physics in 1940 he joined the Research Department of the Royal Aircraft Establishment in Exeter, where he was engaged on defence system research and the early experiments on proximity fuzes. He transferred to the Armaments Department of the Royal Aircraft Establishment in 1942 and worked on sighting systems for aircraft guns and rockets. He was given a permanent appointment to the Scientific Civil Service in the post-war reconstruction scheme and was responsible for the development of fuzing systems for a variety of weapons. He paid a number of visits to Australia to assist in the planning of facilities at the Woomera range and to carry out some of the early trials. In 1954 he joined the team at the Royal Aircraft Establishment responsible for the design of advanced weapon systems, and in 1957 was appointed assistant director of Air Armament Research and Development in the Ministry of Supply. He has been closely associated with the U.S./U.K. *Skybolt* project since its inception. He was elected an Associate of the Institute of Physics in 1941, an Associate Fellow of the Royal Aeronautical Society and a Member of the Institution of Electrical Engineers in 1958.

Mr. A. Stratton

Mr. A. Stratton has been appointed head of the Research and Assessment Group, Weapons Department, Royal Aircraft Establishment, Farnborough. Mr. Stratton was educated at the Skinners' Company's School, Tunbridge Wells, and University College, Exeter, obtaining honours in physics. He joined the Royal Aircraft Establishment in October 1939, his wartime field of work being research and development on radio proximity (*V.T.*) fuzes. This work was recognized by the awards of the United States Medal of Freedom with Bronze Palm and the sum of £2,000 by the Royal Commission on Awards to Inventors. He was appointed senior scientific officer in the post-war Reconstruction Competition (1946) and promoted to principal scientific officer in 1948. In 1954 he was appointed superintendent of Instruments Division in the Instrument and Air Photography Department of the Royal Aircraft Establishment, with the rank of senior principal scientific officer, where he worked on aircraft instruments and inertial navigation. He has published a number of papers in these fields. He was elected a Fellow of the Institute of Physics in 1945, an Associate Member of the Institution of Electrical Engineers in 1953 and a Member of the Institute of Navigation in 1960. In 1951 he obtained an M.Sc. (London) degree in mathematics and in 1957 a B.Sc. (Oxon.) *ad eundem*. He is at present chairman of Convocation, University of Exeter.

Electrical Engineering at Manchester :

Prof. E. H. Rhoderick

Dr. Emlyn Huw Rhoderick has been appointed to a newly created chair in electrical engineering in the Faculty of Technology, Manchester College of Science and Technology. Dr. Rhoderick was educated at Jesus College, Oxford, where he graduated with honours in the School of Natural Science (Physics) in 1941. In 1941 he was employed as junior scientific officer (afterwards scientific officer) at the Radar Research and Development Establishment, Malvern, where he was engaged on the development of microwave radar. He became a research student at Trinity College, Cambridge, in 1945, working at the Cavendish Laboratory in the field of nuclear physics, and graduated Ph.D. (Cambridge) in 1948. During 1948–54 he held the post of lecturer in natural philosophy at the University of Glasgow, where in the last three years he acted as head of the Physics Honours Class. For the academic year 1960–61 he studied as a Fulbright Fellow at Columbia University, New York, working on the radio-frequency spectroscopy of atoms. Since 1955 Dr. Rhoderick has worked at the Services Electronics Research Laboratory (Admiralty), Baldock, as principal and senior principal scientific officer, working on semi-conductors, and on superconductivity in thin films, recently as leader of a research group. He is also at present editor of the *Services Electronics Research Laboratory Technical Journal*.

Scientific and Technical Personnel in the United States

Scientific Manpower Bulletin No. 17 (April 1962), issued by the National Science Foundation, summarizes characteristics of scientists reporting to the National Register of Scientific and Technical Personnel, 1960. The median annual salary of United States scientists in 1960 was 9,000 dollars—a 14 per cent increase on the 1956–58 average. Of the 201,292 reporting, almost half were in private industry or self-employed, 28 per cent were employed by educational institutions, and 16 per cent by Government. Almost 75,000 were employed in research, development or design, nearly 30,000 in teaching and 49,000 in management or administration. The age group 20–29 claimed 18 per cent, 30–39, 40 per cent, and 40–49, 24 per cent. Chemists (53,000), biological sciences (27,000), engineering (24,000), physics (20,000) and the geological sciences (17,000) claimed the largest numbers. Some 25,000 scientists are at present reporting for 1962.

Overseas Students in Britain

THE Association of Universities of the British Commonwealth reports 13,385 students (1,862 women) enrolled for full-time study or research in United Kingdom universities at the beginning of the academic year 1961–62, compared with 12,410 in 1960–61 and 11,284 in 1959–60. Of these, 8,086 came from other parts of the Commonwealth, India sending 1,660 and Nigeria 1,124; 297 were studying agriculture and forestry; 3,415, arts; 165, dentistry; 2,157, medicine; 1,984, science; 2,316, social studies; 2,958, technology; and 93, veterinary science. Of the 5,716 postgraduate students, arts (1,639), medicine (875), science (1,152), social sciences (879) and technology (990) claimed the largest numbers, and most came from India (892), the United States (658), Canada (442), Pakistan (347) and Australia (290). Of the total, 5,850 held an award of some kind and 2,750 were living in college or hall of residence and 10,635 in lodgings or with friends or relatives. There were also 1,981 students enrolled for part-time study or research, of whom 948 came from other parts of the Commonwealth and 956 were postgraduate.

Degree Failures in British Universities

IN a written answer in the House of Commons on May 16, the Minister of Education, Sir David Eccles, gave the number of students with State Awards who failed their first degree examinations at the Universities of Cambridge and Oxford as 13 out of 1,381 in 1956–57 and 28 out of 1,516 at other universities; in 1958–59 the corresponding figures are: 14 out of 1,844 and 37 out of 1,331; and in 1960–61, 11 out of 2,048 and 40 out of 1,507. For Local Education Authority Awards at all universities the figures are: 1956–57, 599 out of 11,121; 1958–59, 697 out of 13,553; and 1960–61, 757 out of 16,022.

Geophysics and Oceanology in the Indian Ocean and Persian Gulf

THE Survey Ships H.M.S. *Owen* and H.M.S. *Dalrymple* returned to the United Kingdom on May 31 after a series of surveys, respectively in the Indian Ocean and Persian Gulf, as a result of which it has been discovered that the East African Continent may extend underwater almost as far as the Seychelles, nearly 1,000 miles from the existing coastline. Work carried out by H.M.S. *Owen* has revealed an offshore zone 200 miles wide and extending about 2,000 miles from Madagascar to Socotra. The zone is characterized by a striking absence of gravimetric and magnetic relief, suggesting that the whole zone may be underlaid by a wedge of sedimentary rocks, several miles in thickness. Geologists working on land in East Africa and Madagascar have suspected that the eastward-tilted Continent might continue beneath the deep water of the Indian Ocean, and the findings of H.M.S. *Owen* this year appear to confirm this. This work has been part of the British contribution to the International Indian Ocean Expedition, jointly sponsored by the International Council of Scientific Unions and by Unesco, and has two objects: the scientific exploration of the marine biology, water circulation and submarine geology of the Indian Ocean; and the encouragment of marine sciences in the countries bordering the Indian Ocean, the rising populations of which may soon compel them to turn to the sea for food. The scientific programme for H.M.S. *Owen* was planned by a Committee set up by the Royal Society at the invitation of the Hydrographer of the Royal Navy, and its execution was entrusted to the Department of Geophysics, University of Cambridge. H.M.S. *Dalrymple* has carried scientists from the Imperial College of Science and Technology, and during the season in the Middle East has obtained approximately 5,500 miles of magnetic profiling using a nuclear spin magnetometer. Although recording took place whenever possible, attention was mainly concentrated on the John Murray Ridge in the North Indian Ocean and its extension in the Gulf of Aden. For this special purpose the ship steamed along six tracks specially chosen to cross the Ridge, while all other profiles were obtained during normal working of the ship.

The City Museum, Sheffield

THE annual report for the year ending March 31, 1961, of the City Museum, Sheffield, records several new displays (Pp. 16+4 plates. Sheffield: The City Museum, 1962). In the Archæology Gallery, a four-year task has been brought to completion by the re-arranging of British material dating from the Palæolithic to Mediæval times. When the headquarters of the York and Lancaster Regiment were transferred from Pontefract to Sheffield in 1960, space for part of the extensive regimental museum was allocated at the Weston Park Museum. In the Natural History Galleries a series of new displays, designed to promote interest in bird protection and the conservation of wild-life in general, were introduced. A group of cases illustrating the National Parks of the Peak District, the Highlands of Scotland and East Anglia proved popular.

Dauntney's School Natural History Society

THE report of Dauntney's School Natural History Society covers the period 1959–61 and consists mainly of summaries of the individual field studies carried out by boys and submitted to the Cambridge examiners under their field work scheme (Pp. 44. West Lavington, Near Devizes: Dauntney's School Natural History Society, 1962). Most of their allotted time is devoted to community studies in woodland and fresh water near the school, and to work in the biological gardens, but after an introductory term boys are encouraged to select for study topics in which they are particularly interested. The subjects studied include *Basidiomycetes* on tree-stumps in Erlestoke Woods by H. T. H. Cromack; the size of *Gammarus pulex* in fast- and slow-running streams by K. Houston; the growth of *Limnaea pereger* in a wild population by F. P. H. Huntingdon; the performance of *Endymion non-scriptus* in open and shaded areas by D. S. I. Taylor; and the effects of temperature on air breathing in *Limnaea stagnalis* (L) by R. L. Page. The report also contains details of the School's biological gardens and the meetings held by the Society.

Electrical Engineering *Conference Report Series*

As one of the several alternative methods for the rapid publication of the proceedings of conferences and symposia, the Papers Committee of the Institution of Electrical Engineers has launched a new series, *Conference Report Series* (1. Pp. ii+27. London: Institution of Electrical Engineers, 1962. 5*s*.). The first number contains a report of the proceedings of the symposium on nuclear electronics held during November 20–December 1, 1961, at Savoy Place, London, which was organized by the Measurement and Control Section of the Institution in conjunction with the British Nuclear Energy Conference. A conference on the same subject was held by the International Atomic Agency at Belgrade during May 1961. The Institution's symposium was held in order to enable those who were not fortunate enough to attend the Belgrade conference to hear and discuss reports on the material presented. Copies of the papers presented at that conference are not yet available, but the proceedings are to be published this year by the Agency. There were three sessions at the symposium devoted to radiation detectors, electronic circuits and techniques, and radiation monitors and instruments, respectively. Contributions included reports on the Belgrade conference by W. Abson, K. Kandiah and D. Taylor, and brief notes by J. B. Birks on improved organic scintillator detectors; Prof. A. W. Merrison and others on data-logging equipment for nuclear physics experiments; and D. E. Barnes on plutonium monitoring.

Standardized Genetic Nomenclature for Mice

THE Committee on Standardized Genetic Nomenclature for Mice has prepared two listings of inbred strains of mice, arranged alphabetically according to standardized designations. These appeared in *Cancer Research* (12, 602; 1952; and 20, 145; 1960). While virtually all investigators who maintain colonies of inbred mice have accepted the standardized nomenclature in theory, a few of them are careless in practice. Of those investigators who do not raise their own animals, some are often ignorant of the rules and may copy incorrect usage from other sources; others who know the rules may at times be careless. The Committee feels that it is as important to use correct designations for strains as to spell ordinary words correctly, and has now made available reprints of the second listing. Copies of this can be obtained from: Dr. Mary F. Lyon, Radiobiological Research Unit, Harwell, Didcot, Berks; Dr. N. N. Medvedev, Laboratory of Inbred Animals, Academy of Sciences of the U.S.S.R., Moscow, Solyanka 14; or Miss Joan Staats, Roscoe B. Jackson Memorial Laboratory, Bar Harbor, Maine, U.S.A.

Fluorescence Microscopy in the Diagnosis of Pulmonary Tuberculosis

THE demonstration of acid-fast bacilli in smears of sputum remains the most rapid laboratory technique for a presumptive diagnosis of pulmonary tuberculosis. The widely used and classical staining technique of Ziel-Neelsen has limitations, however, in Africa, where there are limited laboratory facilities and where there is a shortage of trained laboratory staff. The technique may not always be accurate when used in the large out-patient clinics, for technicians are pressed for time and long and tiresome scanning of smears is often necessary before the presence or absence of bacilli can be assumed. Thus, a more efficient method is required. A method of fluorescence microscopy for the detection of acid-fast bacilli was introduced by Hagemann in 1937 and has been developed by others over the years. The method consists of staining bacilli by the fluorescent dye auramine, to which they are acid- and alcohol-fast, and which has the property of converting rays at the lower end of the spectrum to light of longer wave-length. When auramine-stained bacilli are subjected to a source of ultra-violet light which has been passed through a filter to absorb blue-violet and ultra-violet rays, they fluoresce; if a yellow filter is placed in the eyepiece they appear yellow against a dark field. The fluorescence is clearly visible microscopically, and a magnification of 200–300 times is sufficient to recognize acid-fast bacilli. A paper by Dr. W. J. Bell and Dr. P. P. Brown, of the West African Council for Medical Research, Tuberculosis Research Unit, Ghana, presents evidence for the accuracy of the method of fluorescence microscopy when used by junior technicians in Africa (*Cent. Afric. J. Med.*, 8, No. 1; January 1962).

Medical Research Council : New Research Group

THE Medical Research Council is to establish a Research Group on the Relationship between Organic and Functional Mental Disorders in the Department of Psychological Medicine, King's College, Newcastle-upon-Tyne (University of Durham), under the honorary direction of Prof. Martin Roth.

The International Society on Toxinology

A NEW international society devoted to the advancement of knowledge on the plant and animal toxins was recently formed in Atlantic City, New Jersey. The new society is known as the International Society on Toxinology and will bring together biochemists, pharmacologists, toxicologists, physiologists, immunologists and physicians with interests in the toxins derived from the tissues of plants and animals. Founding officers are: *President*, F. E. Russell, Los Angeles; *Secretary-Treasurer*, P. R. Saunders, Los Angeles; *International Co-Chairmen*, H. Michl, F. Ghiretti, A. de Vries, B. N. Ghosh, S. A. Minton, H. A. Reid, T. M. Yanagita, J. M. Gonclaves, J. F. Gennaro and M. Whiting. The office for the new Society is Box 323, 1200 N. State Street, Los Angeles 33, California. The journal *Toxicon* will become the official organ of the new group and will carry notes and announcements of the Society's activities.

Beit Memorial Fellowships

THE following elections to Beit Memorial Fellowships have been announced: *Junior Fellowships*,

P. P. Dendy, to investigate the effects of irradiation with a microbeam of ultra-violet light on the protein metabolism of cells, at the Department of Radiotherapeutics, University of Cambridge; D. Gompertz, to investigate the effect of pituitary growth hormone on fat synthesis, at the Department of Biochemistry, University College, London; M. R. Lee, to investigate the control of the generation of vasoactive polypeptides in the blood, at the Department of the Regius professor of medicine, the Radcliffe Infirmary, Oxford; Dr. G. F. Rowland, to investigate nucleic acid synthesis in the isolated pre-cancerous nucleus, at the Department of Chemical Pathology, University College Hospital Medical School, London; Dr. Sheila M. Day, to investigate the factors that influence the binding of amines in normal and neoplastic mast cells, at the Department of Pharmacology, Royal College of Surgeons of England, London; E. A. Newsholme, to investigate the importance of the 6-phosphofructokinase reaction in the regulation of muscle glycolysis, at the Department of Biochemistry, University of Oxford; J. S. Wigglesworth, to investigate the cytology of the human placenta in normal and abnormal pregnancy, at the Department of Morbid Anatomy, University College Hospital Medical School, London.

The Royal Institution: Open Days

Open days at the Royal Institution are being arranged this year for June 14–15. To mark the centenary of the birth of Sir William Henry Bragg (1862–1942), who was director of the Davy Faraday Research Laboratory from 1926 until 1942, X-ray crystallographic laboratories in Britain are providing a series of exhibits which illustrate the historical development of the subject. The main emphasis of the research work at present proceeding in the Davy Faraday Laboratory is on the application of X-ray diffraction methods to the study of biological molecules, and a number of rooms in the Laboratory, where some of the latest work in this field can be seen, will be open to visitors. The exhibition will be open each day from 10 a.m. to 1.0 p.m. and from 2.30 p.m. to 6.0 p.m. Further information can be obtained from the Royal Institution, 21 Albemarle Street, London, W.1.

Course on Aerial Photogrammetry

A theoretical and technical course on "Aerial Photogrammetry", arranged by the French National School for Geographic Sciences, will be held at Saint-Mandé, near Paris, during June 18–July 27. The programme of lectures will include: general problems of aerial photogrammetry; problems concerning aerial surveys; principles, construction and adjustment of plotting machines; problems concerning mean scales (1/5,000 to 1/50,000) and small scales (1/100,000 and 1/200,000) plotting; practice of aerial triangulation; mechanical and electronical methods for compensation of blocks in aerial triangulation. There will also be practical instruction on the use of instruments and visits to different places concerned with photogrammetrical activities. Further information can be obtained from the Director, l'Ecole Nationale des Sciences Géographiques, 2 Avenue Pasteur, Saint-Mandé (Seine).

Conferences on Dermatoglyphics

On the occasion of the Second International Conference on Human Genetics, held in Rome during September 6–12, 1961, an organization devoted to research on finger-prints, palms and soles (dermatoglyphics) was formed. Its principal objectives are to promote activity in this field, to distribute information on current investigations, to standardize methods and to hold meetings for the presentation of reports and discussions. Interested workers are invited to communicate with any member of the Organizing Committee: *President*, Prof. Harold Cummins, Tulane School of Medicine, 1430 Tulane Avenue, New Orleans 12, Louisiana; *Chairman*, Dr. José Pons, Universidad de Barcelona, Barcelona; *Secretary*, Mr. Abhimanyu Sharma, 40/*C* Hanuman Lane, New Delhi-1; Dr. Mariassa Bat-Miriam, Israeli Institute for Biological Research, P.O.B. 19, Ness Ziona; Dr. Sarah B. Holt, University College, Gower Street, London, W.C.1; Commissioner C. H. Vogelius Andersen, Danish Identification Bureau, Politigaarden, Copenhagen V; Dr. Margaret Weninger, Universitat Wien, Van Swietengasse 1, Wien IX; Prof. Masaya Yasunaka, Nagasaki University School of Medicine, 1699 Sakomoto-machi, Nagasaki-City.

Announcements

Under the Statute of the Royal Society which provides for the election of persons who either have rendered conspicuous service to the cause of science or are such that their election would be of signal benefit to the Society, the Right Hon. Harold Macmillan has been elected a Fellow of the Royal Society.

Consequent on the acquisition of the shares of J. W. Towers and Co., Ltd., by A. Gallenkamp and Co., Ltd., the name of J. W. Towers and Co., Ltd., has now been changed to A. Gallenkamp and Co. (Northern), Ltd. The two companies will in future both trade under the registered business name of 'Gallenkamp. (Reg. trade mark)'.

The British Cast Iron Research Association is holding open days during July 3–4. Visitors will be able to see the Association's new laboratory, which is to be inaugurated by the Marquess of Exeter on July 3, and a representative selection of the Association's work will be on show. Further information can be obtained from the Publications Officer, British Cast Iron Research Association, Bordesley Hall, Alvechurch, Birmingham.

A symposium on "Sonar Systems", sponsored jointly by the British Institution of Radio Engineers, the Institute of Physics and the Physical Society and the Electrical Engineering Department of the University of Birmingham, will be held in the University of Birmingham during July 9–12. Subjects under discussion will include: propagation; survey equipment; sonar for fisheries; arrays and signal processing. Further information can be obtained from the British Institution of Radio Engineers, 9 Bedford Square, London, W.C.1.

The annual meeting of holders of Nobel Prizes will be held in Lindau during June 24–29. This year the lectures will be given by physicists, among whom will be: Prof. N. Bohr (Copenhagen); Prof. H. C. Urey (California); Prof. R. Hofstadter (California); Prof. J. Franck (North Carolina); Sir John Cockcroft (Harwell); Sir Edward Appleton (Edinburgh); Dr. J. Bardeen (Illinois); Prof. M. Born (Bad Pyrmont); Prof. W. H. Brattain (New Jersey); Prof. W. Heisenberg (Munich). Further information can be obtained from Hans Kiderlen, Nonnenhorn/Bodensee, Uferstrasse 65*a*.

POTATO DISEASES

POTATO production is beset with persistent troubles which all add to uncertainties of cropping, so potently felt in Britain at present. In addition to vagaries of weather, it sustains the heaviest loss from disease of any single crop—28 per cent of total value in west Scotland, and only about half this loss is controllable by economic methods known at present. Here is a challenge, and it is most opportune that the Pathology Section of the European Association for Potato Research arranged a meeting at the Edinburgh School of Agriculture during March 26–29. It was particularly well organized by Dr. A. E. W. Boyd, chairman of the Section, with the assistance of Dr. J. H. Lennard as secretary.

The first session discussed black scurf (*Rhizoctonia solani*) and common scab (*Streptomyces scabies*), two 'nuisance' diseases which reduce market value in times of plenty, out of all proportion to their minute effect on nutritive quality though *R. solani* can also reduce the yield. R. E. Labruyère reported the appearance of both diseases in newly reclaimed virgin polders in the Netherlands; infection by *R. solani* (though not of scab) could best be prevented by treatment of seed tubers with organo mercury compounds. In Sweden, G. Smedgård had used thiram powder (TMTD) as a control of black scurf on the tubers, with increases of yield between 8 and 16 per cent. Elizabeth G. Gray reported that fumigation of washed or brushed tubers with trichloroethylene greatly reduced germination of sclerotia, but warned that the bacterial disease blackleg could be increased by washing and chemical treatment. Organo-mercurial compounds are toxic, and D. C. Graham has investigated the use of safer organo-tin substances; one gave good control of *R. solani* but is at present uneconomic. Soil treatment with PCNB was found by O. Wagn to control both scab and black scurf in Denmark. B. G. Lewis described his experiments on moisture-level in scab infection, a subject on which much information is needed. Control by resistant varieties would be ideal though commercial stocks are all more or less susceptible, but R. K. McKee described the testing of new varieties.

Potato root eelworm, *Heterodera rostochiensis*, is not so much a cause of present loss as a huge menace for the future. The present policy is to avoid potato growth in infested ground; but the amount of eelworm-free land is diminishing exponentially. Again the ideal solution would be to produce resistant varieties, and suitable genes occur in certain wild *Solanum* varieties. There are, however, resistance-breaking biotypes of the parasite, as described by J. M. Dunnett (Scotland) and C. A. Huijsman (Netherlands). An extensive survey by F. G. W. Jones, followed by detailed assessment, showed that resistance derived from *S. andigenum* would be immediately useful on about half the potato fields of Britain, that from *S. multidissectum* on about one in ten and that from *S. vernei* on about nine out of ten. The possibility of obtaining clones resistant to more than one biotype has been investigated by H. W. Howard, using hexaploid *S* × *juzepczukii*, but so far no seedlings with dual resistance have occurred. H. den Ouden showed that eggs from cysts less than a year old gave lower rates of reproduction than those from more mature cysts, and E. Dunn described how 'pre-conditioning' at 32° C. stimulated greater larval emergence than at lower temperatures. In direct control, J. E. Peachey found the most satisfactory assay of performance was by root invasion and that sodium methyl dithiocarbamate was the best of 12 compounds tested. J. Grainger described practical 'disease escape' where first-early potatoes can grow before the eelworm becomes active at a soil temperature of 7° C. A suitable variety must be able to devote a large proportion of its dry weight to tuber production during low temperatures and short, dull days, and, so far, none better than the variety Epicure has been found. He also demonstrated a new type of tractor-mounted machine for mixing the cheaper non-volatile control materials very intimately with the soil mass, thus bringing the possibility of control sufficiently economic for field use.

An urgent problem with bacterial disease is to exclude from temperate countries the pathogens *Pseudomonas solanacearum*, causing brown rot, and *Corynebacterium sepedonicum*, giving a tuber ring rot Bacteriologists held a separate session under the chairmanship of Dr. D. C. Graham as a result of the European Plant Protection Organization conference on this subject in Paris, 1960. A. C. Hayward reported four strains of the brown-rot organism and the discovery of such variants makes it more imperative than ever to avoid the introduction of this disease on ware potatoes imported during the present potato shortage in Britain. International quarantine arrangements make a co-operative approach impossible, so the value of such consultations as were held in Edinburgh is greatly enhanced.

Late blight, *Phytophthora infestans*, is the most serious potato disease at present. G. A. de Weille showed that bright sunshine reduced spore germination by lowering air humidity and by direct inactivation. Sunshine and rainfall forecasts can be used to predict the progress of crop infection. I. F. Storey found that only some 'Beaumont' periods actually forecast the first appearance of the disease, and V. Mélard compared genetically produced field resistance of the foliage with hypersensitive resistance and correlated both with tuber resistance, where the disease causes the heaviest loss and that most difficult to control.

The production of virus-free potato seed has helped to stabilize yield more than any other factor, and the process could be carried further if transmitting aphids on the crop could be controlled. Menazon, a systemic insecticide, has been used by J. F. Newman as a tuber dressing to protect the young sprouts for eight weeks, and C. E. Taylor reported a correlation between severity of aphid attack and physiological state of the host plant. Short communications were made by Maria Kostrowicka (unusual symptoms of potato rots), Mary Noble on races of wart disease which can attack 'resistant' varieties, and E. P. Keller on the detection of tuber discolorations by the relative transmission of strong light through them. Visits were made by members of the conference to the Scottish Plant Breeding Station, Pentlandfield, for demonstration of genetic resistance to blight, root eelworm, scab and viruses, and the Agricultural Scientific Services Station of the Department of Agriculture and Fisheries for Scotland, for disease testing, eelworm assessment and experimental washing and disinfection. Visits were also made to the original Wedderspoon plant at Castleton, Eassie, for commercial washing and fungicidal dipping, and a store at Muthill, Crieff, where the palette system of storage is utilized, and where fungicidal dipping of cut ware tubers is carried out before planting. An informal reception by the Potato Marketing Board completed the proceedings.

Shortage of potatoes engenders public clamour and the acceptance of relatively low standards of quality: excess of supply excites less comment, but brings a fussy rejection of tubers with but slight blemish from scab or blight. Neither extreme is good, and the Potato Marketing Board has gone as far as it can by administrative means to steer between plenty and scarcity. The only valid long-term solution requires the technical discovery of an economic method of preserving surplus production for human food in times of shortage, and the Board has initiated a research programme that includes this. Such a technical solution would, moreover, contribute to the larger question of adjusting the world's food supply to its growing population. J. GRAINGER

THE BIOLOGICAL ENGINEERING SOCIETY

THE Biological Engineering Society held its second meeting of the year in the Physiological Laboratory, Cambridge, during March 23 and 24, under the chairmanship of the president, Prof. R. Woolmer. Sir Bryan Matthews, the guest speaker, described some engineering methods in physiology. Sir Bryan gave some instances both of the way in which apparatus has been designed at Cambridge, both past and present, to assist in teaching and research, and of the ways in which advanced engineering principles are found in biological material; the mammalian ear was invoked as an elegant example here.

P. E. K. Donaldson (Physiological Laboratory, Cambridge) described a machine for the automatic simulation of human skills. The simplest skills seem to be those of the $S \to R$ kind, in which S and R can each be described by a single continuous variable. Tracking tasks, and tasks involving the stabilization of unstable systems (for example, bicycle riding) require skill of this class. It has been known for some time that human operators can be represented quite closely by relationships of the form:

$$R = e^{-p\tau} (Ap + B + C/p) S$$

Mr. Donaldson described a machine which automatically forms an image of a human operator performing a simple balancing trick, and in so doing finds values for A, B and C which, on the average, give the best fit. It is hoped to develop this device so as to be able to describe analytically what happens when an individual's skill improves with practice, or when it deteriorates in consequence of various kinds of distraction.

Dr. H. Barlow (Physiological Laboratory, Cambridge) discussed learning machines and generalization. Dr. Barlow felt that designers of existing learning machines, or of proposed learning machines, are trying to achieve too much too quickly. These machines can be regarded as linking units in which input data from the environment are acted on by a number of 'demons' which operate on the inputs in a variety of ways to form the outputs of the machine. Some sort of 'teacher' monitors the outputs in the light of some criteria, 'rewarding' the demons when their output is deemed valuable and 'punishing' them when it is not. Though such systems can be made to work, they are characteristically unable to do any kind of generalization, for example, to respond correctly if gaps or mistakes occur in the input data.

What is needed in order to generalize and fill gaps is knowledge of the statistics of the input. This leads to the idea that linking units should be preceded by a 'precoder', the function of which is to form, from the raw inputs derived from the environment, new signals with known predetermined statistical properties. It is these new signals which are fed to the linking unit. Such precoding may be done by a demon-flogging feedback technique, as is done in the linking unit itself, but with some important differences: the rate of feedback of information is much larger than the 1·6 bits per trial gained in the linking unit (outcome of each trial 'reward', 'punish' or 'neutral', $\log_2 3 = 1{\cdot}6$); the statistical requirement can be built in; and the teacher does not need to have access to the raw inputs. The output of the precoder is simpler than the raw input, since its statistics are now known, and forms a more suitable input to the linking unit.

The dynamics and operating characteristics of a common artificial kidney system were described by H. A. F. Dudley (Department of Surgery, University of Aberdeen). Dr. Dudley has been carrying out some performance measurements on an artificial kidney of the twin-coil type, the channels being 20 m. long. The performance of such a device should be described by:

$$D = V\left[1 - \exp - \frac{PS}{V}\right]$$

where V is the rate of flow of blood, D is the rate of flow of filtered blood in the output, P is the permeability constant for the 'Cellophane' membrane, and S the surface area of the membrane. For small values of V the theoretical performance can be obtained in practice, but for higher values, which are nevertheless within the range of flow-rates possible in human subjects, the artificial kidney falls far short of what may be expected; especially if the output blood pressure is high. The discrepancy seems to be caused, at least in part, by a decline in the surface-to-volume ratio of the blood channel toward the output end. The deficiency can probably be remedied by a change in the design of these instruments; but in any event it is clear that preliminary work with models is necessary to produce an artificial kidney to meet a previously laid down specification.

R. L. Gregory (Psychological Laboratory, Cambridge) gave a talk on "Digital Recording for the Poor Man".

It frequently happens that experimental results are recorded in a manner which retains more information than is actually required. For example, in measuring a quantity by averaging a number of determinations the mean value and the standard deviation may be important, whereas the serial order in which the readings are obtained is not. Mr. Gregory described a simple recorder he has designed in which advantage is taken of the economy possible here. A display is built up by dropping steel balls into cells in a 'Perspex' sheet or block. In one application the recorder builds up, from balls, a histogram showing the distribution of a reaction time. When the stimulus is delivered, a ball is transferred from the magazine to a moving belt, which carries it over a line of cells. When the subject responds, the ball is released and drops in the appropriate cell beneath it. The process repeats with the delivery of the next stimulus. If the reaction time is the same, the new ball will fall into the same cell as its predecessor; in general the time will be slightly different, and the ball will fall into a neighbouring cell. Mr. Gregory pointed out how easy it should be to find the mean and standard deviation of the completed display; the former by finding where it balances on a knife-edge, and the latter by measuring its moment of inertia. So far as the display proper is concerned, there is no reason why the base of the histogram should not be some quantity other than time; the ball dropper can be positioned by an appropriate servo-mechanism. Further, the base of the histogram can be plane rather than linear, so that 'solid' models of joint frequencies may be built up.

Electrochemical recorders and memories were discussed by H. S. Wolff (Bio-engineering Laboratory, National Institute of Medical Research, Hampstead, N.W.3).

Mr. Wolff began with a disavowal; what he was going to talk about were proposals rather than achievements. He needed to produce data recorders very much smaller than those at present in general use, sufficiently small to be worn by human subjects for long periods without causing inconvenience or discomfort. A possible solution was a small electrochemical cell possessing two anodes and one cathode.

One anode would be of simple metal, the other of a long-life radioisotope of the metal, for example, nickel and nickel-64. The quantity to be recorded would control the mark/space ratio of a multivibrator, which in turn would switch plating current between the two anodes. In this way, the quantity to be recorded would be laid down as a fluctuation in the proportion of radio nickel with the depth of the coating built up on the cathode. Such a record could be read back once, by unplating the cathode again and measuring the radioactivity of the electrolyte solution with a suitable detector.

Another problem was some way of storing a number without the continuous expenditure of energy. In contemporary analogue computing practice this is done by a servo-driven potentiometer; this technique works quite well, but is neither very small nor very cheap. An arrangement which would be both small and cheap would be to have a junction photocell with between it and a source of illumination a semi-transparent electro-plated film; the output of the photocell would depend on the thickness of the electro-deposited layer. It remained to be seen whether it would be equally satisfactory in other respects.

"Monkey Perimetry", was the subject of a paper by L. Weiskrantz (Psychological Laboratory, Cambridge). Dr. Weiskrantz and Dr. A. Cowey have been examining the effect of experimentally produced brain lesions on the field of vision of monkeys. To map the boundaries of a monkey's visual field, it is clearly not possible to use the same technique as is used with human subjects. The best that can be done is to train the monkey to respond in a recognizable way if it sees a small light flashed on; then to flash lights on, one by one, a very large number of times and from a number of different directions, recording each time where the monkey was looking. By subtracting the co-ordinates of the monkey's point of regard from the co-ordinates of the light flashed, one can—by knowing also whether the monkey saw the light or not—build up eventually a map of the monkey's perimeter of vision.

The problem was to measure where the monkey was looking. This was solved by having in front of the monkey, in addition to the field of small test lights, four bigger lights permanently switched on; one above and one below the test field in the sagittal plane, and one each side of the test field in the coronal plane. The monkey's eye is photographed during each presentation of a test light. In the photograph the four are seen reflected in the monkey's eye as four bright points arranged round the pupil. By measuring the distances from the bright points to the edge of the pupil, the direction of gaze can be inferred.

Unfortunately, such measurements are sensitive to translations of the monkey's eyeball as well as to rotations; but this difficulty is met by obliging the monkey to look through a peephole. The precision of each determination obtained by the technique is estimated at plus or minus two degrees of arc.

R. H. J. Brown (Zoological Laboratory, Cambridge) described the measurement of the ground reaction of the jumping locust.

Dr. Brown had carried out a rough calculation to establish the peak tension achieved in the extensor muscle of a locust's tibia when it jumps. This came out to about 1·5 kgm. and it was felt that this remarkable figure needed some experimental confirmation; the apparatus described was built in consequence.

The locust jumps off a platform stiffly mounted but capable of movement in the vertical and one horizontal direction; such movement is coupled to two capacitance transducers. In this way the transducers measure the horizontal and vertical components of the locusts's ground reaction in jumping off, effectively, a rigid platform. The damping of the mechanical system is rather below critical, and the resonance occurs at 500 c./s.; the sensitivity is 40 pFs./kgm.

In the electronic gear associated with each transducer, the capacitance change alters the frequency of an inductance-capacitance oscillator and hence the voltage output of a coupled-in tuned detector circuit; this voltage is the output of the device and may conveniently be displayed on a cathode ray oscilloscope. The sensitivity is 20 V. per pF., giving an overall sensitivity in each of the orthogonal directions of 800 V./kgm.

The equipment is not fully developed yet, but preliminary experiments confirm the earlier calculation; the locust can indeed produce a tension of 1·5 kgm. when it jumps.

P. E. K. DONALDSON

MANAGEMENT AND RESEARCH WORKERS

IN both industry and Government, a costly and dangerous trend is emerging—a trend towards a kind of management system the pattern of operation of which is incompatible with that required for highly creative performance by scientific and engineering staff. It is a trend toward tighter budgetary controls and tighter organization of the work. It is brought about by the impact of greater competition and, even more, by faulty information concerning the relative effectiveness of various approaches to the reduction of cost and improved performance.

Prof. Rensis Likert suggests in the March issue of *International Science and Technology* that this is a dangerous trend because tighter controls, while appearing to provide desired results over a short-run period, may damage an organization over a longer span of time. As a counter-measure, he proposes a management system which enables scientists and engineers to function at their most creative level. This is a system which has evolved from an extensive programme of research by the Institute of Social Research of the University of Michigan. From the studies a number of observations concerning the performance of technical people has emerged.

When communications within the organization is frequent, scientists and engineers are likely to perform better. For example, patent applications by technical personnel are higher in such organizations, and employee evaluations of one another are also higher. Frequent communications with colleagues who think differently from one another also improve an organization's performance. Scientists who do communicate with one another, but who are not conscious of a need for competent colleagues—who maintain an independent frame of mind—tend to be better performers than those who are more dependent.

Scientists and engineers who see their administrative chief often perform better than those who do not. Their performance is better still when they can also set their own technical goals, or at least have some influence on their chief in setting those goals. Best performance is observed when the scientist has high self-determination combined with free access to someone in authority. The potentialities of younger subordinates are best developed by the supervisor who can maintain the difficult synthesis of close interest in the young man's work without domination of it. If the technical man's personal motivation is low and, if he is not deeply involved in his work, it is not advisable to allow more than moderate self-determination in his work. If his motivation is high, then full self-determination leads to best results.

These observations point to the important general conclusion that scientists and engineers are likely to be most creative when their supervision is such that they feel substantial freedom in their work—in selecting their problems and goals, in deciding on the approach to achievement, and in interpreting their data—and when they have frequent interaction with their superiors. These findings are valid for the administration of basic research, developmental research, and engineering. Such conclusions are often greeted with scepticism. To some it seems that the conclusions are obvious, needing no research to prove its validity. Many research directors argue that "my people do feel substantial freedom". Prof. Likert counters with examples to show that the true feelings of a manager's subordinates are probably quite different from what he believes them to be.

The other kind of scepticism involves a more traditional bias: if you allow too much freedom people will take advantage and the organization will suffer. Here studies have proved the reverse of this, but they have also shown that it takes time to institute such a programme. During a short period of, say, one year, the kind of programme proposed is likely to prove less productive than one that is oriented round tighter controls.

T. H. HAWKINS

EDUCATION RESEARCH IN BRITAIN

IN reply to a question in the House of Commons on April 19, the Minister of Education, Sir David Eccles, said that he had offered £5,000 a year for three years to the Educational Foundation for Visual Aids towards the running costs of its new experimental development unit; £16,000 over four years to the National Foundation for Educational Research for research into the relative merits of block release and day release; about £12,000 over three years to the University of Sheffield for research into the logical programming of mathematics syllabuses; and about £9,500 over four years to the University of Manchester for a sociological study in grammar schools. He expected that actual grants in 1962–63 for these projects would total about £12,000, and he was considering other applications.

Later, on April 19, in a debate on educational research opened by Mr. J. Boyden, the adequacy of the £20,000 which the Minister was making available for educational research was challenged. Starting with the comment in the Crowther Report that in a consistent programme of educational development almost the first step should be to review the provision for statistics and research, Mr. Boyden strongly urged more generous support for the educational research foundations. He also quoted Sir Howard Florey's appeal to the Parliamentary and Scientific Committee for greater support for university research. The universities needed more accommodation, more qualified and technical assistance and more adequate funds for research. In particular, evidence submitted to the Robbins Committee from the British Association for the Advancement of Science had been concerned with the relative lack of research facilities in sociology, social psychology and social anthropology. The lack of consistent policy in developing the social sciences within the university framework had very greatly added to the difficulties of building up a body of knowledge and methodology suitable for the study of the rapidly changing social conditions in Britain and elsewhere. It was still insufficiently realized that social fact-finding, by means of intensive and extensive field and documentary research, was both essential and very expensive. Finally, besides urging that every major educational undertaking should be so far as possible based on the results of research, Mr. Boyden suggested several questions in which research could provide a guide to policy; he also stressed the need for stable careers in educational research, and thought that a Council for Educational Research was desirable.

Mr. P. Goodhart thought that besides research into the problems of learning there was even greater need for research into the technological problems of British outlook. Mr. S. Irving suggested that one reason for the neglect of educational research was the tendency to regard education as an art and not a science. Supporting the idea of a separate Council for Educational Research, he thought more co-ordination was needed, but that the main effort in research should not come under the establishment responsible for the administration of our educational system. He thought Britain could profitably spend £25,000 a year on such research, and in this view he was supported by Mr. A. Albu, who, however, thought that educational research should be part of a wider field—that of a social science or human sciences research council, rather than a separate educational research council. Mr. F. Willey, supporting the idea of an educational research council, thought that such a council should be responsible to the Lord President of the Council, and thought there should also be a close relationship with the Ministry of Education.

In replying to the debate, which he welcomed, Sir David Eccles agreed that the tendency to regard education as an art instead of a science might be one reason for the neglect of educational research, although more such research was proceeding than was generally known. Referring to the administrative changes which were in progress to expand research and intelligence in the Ministry, drawing largely on the Inspectorate for the staff of the new Curriculum Study Group, Sir David said besides this Group there was a new Research and Intelligence Branch and a much stronger Statistics Branch. For the moment, the main task of the Curriculum Study Group would be to identify gaps in our knowledge which might be filled by research, and the Research and Intelligence Branch would then see which of these gaps could be filled and by whom. Two kinds of project were visualized. The first of these would be organized from outside the Ministry, and here Sir David hoped to gain the assistance of a committee of experienced advisers, while the second would be organized within the Department to assist the Minister in policy decisions. At present the Curriculum Study Group was engaged on a study of examinations below the level of the General Certificate of Education arising out of the Beloe Report.

A new consortium of manufacturers and local authorities under the ægis of the London County Council, called the Science Equipment Consortium, was doing for science equipment what had been done for some building materials by the Architects and Buildings Branch. Besides the field of science teaching being taken up in the Nuffield Foundation project (see *Nature*, 194, 238; 1962) there was the whole field of visual aids. In conclusion, Sir David agreed as to the importance of stable careers for research workers, expressing also the opinion that some interchange between teaching, administration and research would be useful.

THE WOOL INDUSTRIES RESEARCH ASSOCIATION

THE report of the director of research*, Dr. A. B. D. Cassie, for 1961, presented at the forty-third annual general meeting of the Wool Industries Research Association on April 11, refers to continued investigations into the causes of seasonal variation in wool production, including an intensive study of the causes of winter thinning or break in the staple, and of the incidence of shedding of fibres. Much work has been done on the identification and quantitative determination of different kinds of fibres in blends and an automatic amino-acid analyser based on the estimation of amino-acids as their copper complexes has been constructed. Extensive studies on the fractionation of α-keratose and γ-keratose have shown them to be heterogeneous mixtures of similar peptides which are very susceptible to hydrolysis in alkaline media, and α-keratose and γ-keratose are now believed to be sub-units of a protein structure of very high molecular weight. The —SS— and —SH contents of wool have been determined by polarographic methods which measure the uptake of various mercurials by virgin and reduced wool. Evidence has been obtained that the differences in the reactivity of the cystine fractions from wool keratin cannot be attributed to differences in accessibility of the cystine, to whether cystine forms intra- or inter-chain linkages, or to whether cystine is located in the fibrillar structure of the fibre or the matrix surrounding the fibrils. Difficulties in measuring accurately diffusion of dyes in keratin have been largely overcome by using thin uniform sections of horn keratin cut by microtome to a thickness of about 7μ.

Dr. Cassie also refers to further developments with the tension regulator developed for fitting to the Noble comb for controlling feed; to a continuing examination of the fundamental causes of fly waste; to further work on the effect of acid dyeing on the properties of carpet yarns and carpets. A survey of woollen and finishing operations following the tinter was commenced and attention directed to scouring in package form of worsted yarn containing a castor/sperm type combing oil.

In his chairman's address at the annual general meeting, Mr. F. W. Hirst referred to the growth of co-operation and instanced the satisfactory shrink-resistance of knitted garments to-day resulting from the joint efforts of the Hosiery Research Association and the use of a Woollen Industries Research Association shrink-resist process. A Committee of Chairman and Directors of the Textile Research Association had considered ways of promoting closer working of Associations. Healthy co-operation between the industry and the International Wool Secretariat was noticeable, while another example of co-operation was to be seen in the resolution of problems of industrial relations by discussion between management and the Unions.

WELFARE OF FARM ANIMALS

THE range of subjects dealt with by the Universities Federation for Animal Welfare, as shown by the Spring issue of the *U.F.A.W. Courier*, appears to be worth special comment in that some of them may be taken for granted by many scientific workers or given less than the necessary attention.

A reprint from *Nature*, September 30, 1961, about the symposium on the assessment of pain organized by the Federation, is apposite in a publication of its own and an article based on a lecture given by E. C. Straiton at its summer congress, 1961, on "Unnecessary Cruelties among Farm Animals", which gives emphasis to matters that are constantly under-emphasized by many people.

Straiton's theme is that farm people often, or more than often, assume too easily that the reactions of animals to pain are vastly less than might be guessed by comparison with those of human beings and that, as a corollary, there is little or no objection to the infliction of cruelty when it is done in the guise of attention to the welfare of the individual. This could be described as a cutting article, and, perhaps, this approach was suitable in order to give emphasis to many practices which are in constant operation, many of them receiving some sort of sanction in that they have been accepted for a very long time. He stated that the vast majority of working farm dogs are cruelly treated, inadequately fed, kept tied up with no water available, very often on a short chain and inadequately sheltered. He gave many instances in his experience of stupid, unskilled use of great force in attempts to calve cows, brutality in castrating farm animals, and other practices. He gave strong personal opinions about discomforts and worse from housing cloven-footed animals on accommodation with slatted floors, about the use of instruments for castrating by crushing the tissues, and about the methods of raising calves for marketing as veal by the use of the new methods designed to provide economical farm practice and at the same time veal of the type that appeals to the retail purchaser.

The issue reports Sir Thomas Dalling's account, given at the summer congress, of the international bodies which are concerned with veterinary activities designed to improve the standards and economy of animal husbandry by attention to animal health in the under-developed countries. W. A. POOL

AGGREGATION OF BLOOD PLATELETS BY ADENOSINE DIPHOSPHATE AND ITS REVERSAL

By PROF. G. V. R. BORN

Department of Pharmacology, Royal College of Surgeons of England, London

IN 1956 it was shown that blood platelets contain adenosine triphosphate (ATP) in extraordinarily high concentrations[1] and that most of this ATP breaks down rapidly when platelets are suspended in plasma which is clotting[2,3] or whenever platelets undergo viscous metamorphosis[4]. The suggestion was made[5] that if this breakdown involved ATP situated on the surface of the platelets, the large net negative charge on platelets[6] might be diminished and their tendency towards adhering to each other enhanced.

Recently, it has been found that platelets can be made to aggregate in plasma and to adhere to other surfaces by adding adenosine diphosphate (ADP) (ref. 7). Twenty-two nucleotides were tested for this effect; it was brought about only by ADP and by deoxyadenosine diphosphate. Since it is likely that ADP is produced by platelets themselves whenever their ATP breaks down, the adhesion and aggregation of platelets that occur in the initial stages of thrombosis may well be initiated by ADP. This effect has therefore been investigated by a method, recently described[8], with which the rate at and extent to which platelets aggregate can be determined quantitatively.

About 80 ml. of human blood was mixed with just enough sodium citrate (3·8 mgm./ml. blood) or heparin (0·01 mgm./ml. blood) to prevent clotting. As cooling increases the tendency of platelets to aggregate, the experiments were done at room temperature of 20°–22° C. The blood was centrifuged at $500g$ for 20 min. The plasma, usually about 35 ml. and containing 10^8–10^9 platelets/ml., was transferred with a siliconed capillary pipette into a plastic measuring cylinder.

A sample of 3 ml. was pipetted into a Spinco centrifuge tube, made of transparent plastic, which was inserted into a Unicam *SP* 400 absorptiometer. Light at a wave-length of 600 mμ was passed through the tube. The dark current was set at infinity and the optical density of distilled water at zero. The optical density of platelet-rich plasma was proportional to the concentration of platelets in it, provided the optical density of platelet-free plasma was subtracted.

The platelet-rich plasma was stirred by a small iron rod covered in polythene which was rotated magnetically. Stirring was stopped when readings were taken. When plasma was stirred gently there was no significant change in the concentration of platelets or in the optical density; this showed that the platelets did not stick to the tube or to the stirrer.

When platelet-rich plasma was stirred vigorously the concentration of platelets usually decreased slightly and so did the optical density (Fig. 1). The decrease was mostly in the first half-hour; after that it was very slow or absent. Presumably a small proportion of the platelets was broken up by vigorous stirring.

All additions were made to the plasma while it was being stirred. When substances were added which caused the platelets to aggregate, the rate and extent of aggregation increased as the rate of stirring was increased up to about 1,000 r.p.m. In the experiments described here stirring was always at this rate.

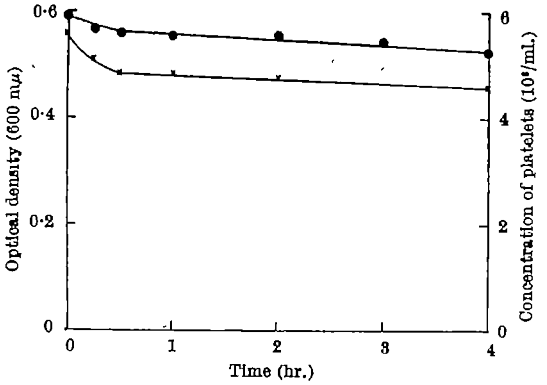

Fig. 1. Effect of vigorous stirring on the concentration of platelets (×) and on the optical density (●) of platelet-rich plasma. In the experiments illustrated by this and by Figs 2-4, human plasma was used containing sodium citrate (3·8 mgm./ml.); and the stirrer in it rotated at 1,000 r.p.m.

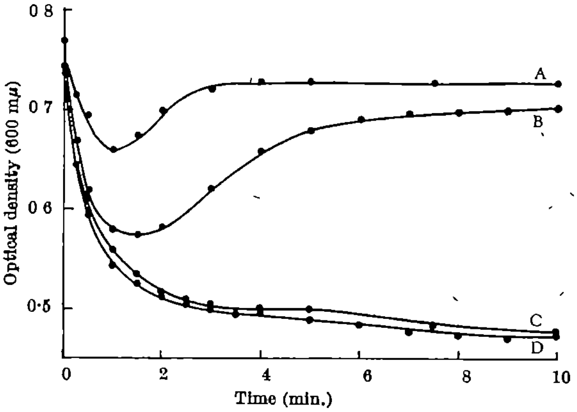

Fig 2. Effect of adding ADP on the optical density of plasma containing 4·75 × 10^8 platelets/ml. ADP was added at 0 min. to give the following concentrations. 2·5 × 10^{-7} M (curve A); 5 × 10^{-7} M (curve B); 1 × 10^{-6} M (curve C); and 2·5 × 10^{-6} M (curve D)

When ADP was added to platelet-rich plasma the optical density decreased immediately; at the same time the platelets could be seen to aggregate. Fig. 2 shows that the rate and the extent of the decrease depended on the concentration of added ADP; both were maximal when the concentration of ADP was greater than 1 × 10^{-6} M. The lowest concentration that brought about a fall in optical density was about 1 × 10^{-7} M, that is, about 0·04 μgm./ml.; this is similar to the ADP concentration which made platelets aggregate under the conditions used by Gaarder *et al.*[7].

Fig. 2 also shows that with the higher concentrations of ADP the optical density remained low and the platelets remained aggregated. However, when the concentration of added ADP was less than about 1 × 10^{-6} M the optical density began to increase again after 1–2 min., and after 10 min. it was almost the same as at the beginning, suggesting that the aggregation produced by ADP was reversible. This was confirmed by microscopy, which showed that as the optical density increased the size of the aggregates diminished until the concentration of single platelets was almost the same as it had been before the addition of ADP. These results suggested that the dispersion of the aggregates might be due to the disappearance of ADP, presumably because it is broken down to adenosine monophosphate (AMP)[9] which, unlike ADP, does not cause platelets to aggregate[7].

The aggregation brought about by ADP is reversed by AMP. In Fig. 3, curve A shows the fall in optical density of a sample of platelet-rich plasma when ADP was added; the platelets remained aggregated for 20 min. Curve B shows the changes in optical density of another sample of the plasma when ADP was added 2 min. after adding AMP at the same molar concentration. The optical density fell rapidly at first, but within 2 min. it began to increase and continued to do so for 20 min.; by then the aggregates had almost entirely dispersed.

It may be concluded that AMP antagonizes the aggregation of platelets by ADP. This strongly suggests that the reversal of aggregation observed with low concentrations of added ADP is due to its breakdown to AMP. The aggregation of platelets by ADP is antagonized also by ATP but less effectively than by AMP; this is shown in Fig. 4.

In human plasma AMP is broken down further to inosine monophosphate, inosine, and hypoxanthine[9]. Whether these substances affect the aggregation brought about by ADP has still to be established.

The mechanism by which ADP brings about the aggregation of platelets is unknown. Experiments performed so far suggest that platelets and ADP interact stoichiometrically and that calcium or magnesium is required as well as ADP. The antagonism of AMP and ATP towards aggregation by ADP may be because they compete either for specific 'aggregating sites' on the platelets or for calcium or magnesium.

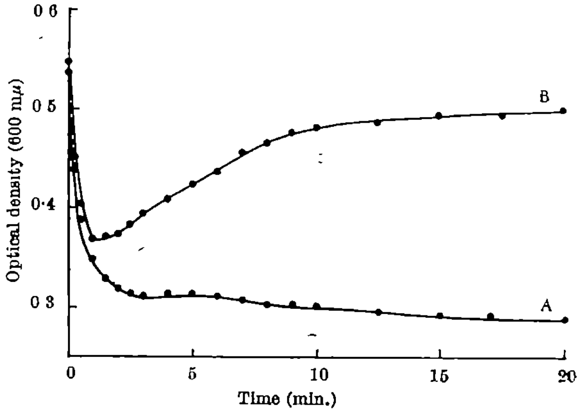

Fig. 3. Effect of adding ADP on the optical density of plasma containing 4·2 × 10^8 platelets/ml., without (curve A) and with (curve B) the addition 2 min. previously of AMP. The concentrations of AMP and ADP were 1 × 10^{-6} M

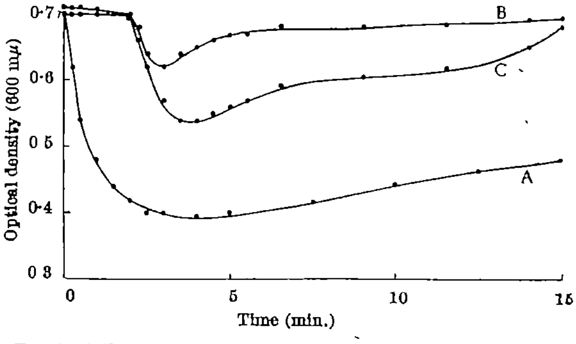

Fig. 4. Effect of adding ADP on the optical density of plasma containing 8·93 × 10^8 platelets/ml., without (curve A) and with the addition 2 min. previously of AMP (curve B) or of ATP (curve C). For A, ADP was added at 0 min. and, for B and C, at 2 min. The concentrations of AMP, ADP and ATP were 2 × 10^{-5} M

The specificity of ADP in making platelets aggregate suggests that this effect may be significant physiologically in the following way: when a blood vessel is injured ATP is broken down in damaged cells which release enough ADP to make a few platelets adhere to the damaged endothelium and to each other. At the same time tissue thromboplastin is released so that a little thrombin is formed. This brings about viscous metamorphosis in nearby platelets[10] during which their own ATP is broken down to ADP (refs. 2 and 11). The ADP, whether it is on the surface of the platelets or released with their granules, causes more platelets to adhere, so that the aggregate of platelets grows until it forms a hæmostatic plug. Pathologically, the aggregation of platelets is an immediate cause of thrombosis. This aggregation may involve ADP if pathological changes cause ADP to be released from cells in the vessel walls or in the blood.

In hæmostasis and in thrombosis platelets remain aggregated for some time before fusing together. Since released ADP presumably disappears by diffusion and by breakdown to AMP, the aggregates should disperse again unless they are maintained by ADP bound to the platelets' surfaces or by its continued release; or by another mechanism altogether.

In citrated plasma platelets can be made to aggregate by adding calcium (without necessarily inducing clotting at the same time[8]). Since calcium is required for aggregation by ADP, it may be that ADP is required for aggregation by calcium, the basic mechanism being the same. Both considerations suggest that the surface membranes of platelets contain ADP.

If it can be shown that ADP takes part in the aggregation of platelets in blood vessels it is conceivable that AMP or some other substance could be used to inhibit or to reverse platelet aggregation in thrombosis.

PHOSPHORYLASE ACTIVITY IN HÆMIC CELLS

By DENNIS QUAGLINO and Dr. F. G. J. HAYHOE

Department of Medicine, University of Cambridge

In 1955 Takeuchi and Kuriaki[1] described a histochemical method for the detection of phosphorylase in animal tissues, based on the specific staining reaction of newly synthesized polysaccharide derived from glucose-1-phosphate as a result of enzyme activity.

Following the biochemical demonstration by Rohdewald[2] of phosphorylase activity in horse leucocytes, Takeuchi and Kinoshita[3] looked for the enzyme histochemically in blood cells. While phosphorylase activity could readily be shown in the leucocytes of inflammatory lesions, using frozen sections, its presence was less easy to detect in ordinary blood and bone marrow smears. The authors eventually succeeded in obtaining fairly good staining results by fixing the smears for not more than 60 sec. in methanol, incubating in a specially prepared substrate for 2 hr. at 37° C. and staining with iodine, when the newly synthesized polysaccharide stained blue or violet blue. Muscle adenylic acid was found to enhance the reaction, which also required the presence of small quantities of glycogen, acting as a primer.

In human blood and bone marrow smears the enzyme was found in mature neutrophilic and eosinophilic granulocytes, in metamyelocytes, myelocytes and promyelocytes, but not in erythrocytes, monocytes, lymphocytes or basophils. Megakaryocytes showed only a weakly positive reaction. Hæmic cells from pathological conditions were not examined. Takeuchi and Kinoshita concluded that the histochemical demonstration of phosphorylase in blood cells was considerably more difficult than in other tissues, and required the utmost care and skill, and, perhaps because of technical problems, little further work in this field has been reported. According to Pearse[4], however, the method has proved reliable in tissue sections, can be reasonably interpreted, and deserves widespread use. We have recently renewed earlier attempts to examine the enzyme in human hæmic cells, using a modified substrate containing polyvinyl-pyrrolidone and a high concentration of glucose-1-phosphate as suggested by Eränkö and Palkama[5].

Several different fixative procedures were tested, including treatment with methanol for less than 60 sec., as recommended by Takeuchi and Kinoshita[3]. This method gave reasonably satisfactory results; but stronger reactions of similar distribution were obtained after fixation with 70 per cent acetone for 30 sec. at room temperature. It was found that blood and bone marrow smears showed better final preservation if left to dry in air for 3–4 hr. before being fixed. After fixation the slides should not be washed but blotted dry before incubation in the substrate solution. The incubation medium is prepared by dissolving 400 mgm. of glucose-1-phosphate, 40 mgm. of adenosine-5-phosphate, 8 mgm. of glycogen, 720 mgm. of sodium fluoride, and 3·6 gm. of polyvinyl-pyrrolidone in 8 ml. of alcohol and 40 ml. of 0·1 *M* acetate buffer *p*H 5·9 and adding 0·1 ml. of insulin 40 I.U./ml. The solution is then filtered and should be renewed every 4–5 days, especially if used frequently. The fixed smears are incubated in the substrate solution for 2 hr. at 37° C. After incubation the preparations are immersed in 40 per cent alcohol for 2 min., allowed to dry and transferred to 0·32 *M* sucrose solution for 5 min. Finally, the preparations are exposed for 5 min. to Gram's iodine made up in 0·32 *M* sucrose solution, and mounted in iodine–glycerine. When

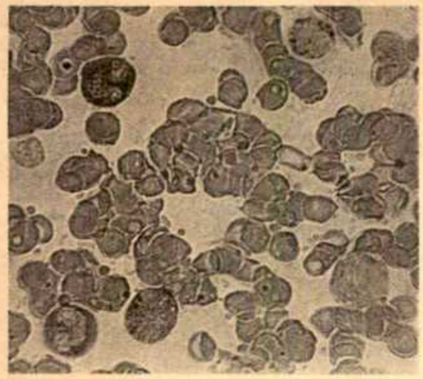

Fig. 1. Two neutrophil polymorphs, an eosinophil, a basophil, a neutrophil metamyelocyte and two negative erythroblasts from normal bone marrow

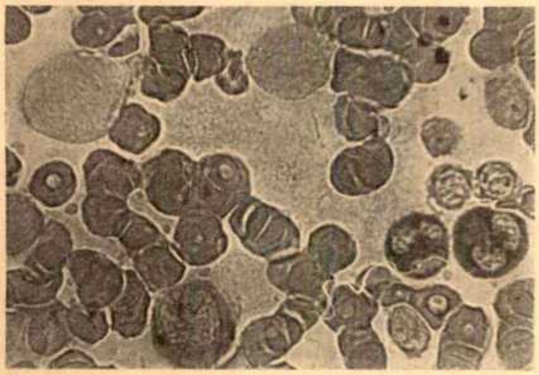

Fig. 2. Neutrophil granulocytes from a normal bone marrow, showing increasing positivity with increasing cell maturation. Two negative erythroblasts are also present

slides are incubated in a solution from which glucose-1-phosphate has been omitted no staining reaction is visible.

Staining reaction and distribution in hæmic cells (Figs. 1–4). A dark blue or violet blue coloration indicates the sites of phosphorylase activity. Positive reactions were found in all cells of the neutrophil granulocyte series, the earliest, myeloblasts and promyelocytes, showing faint diffuse cytoplasmic staining, and later members of the series showing positivity increasing in intensity with cell maturation. Eosinophils were similarly positive, the reaction being localized in the cytoplasm around the specific granules. Basophils contained coarse positive granules. Monocytes and lymphocytes showed variable reactions, some being negative and others having diffuse or granular positivity of varying intensity. Megakaryocytes and platelets showed diffuse positive staining with occasional coarse granules. Cells of the erythroid series appeared normally to be completely negative.

This pattern of distribution follows very closely that of pre-formed glycogen as demonstrated by the periodic acid–Schiff reaction, controlled by salivary amylase digestion, and a similar parallelism has been observed in studying phosphorylase cytochemistry of hæmic cells in pathological states. Thus mature granulocytes in acute infections, in chronic myeloid leukæmia and in the acute leukæmias are generally rich in glycogen and were found to be rich in phosphorylase. In chronic lymphocytic leukæmia again the phosphorylase reaction in lymphocytes showed a close correlation with the extent of positivity to periodic acid–Schiff reagent. Primitive cells from 15 cases of acute leukæmia were examined by both techniques, and once more a parallel was observed between glycogen and phosphorylase content, both in the proportion of cells showing positivity and in the intracellular disposition of the reaction, whether diffuse or granular.

The action of phosphorylase would lead one to expect its distribution in cells and tissues to be similar to that of glycogen; but the similarity observed in hæmic cells is unexpectedly close. That the phosphorylase reaction is not in fact staining pre-existing glycogen is shown by the clear negative results obtained when glucose-1-phosphate is omitted from the substrate; but we are inclined to believe that the existence of pre-formed glycogen in the cell does in some way dictate the apparent cytochemical localization of phosphorylase activity, perhaps by acting as an in-built primer supplementary to the primer included in the substrate mixture. This is not to say that the distribution of cytochemically demonstrable phosphorylase and that of glycogen are necessarily identical; polymorphs, for example, show much greater variability in phosphorylase content than in periodic acid–Schiff positivity while leukæmic primitive cells may show both diffuse and coarsely granular phosphorylase staining when the periodic acid–Schiff reaction shows only coarse granules. Again, in certain cases of acute leukæmia where the majority of primitive cells were entirely negative to periodic acid–Schiff reagent we have observed weak diffuse phosphorylase staining in the cytoplasm of blast cells which must have been negative to periodic acid–Schiff reagent.

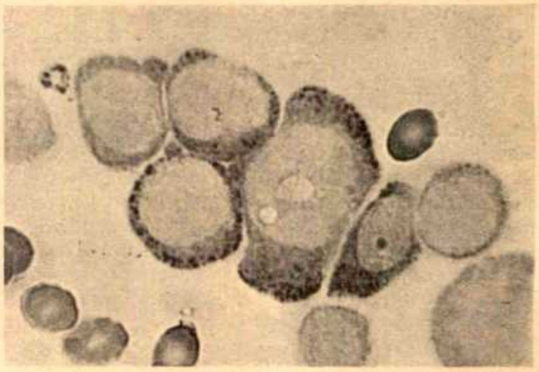

Fig. 3. Lymphoblasts from acute leukæmia showing granular phosphorylase positivity

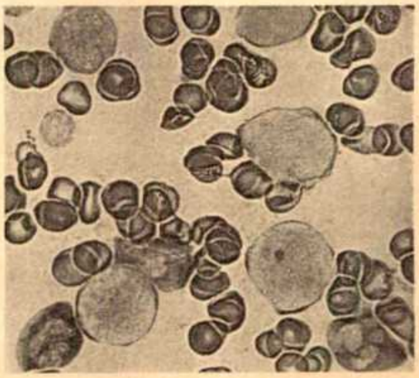

Fig. 4. Weak phosphorylase reaction in leukæmic myeloblasts

For the most part, the iodine staining in this reaction gives a blue colour, but a violet or brownish tinge may be seen occasionally, especially at sites of probable concentration of pre-existing glycogen, such as the coarse granules or blocks which occur in some lymphoblasts. This variation in colour is discussed by Takeuchi[6] and is presumably related to the chain-length of the polysaccharide produced through the synthesizing action of the phosphorylase, and the possible effect of branching enzyme on chains above a critical length.

HÆMOGLOBIN–LEPORE$_{\text{HOLLANDIA}}$

By J. BARNABAS and C. J. MULLER

Department of Pædiatrics, University of Groningen

In a previous communication Neeb *et al.*[1] reported the occurrence of an abnormal hæmoglobin, identified as Lepore hæmoglobin, in a Papuan family, two members of which suffered from an anæmia which clinically presented itself as thalassæmia major. In members of the family heterozygous for this trait, in addition to about 12 per cent of the abnormal hæmoglobin, there was approximately 2 per cent of Hb–A$_2$, small amounts of fœtal hæmoglobin being occasionally present. In the homozygous carriers of this abnormality there were approximately 26 per cent of the abnormal component, 74 per cent of Hb–F and traces of Hb–A$_2$. To avoid confusion with the originally described Lepore abnormality[2], the Papuan Lepore abnormality will be designated as hæmoglobin–Lepore$_{\text{Hollandia}}$, for short Hb–Lep$_{\text{Holl.}}$, after the town where it was discovered.

The differences between Hb–Lep$_{\text{Holl.}}$ and the normal pigments have been investigated by means of peptide pattern and amino-acid analysis.

Hæmoglobins Hb–Lep$_{\text{Holl.}}$, Hb–A$_1$ and Hb–A$_2$ were prepared by using carboxymethylcellulose (CMC) chromatography[3]. (Hb–A$_1$ and Hb–A$_2$ were obtained from normal adults. No difference, however, could be demonstrated between these and the corresponding components of carriers of the Hb–Lep$_{\text{Holl.}}$ trait.) After concentration of the isolated fractions on CMC, the hæmoglobins were dialysed. The purity of the samples were checked by starch-block electrophoresis at pH 8·6 (ref. 4). Whenever necessary, the hæmoglobin fractions were re-chromatographed on CMC.

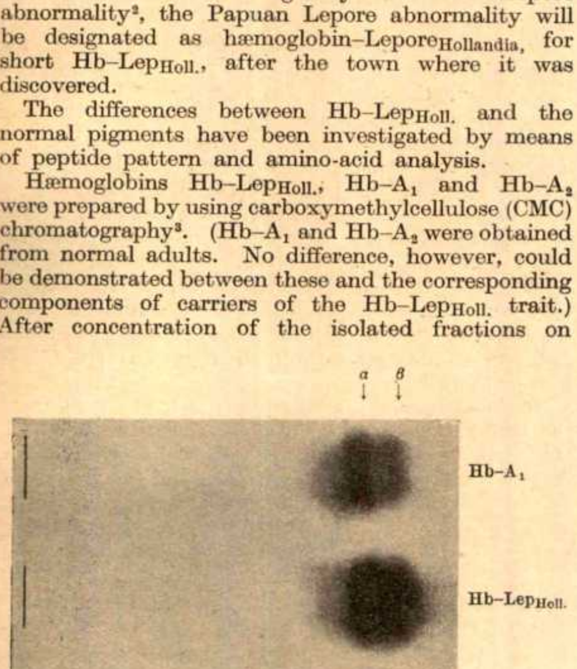

Fig. 1. Electrophoretic behaviour of Hb-Lep$_{\text{Holl.}}$, Hb-A$_1$ and Hb-A$_2$ on starch-gel at pH 1·8

The electrophoretic behaviour of the separate polypeptide chains of the hæmoglobins by means of starch-gel electrophoresis at pH 1·8 (ref. 5) is illustrated in Fig. 1. It may be seen that the α-chains of Hb–Lep$_{\text{Holl.}}$ behave similar to those of the normal pigments, while the non-α-chains of Hb–Lep$_{\text{Holl.}}$ have the same electrophoretic mobility as the β-chains of Hb–A$_1$.

Hæmoglobins Hb–Lep$_{\text{Holl.}}$, Hb–A$_1$ and Hb–A$_2$ were also compared by fingerprinting. Tryptic digests and the fingerprints were prepared in the usual manner[6]. In addition to butanol–acetic acid–water (3 : 1 : 1) as the chromatographic solvent, butanol–pyridine–acetic acid–water (30 : 20 : 6 : 24) (ref. 7) was found to give a clear-cut separation of the tryptic peptides of the hæmoglobins. The fingerprints were also stained for sulphur, histidine, arginine and tyrosine as described[3]. The tracings of the typical fingerprints obtained by using the second solvent combination are presented in Fig. 2. It is evident that peptide Lep$_{\text{Holl.}}$–12 and Lep$_{\text{Holl.}}$–26 resemble those of Hb–A$_2$, while the mobility of peptide Lep$_{\text{Holl.}}$–25 is more or less similar to that of Hb–A$_1$. The arginine-positive peptide A$_1$–26 has a higher anodic mobility and is clearly separated from the adjacent sulphur-containing peptide A$_1$–25, while the peptides Lep–2$_{\text{Holl.}}$6 and A$_2$–26 have lower anodic mobilities than the corresponding peptide 25 of these hæmoglobins and have the same position as the α-chain peptide 23. The mobility of the tryptophan-positive peptide 12 of both Hb–Lep$_{\text{Holl.}}$ and Hb–A$_2$ is markedly different from that of Hb–A$_1$.

In the peptide pattern of Hb–A$_2$ an extra peptide (X) was observed in conformity with the observations of Ingram and Stretton[8]. This peptide could not be observed when butanol–acetic acid–water (3 : 1 : 1) was used as the chromatographic solvent[9]. The absence of peptide X in the peptide patterns of Hb–Lep$_{\text{Holl.}}$ and Hb–A$_1$ is noteworthy.

The differing peptides 25, 26 and 12 of all the three hæmoglobins were isolated by subjecting the tryptic digests to repeated high-voltage electrophoresis (8 kV., 60 min.), followed by chromatography of the appropriate fractions on paper. The purified hæmoglobin peptides were hydrolysed with 6 N hydrochloric acid for 18 hr. under nitrogen and were

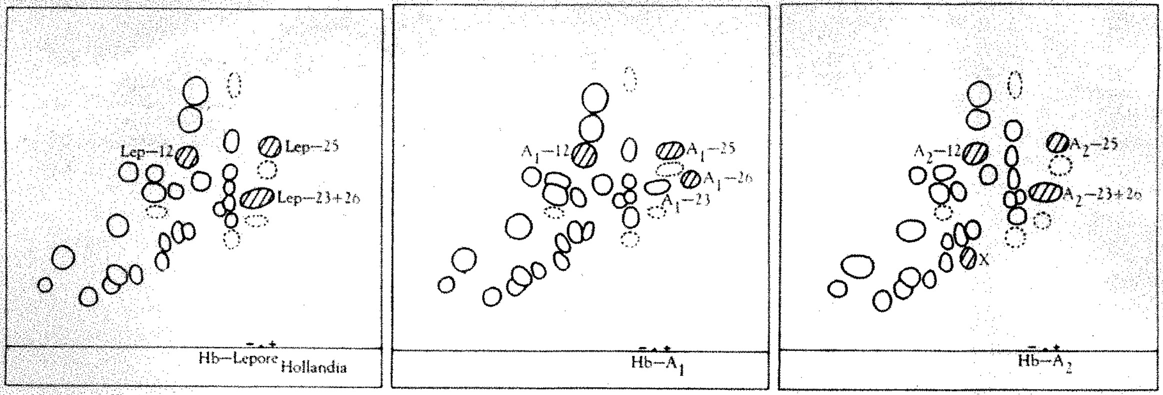

Fig. 2. Tracings of the fingerprints of tryptic digests of Hb-Lep$_{\text{Holl.}}$, Hb-A$_1$ and Hb-A$_2$. Electrophoretic buffer: Michl's buffer pH 6·4. Chromatographic solvent: butanol–pyridine–acetic acid–water (30 : 20 : 6 : 24)

analysed for their constituent amino-acids[3], the results of which are presented in Table 1.

Table 1. COMPARISON OF THE AMINO-ACID COMPOSITION OF THREE DIFFERENT TRYPTIC PEPTIDES OF HB-LEP$_{\text{Holl.}}$ WITH THE SEQUENCE OR COMPOSITION OF THE CORRESPONDING PEPTIDES OF HB-A$_1$ AND HB-A$_2$

A$_2$–12	(*thr*,ala,val,*aspNH$_2$*,ala,leu,try,gly,lys,)[8]
Lep$_{\text{Holl.}}$–12	(*thr*,ala,val,*aspNH$_2$*,ala,(i)-leu,try,gly,lys.)

Examination of peptide 25 from all the three hæmoglobins showed that Hb–Lep$_{\text{Holl.}}$–25, like A$_1$–25, contained threonine, which was absent in A$_2$–25. The latter peptide contained a serine more than peptide 25 of Hb–A$_1$ and Hb—Lep$_{\text{Holl.}}$. Examination of peptide 26, on the other hand, revealed that the amino-acid composition of Lep$_{\text{Holl.}}$–26 was identical with that of A$_2$–26, which differs from A–26 by the exchange of glutamic acid in A$_1$–26 by alanine in A$_2$–26. The peptide 12 of Hb–Lep$_{\text{Holl.}}$ likewise had the same amino-acid composition as that of Hb–A$_2$, both having one asparagine more and one serine less than A$_1$–12.

Hæmoglobins Hb–Lep$_{\text{Holl.}}$ and Hb–A$_2$ were analysed for their constituent amino-acids on a Moore and Stein automatic amino-acid analyser (Table 2). The carefully purified hæmoglobin fractions were hydrolysed for 48 hr. in 6 N hydrochloric acid under nitrogen, prior to the analysis.

Table 2. AMINO-ACID COMPOSITION OF HYDROLYSATES OF HÆMOGLOBINS HB-LEP$_{\text{Holl.}}$ AND HB-A$_2$

(Values are given as gm. amino-acid/100 gm. protein)

Amino-acid	Hb-Lep$_{\text{Holl.}}$ 48 hr.	Hb-A$_2$ 48 hr.	Hb-F [11] 22 hr.	Hb-A$_1$ [11] 22 hr.
Aspartic acid	10·6	10·9	9·8	9·6
Glutamic acid	7·0	7·8	7·0	6·6
Glycine	4·3	4·7	4·3	4·3
Alanine	9·3	9·9	8·5	9·2
Valine	8·7	8·9	8·9	10·4
Leucine	14·2	13·7	13·6	13·9
Isoleucine	0·5	—	1·4	—
Serine	3·8	4·1	5·4	4·0
Threonine	5·2	4·8	6·2	5·1
Methionine	1·3	1·3	1·6	1·3
Phenylalanine	8·1	7·7	7·1	7·3
Tyrosine	2·9	2·9	2·5	3·1
Histidine	8·3	8·2	7·6	8·3
Lysine	9·5	10·0	10·0	9·3
Arginine	2·7	3·6	3·1	2·8

It is evident from Table 2 that in agreement with Ingram and Stretton[8] and contrary to a report of Rossi-Fanelli *et al.*[12], no isoleucine is present in Hb–A$_2$. Hb–Lep$_{\text{Holl.}}$, on the other hand, contains appreciable amounts of isoleucine amounting to 2 residues per molecule. To find out which of the sub-units of Hb–Lep$_{\text{Holl.}}$ contained this amino-acid, the purified Hb–Lep$_{\text{Holl.}}$ was separated into chains by the method of Wilson and Smith[13], and the chains were separately analysed for their constituent amino-acids. It was observed that the non-α-chains accounted for all the isoleucine present in the total hydrolysate of Hb–Lep$_{\text{Holl.}}$.

From these results it may be concluded that all the amino-acid differences observed between Hb–Lep$_{\text{Holl.}}$ and the normal pigments occur in the non-α-chains, whether the non-α-chains of Hb–Lep$_{\text{Holl.}}$ are compared with the β-, the γ-, or the δ-chains; in any event, more than a single amino-acid is different. This is contrary to what has been observed for a mutant human hæmoglobin polypeptide chain, where normally only one amino-acid substitution occurs. The amino-acid analysis of the peptides 25, 26 and 12 indicate that the non-α-chains of Hb–Lep$_{\text{Holl.}}$ may bear characteristics of both the β- and δ-chains, whereas the presence of isoleucine in the non-α-chains suggests a faint relationship to the γ-chains of fœtal hæmoglobin.

This investigation was supported by a grant from the Dutch Organization for Pure Research (Z.W.O.). One of us (J. B.) thanks the Netherlands Bureau for International Technical Assistance for the award of a Netherlands Government Scholarship.

A SUB-MOLECULAR MECHANISM OF GEL FORMATION IN SICKLE CELL HÆMOLYSATE

By Dr. MAKIO MURAYAMA

National Institutes of Health, U.S. Department of Health, Education, and Welfare, Bethesda, Maryland

THE optical rotation of normal adult, sickle cell trait, and fœtal carbon monoxyhæmoglobin was investigated by Havinga[1], who found no significant differences among them using the red light obtained from a cadmium lamp.

The examination of optical rotatory dispersion of normal and sickle cell hæmolysate reported here was undertaken because the abnormal hæmolysate has a negative temperature coefficient of gelation[2], that is, its deoxygenated solution of sufficient concentration gels at 38°, but it liquefies reversibly when cooled to 0°. The primary object of this investigation is to shed some light on the underlying mechanism of gel (sickle cell) formation.

It was known that oxygen, carbon monoxide, alkyl isocyanides, nitrosobenzene, and the like as well as sulphydryl blocking reagents (such as heavy metal ions, *para*-chloromercuribenzoate, *N*-ethylmalimide, etc.) prevent gelling by introducing steric hindrance. The amperometric titration study of sulphydryl groups also suggested conformation change of hæmoglobin molecule with temperature; at 0°, 50 per cent of the groups are sterically hindered, whereas all of them are accessible to the titrating reagent at 38°. As it was suspected, all of them are also titratable if the molecule is loosened with denaturing agent. The energy barrier due to steric hindrance for those SH groups not titratable at 0° amounts to about 2 kcal./mole[3]. Due to conformational changes of hæmoglobin molecules, the reported number of amperometrically titratable sulphydryl groups varies from 2 to 8 per molecule[4]. The present report on the optical rotatory dispersion studies of normal and sickle cell hæmolysates at 0° and 38° is consistent with the notion of dynamic conformational change of the hæmoglobin molecule.

Hæmolysates were prepared in the usual manner[3]. The solution for the optical rotatory dispersion study was centrifuged in a high-speed centrifuge at about 16,000 r.p.m. (32,700*g*) for 30 min. The solution was then filtered through a 'Millipore' filter paper *HA* (pore size, 0·45μ). A recording spectropolarimeter (model No. 260/655/850, Rudolph Instruments Engineering Co., Little Falls, New Jersey) was used, with the following modifications: the light source was changed to an Osram xenon high-pressure lamp, *XBO* 150, the voltage to the photomultiplier tube was increased to gain sensitivity, and the commutator was replaced by a magnetic one. The light path was 1·0 mm. and the half-intensity band-width of 20 mμ was used throughout the study. Molecular rotation was obtained by multiplying the specific rotation by the ratio, mol. wt./100. The concentration of hæmolysates was 11 gm./100 ml. A more dilute solution of 4 gm./100 ml. of hæmoglobin was used to obtain data in the Soret band.

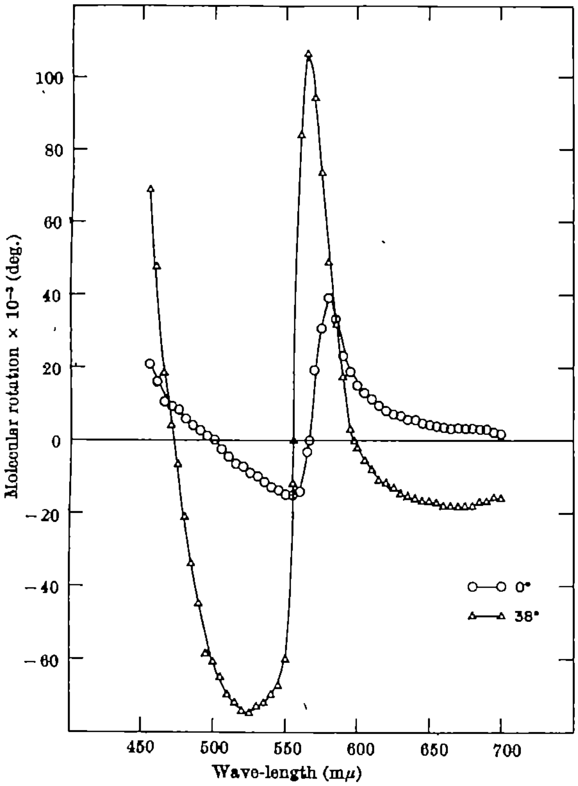

Fig. 1. Optical rotatory dispersion curves for deoxygenated sickle cell hæmolysate at 0° and 38°

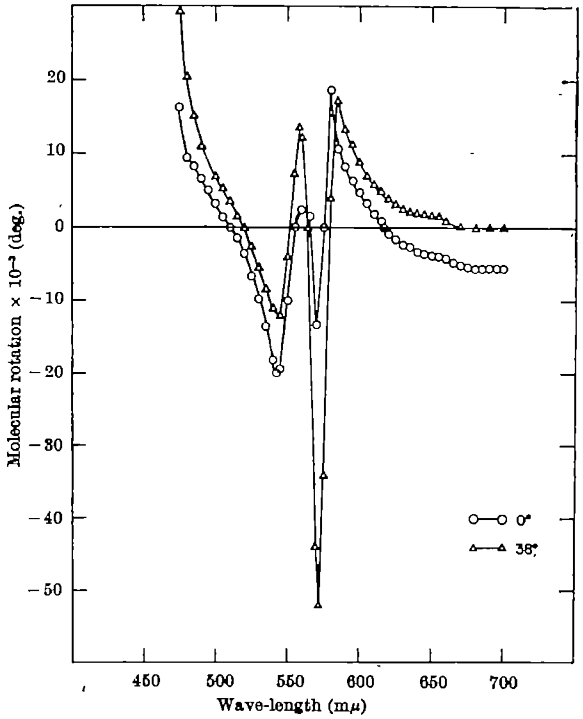

Fig 2. Optical rotatory dispersion curves for oxygenated sickle cell hæmolysate at 0° and 38°

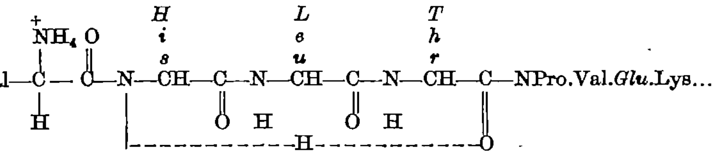
It is generally recognized that optical rotatory dispersion study is one of the best methods for detecting changes in conformation of very large optically active molecules[4]. The present investigation indicates that the sickle cell hæmolysate shows a much greater conformational change with temperature than the hæmolysate of normal hæmoglobin. It was observed that the amplitude of the positive Cotton effect (in the 560-mμ region as well as in the Soret band) at 0° is increased reversibly by about three times when the solution is warmed to 38° (Fig. 1); the hæmolysate of the normal hæmoglobin undergoes but a slight increase in the amplitude of the positive Cotton effect. The oxygenated hæmolysate of sickle cell hæmoglobin shows a similar increase in the amplitude of the Cotton effect, but the magnitude is smaller.

Fig. 2 shows that the oxygenated solution gives a multiple Cotton effect; the amplitude of the positive Cotton effect at 560-mμ region is increased with temperature. The oxygenated hæmolysate of normal red cells undergoes but a slight change in the same conditions.

So far as is known the only chemical difference between the normal hæmoglobin (Hb-A) and the sickle cell hæmoglobin (Hb–S) is in one amino-acid residue of the β-chain[5]. The hæmoglobin molecule consists of two pairs of peptide chains; one pair is designated the α-chain (N-terminal sequence is Val.Leu. . .) and the other the β-chain (N-terminal sequence is Val.His.Leu. . .)[6]. The amino-acid interchange is located in the sixth residue from the N-terminus[7,8]. The amino-acid sequences of the first 8 amino-acid residues from the N-terminal amino-acid of β-chains for Hb–A and Hb–S are as follows[7,8]:

	1	2	3	4	5	6	7	8
Hb-A	Val.	His.	Leu.	Thr.	Pro.	*Glu*.	Glu.	Lys.
Hb-S	Val.	His.	Leu.	Thr.	Pro.	*Val*.	Glu.	Lys.

This interchange of amino-acid residue results in a loss of one negative charge per β-chain on part of Hb–S molecule. Because the molecule is known to have two-fold axis of symmetry[9], these glutamyl residues must exert electrostatic repulsion between the β-chains of Hb–A (near the NH_2-terminal residues). But in Hb–S molecule, the minus charge of the seventh glutamyl might be essentially neutralized by the positive contribution from the epsilon amino-group of the eighth lysyl residue. It appears from model-building experiment with precision components that the amino terminal valyl residue interlocks with the newly introduced valyl residue at position 6 in sickle cell hæmoglobin molecule; this allows cyclization of the peptide chain from histidyl to threonyl by hydrogen bonding as shown schematically below.



$$\mathrm{Val{-}\underset{H}{\overset{\overset{+}{N}H_4}{C}}{-}\overset{O}{\overset{\|}{C}}{-}N{-}\overset{His}{CH}{-}\underset{O}{\underset{\|}{C}}{-}\underset{H}{N}{-}\overset{Leu}{CH}{-}\underset{O}{\underset{\|}{C}}{-}\underset{H}{N}{-}\overset{Thr}{CH}{-}\underset{O}{\underset{\|}{C}}{-}NPro.Val.\mathit{Glu}.Lys\ldots}$$

When the sixth residue is glutamyl as in Hb–A, it appears that this ring closure does not occur. In Hb–S at 38° this segment of the peptide chain is stabilized through this cylization by hydrogen bonding, thus the freedom of rotation about bonds in rings formed is restricted. This is the condition necessary for one of the Kautzmann and Eyring rules which states: "Those influences which tend to restrict freedom of orientation about bonds will tend to increase the order of magnitude of the optical activity"[10]. But at 0° the hydrogen bond under question appears to be transferred in a process of hydration (because hydrophobic bonds are weaker at 0°, but on the other hand, the hydrogen bond approaches its maximum at the ice point) and the chain appears to assume a conformation (of no ring formation) as in the β-chains of Hb–A; thus the numerical value of the optical rotation is diminished.

I thank Mr. Kenneth McCoy, Georgetown University, Washington, D.C., for providing sickle cell hæmoglobin specimens for this work. I also thank Mr. Harold K. Miller for help in making the needed modification on the instrument.

ANTIGEN- AND ANTIBODY-COMBINING PROPERTIES AND THEIR INFLUENCE ON THE IMMUNE REACTION OF RED CELLS

By Dr. HAROLD S. GOODMAN

Departments of Medicine and Microbiology, University of Chicago

HUMAN blood group A erythrocytes from different individuals have been sub-grouped on the basis of their agglutination with human anti-A sera[1]. A_1 cells are more strongly agglutinated than A_2 cells, using anti-A sera; an anti-A serum absorbed with A_2 cells provides a serum with antibodies capable of agglutinating A_1 cells. A_3 cells give microscopic clumps of agglutinated cells surrounded by a large number of free cells. A_4 cells are not agglutinated by most anti-A sera obtained from B individuals, but are weakly clumped by anti-A sera derived from O individuals. Still weaker variants of the A antigen have been described and variously designated A_0, A_x, A_5 and A_6. These differences in the serological properties of the A sub-groups have been shown by numerous family studies to be a stable heritable characteristic of the A antigen[1]. The characteristic agglutination of the human A sub-groups suggested differences in their combining properties.

Studies in this laboratory have been concerned with antibody heterogeneity with respect to combining properties. In the work reported here an attempt

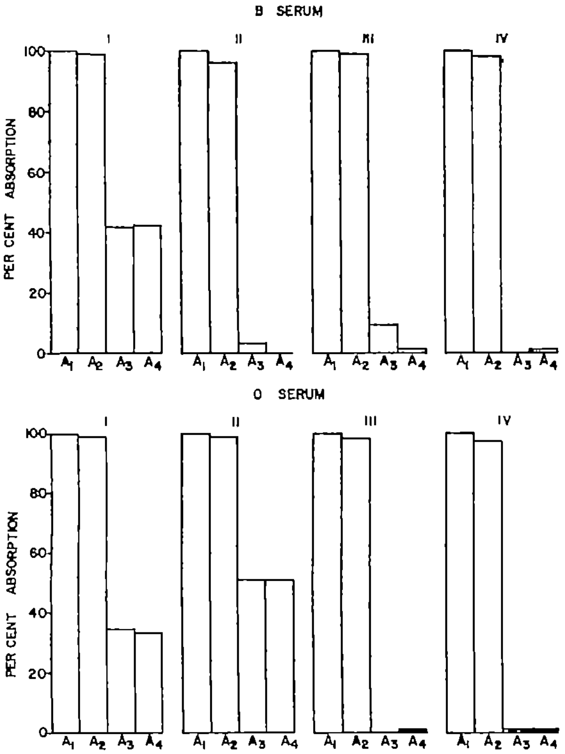

Fig. 1. Comparison of the percentage of agglutinin absorption by different human A sub-groups. Agglutinin determinations made with A_1 cells

was made to demonstrate how differences in antibody-combining properties may be related to differences in the combining properties of the human A sub-groups. These findings have provided information relevant to the general subject of the nature of antigen and antibody-combining sites.

Antibody heterogeneity can be shown to exist within and between human anti-A antibody populations and related to the combining properties of the human A sub-groups. Human anti-A sera were exhaustively absorbed with cells of different A sub-groups and with an O cell control. The amount of antibody activity remaining after absorption was quantitatively determined[2] using A_1 cells, and the percentage of absorbed agglutinin activity was calculated. It can be seen in Fig. 1 that different percentages of antibody activity were removed by different A sub-groups, and that these percentages differed from one antiserum to another. These results suggest a heterogeneity both within and between antibody populations. Qualitative differences in the A sub-group antigens were indicated by the failure of the individual A sub-groups to absorb completely the A antibodies. The absorbed A sub-group sera were also tested for their hæmolytic activity for A_1 cells and for their ability to cross-react with sheep cells. Both hæmolytic activity and cross-reacting antibodies were completely removed by A_1 cells, partially by A_2 cells and little or not at all by A_3 and A_4 cells.

Quantitative differences in the amount of A antigen present on the cells of the different A sub-groups are indicated in Fig. 2, in which the antibody-combining capacity of the A sub-groups has been compared. Such differences in the quantitative absorption of antibodies by the human A sub-group probably contribute to their characteristic serological properties.

Antibody heterogeneity was also examined by a column chromatographic method[3] which takes advantage of the thermal dissociation characteristics of the specific antigen–antibody complex. This method permits quantitative characterization of an antibody population in terms of its combining properties as well as providing a means for isolating antibody fractions differing in their combining properties. The results of a thermal fractionation of a human A iso-antibody population on a column composed of A_1 cells are presented in Fig. 3 and illustrate the extent of heterogeneity existing within this antibody population. The fractionation of different anti-A sera (Fig. 4) indicates the high degree of heterogeneity which may exist between different serum samples.

Fractions obtained by thermal elution were compared for their ability to agglutinate cells of different human A sub-groups, to produce hæmolysis of A_1 cells and to cross-react with sheep cells. The weakly reacting A_3 and A_4 cells could be agglutinated only by that antibody eluted at temperatures above 45° C., even though the serum fractions being compared had equal agglutinin activity for A_1 cells. On the other hand, antibody eluted at temperatures below 15° C. could only produce agglutination of A_1 cells. Anti-A hæmolytic activity and antibody cross-reacting with sheep cells were closely associated with those fractions of antibody eluted at lower temperatures.

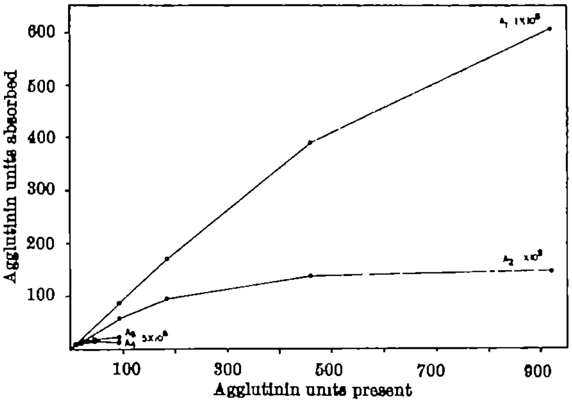

Fig. 2. Comparison of the agglutinin-combining capacity of the human A sub-groups. The human anti-A serum used for this experiment contained antibody, 50 per cent of which was capable of combining with the A_3 and A_4 cells. Varying concentrations of antiserum were absorbed with a constant concentration of cells of different human A sub-groups. The number of unabsorbed agglutinin units was determined on each of the supernates and unabsorbed control sera using A_1 cells for titration. The number of antibody units absorbed was calculated from these data

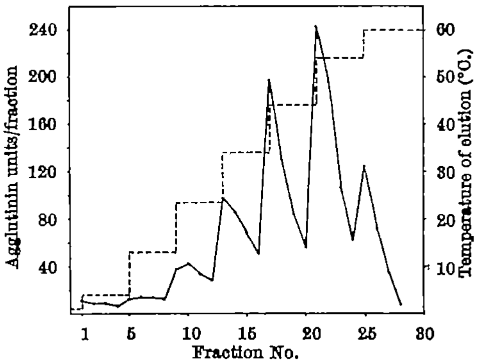

Fig. 3. Thermal fractionation of a human anti-A serum on a column composed of A_1 cells. Agglutinin activity of fractions determined quantitatively (ref. 2)

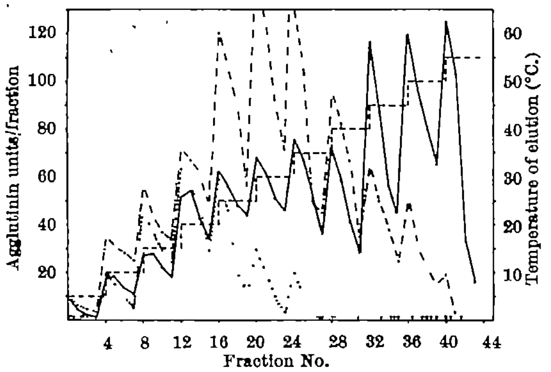

Fig. 4. Comparison of the thermal fractionation of different human anti-A sera

Landsteiner[4] established the chemical basis of the antigen–antibody reaction and showed that antibody specificity is a function of the complementarity of the physico-chemical configuration of the antibody-combining site to that of the antigenic determinant. Pauling[4] analysed the chemical forces involved in antigen and antibody interaction, and provided further evidence for the complementary configuration of the antigen- and antibody-combining sites as a basis for the stability of their union. The nature of heterogeneity in terms of the combining properties of antibody has been a subject of speculation although it is well known that the stability of the antigen–antibody complex formed by antibody molecules may vary widely within a single antibody population[5–7]. The difficulty of dealing with such antibody heterogeneity is evident in such diverse areas as physico-chemical investigations of antigen–antibody interaction[8] and serological reactions of the human blood groups[8,9].

In this work antibody heterogeneity was examined by thermal elution and exhaustive absorption. A major aspect of the work was the examination of the human A sub-groups to determine the bases for their difference in serological behaviour and the relationship of their serological properties to antibody heterogeneity.

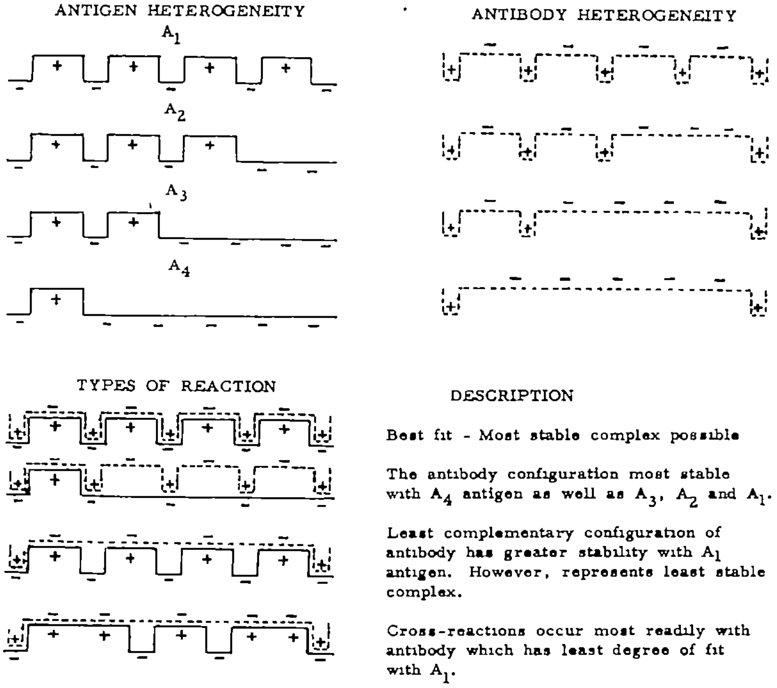
Differences in the physico-chemical structure of the human A sub-groups have been indicated by their immunological behaviour[1] rather than by chemical methods. The absorption of an anti-A serum with A_2 cells results in a serum which is capable of reacting with A_1 cells but not with cells of the weaker A sub-groups. Antibody eluted from sensitized A_2, A_3 and A_4 cells produces stronger and higher titred agglutination with A_1 cells. Structural differences in the A sub-groups are also indicated by the fact that A isoantibodies are commonly found in individuals who have the weaker A sub-groups. In addition to indicating physico-chemical differences in the A sub-groups, these findings suggested an inter-relationship between the human A sub-groups indicative of a type of antigenic heterogeneity related to the heterogeneity of the antibody.

Assuming that the temperature required for elution of A antibodies from the A antigen is related to the degree of complementarity between the antibody-combining site and the antigenic determinant, the A antibodies requiring the highest temperature for elution would have a more complementary configuration for the A determinant than the A antibodies eluted at lower temperatures. This premise provides a basis for interpreting the experimental findings of the human A sub-groups: (1) a greater percentage of antibody was recovered from an A_2 column than from an A_1 column[3]; (2) the tested A sub-groups reacted best with antibodies eluted at higher temperatures; (3) the antibody remaining after absorption with A_2 cells reacted only with A_1 cells[1]; (4) the antibody eluted from A_3 and A_4 cells reacted best with A_1 cells[1].

The human A sub-groups apparently do not reflect different antigenic determinants for which there are a number of specific antibody configurations. If the A antigen has several different antigenic determinants, antibodies would be formed with an equally strong binding for the individual determinants. If an A sub-group represents one or more of such determinants, at least part of the antibody population could be bound equally well by any of the A sub-groups. This interpretation of multiple antigenic determinants being responsible for differences in the serological behaviour of the human A sub-groups is contra-indicated primarily by the observation that all antibodies with A specificity form more stable complexes with A_1 cells than with other A sub-groups. Consequently, there is probably a single antigenic determinant or physico-chemical configuration for the A antigen which is most 'ideally' represented on A_1 cells. The reactions of the A sub-groups with different fractions of antibody obtained by thermal elution indicated that the antibody molecules forming the most stable complexes with A_1 cells are also the same antibody molecules which form the most stable complexes with A_3 and A_4 cells. Therefore, the A antigen as represented by the more weakly reacting A sub-groups would appear to be related structures of the A antigen as found on A_1 cells. The A sub-groups may possess only minor variations of such a nature that the most specific antibody configuration for the A determinant (as represented on A_1 cells) also forms the most stable complex with all variants of the A antigen.

Anti-A hæmolytic activity and cross reactions with sheep cells in this work also provided information which could be interpreted on the basis of the configuration of the combining site of antibody responsible for these reactions. Both anti-A hæmolytic activity and sheep cell cross-reactions were associated with antibody which could be eluted at lower temperatures. Similarly these antibodies were not absorbed by the weakly reacting A_3 and A_4 cells, were partially absorbed by A_2 cells and completely absorbed by A_1 cells. These results agree with results obtained by Winstanley, Konugres and Coombs[10] and Konugres and Coombs[11] on the correlation of the A hæmolysin titre and the cross-reaction with group A pig cells of human anti-A sera. They also agree with results obtained by Owen[12] on the cross-reactions of human B isoantibodies with various animal cells.

The cross-reactions of human isoantibodies with heterologous antigens may also be interpreted on the basis of configuration of the antibody-combining sites. Assuming that the antibodies formed in response to an antigenic determinant constitute a spectrum differing in the degree of fit for the determinant, the antibody with the highest degree of fit would be expected to be the most specific and, conversely, the antibody with the least degree of fit, the least specific. The latter type would have the greatest possibility of cross-reacting with another antigenic determinant of related physico-chemical structure. The thermal elution characteristics of the cross-reacting antibodies appear to agree with this interpretation. Although gross differences in the physico-



ANTIGEN HETEROGENEITY

DESCRIPTION
Best fit - Most stable complex possible
The antibody configuration most stable with A_4 antigen as well as A_3, A_2 and A_1.
Least complementary configuration of antibody has greater stability with A_1 antigen. However, represents least stable complex.
Cross-reactions occur most readily with antibody which has least degree of fit with A_1.

Fig. 5. Diagrammatic representation of the antigen–antibody configurational relationships as represented by the reactions of human anti-A isoantibodies and the human A sub-groups

chemical properties of antibody such as molecular weight and electrophoretic mobility may be associated with characteristic differences in combining properties, it is questioned whether such properties have any direct effect on antibody specificity.

Pressman and Siegel found that antibody prepared by immunization with one haptene was bound more firmly by a heterologous but similar haptene[13]. If antibody heterogeneity exists for a single antigen and if the antibodies vary in their degree of fit for this antigen, it would be expected that part of the antibody population might fit a cross-reacting antigen better than the homologous antigen. In other words, antibody molecules may be formed the structure of which would not be completely complementary for the homologous antigens. Related antigens may have physico-chemical configurations more nearly complementary for antibody variants than the homologous antigen.

The reactions involving the thermal elution fractions of human anti-A sera and the A sub-group absorbed sera, with human A sub-group cells or with sheep cells raise questions with respect to the definition of cross-reacting antigens. Cross-reacting antigens have been assumed to indicate a similarity in physico-chemical configuration. Antibody heterogeneity has been presented in this discussion as a progressively decreasing complementarity of an antibody-combining site to a basic antigen configuration. That portion of the antibody population having a less complementary configuration for the homologous antigen more readily combines with a similar physico-chemical structure found in another antigen. This prediction appears to be validated by the cross-reactions of human anti-A serum with animal cells.

The human A sub-groups may also be defined as cross-reacting antigens, having similar but not identical physico-chemical structure. However, in contrast to cross-reacting antigens, which reacted with antibody of less specific configuration, the A sub-groups reacted with antibody possessing a more specific configuration. Consequently, the A sub-groups probably represent differences in physico-chemical configuration unlike those associated with cross-reacting animal cells. Therefore, the physico-chemical differences associated with the human A sub-groups may be described as variants of an antigen to distinguish them from the physico-chemical differences associated with heterologous cross-reacting antigens. Race and Sanger[1] suggested that human A sub-groups represent segments of a continuous spectrum of antigenic variants. The isolation of serological variants similar to the human A sub-groups from a single individual's cell population[14] lends support to the idea of antigenic variants. A spectrum of variants was also suggested by Renton and Hancock[15] for the Rh_0 antigen.

The conclusion of this investigation may now be summarized. A human A isoantibody population includes a spectrum of antibodies differing in their degree of complementarity for a single human A antigenic determinant. The human A sub-groups represent segments of a continuous spectrum of antigenic variants related to one basic structure for the A antigen. All variants of the human A antigen form a more stable complex with those antibody molecules having the most complementary configuration for the A determinant. Finally, cross-reactions with heterologous antigens occur most readily with that portion of the human A isoantibody population having a less-specific configuration for the human A determinant. An attempt to indicate the salient configurational relationships suggested by the reactions of the human A isoantibodies and the human A sub-groups is presented in Fig. 5.

SINCE the publication of the communication by Jacobson *et al.*[1] many authors have directed their attention to the kidney as the site of erythropoietin formation, and Naets[2] suggests the importance of developing an adequate method for the demonstration of erythropoietin with extracts of renal tissue.

For our experiments, tissue extracts of kidney, spleen and liver of normal pig were prepared using the technique for obtaining rennin[3]. In the case of renal extracts, only the cortical region was used. The technique was as follows: (*a*) Extract the minced tissue with saline, adding three volumes of 6 per cent sodium chloride, agitating and covering it with 1 cm. of toluol; leave for about 20 hr. at room temperature (always below 30° C.); (*b*) separate the tissue, fat and toluol by filtration through gauze and centrifugate, proceeding with the liquid thus obtained; (*c*) add concentrated acetic acid to *p*H 3·8, then merthiolate 1/5,000; later filter. After several hours, a light yellow liquid is obtained. Later purification followed two different stages:

(1) Add 39 gm. ammonium sulphate for every 100 ml. of filtered liquid. Filter and dissolve the precipitate with a 0·9 per cent saline solution. Dialyse with tap-water until the ammonium sulphate is completely separated, then add 0·9 gm. sodium chloride per 100 ml. and 1/5,000 merthiolate. This constitutes the crude rennin-type extract.

(2) The light yellow filtrate liquid is then taken to *p*H 5·5 and placed in a boiling water bath for 10 min.[4]. It is then filtered and the liquid obtained taken to *p*H 4·5 with 0·1 *M* acetic acid. As soon as this is cooled (4° C. or less) add 4 volumes of ethanol at the same temperature[5], slowly and continuously stirring; leave overnight in a refrigerator. Next day the precipitate is separated in a refrigerated centrifuge at 0° C. and then dissolved in a *p*H 8·0 buffer of 0·01 *M* phosphate. The solution thus obtained is again centrifuged at 0° C. and 14,000 r.p.m. for 15 min. to separate and discard the insoluble material. Thus the alcohol-boiled extract is obtained.

The quantity of positive biuret material[6] was determined in all extracts.

The erythropoietic action was determined by intraperitoneal injection in starved rats and then measuring their erythropoietic activity with the test devised by Hodgson *et al.*[7,8], using iron-59. The duration of starvation and the quantity of extract injected in a total of two injections in successive days is given in Table 1. 24 hr. after the second injection of the extract, 1–3 μc. of iron-59 of high specific activity incubated with normal rat plasma was given to each rat in the saphena. 3 hr. later the rats were bled through the abdominal aorta and the percentage of the dose of iron-59 was determined in the plasma, erythrocytes and liver. Volume of plasma was measured by injecting normal rat plasma labelled with iodine-131 following McFarlane's method[9].

The radioactivity was measured in a well scintillator with a γ-ray spectrometer (analyser computer, model 132, from the Nuclear Chicago), making the corresponding correction for the activity incidence of iron-59 at the peak of iodine-131.

The plasma iron was determined by the technique of Schade *et al.*[10], making a pool of the plasma with the same number of c.p.m. of iron-59 in 1 ml. of plasma.

With the results obtained the time constant (*K*) of disappearance of iron-59 from plasma and the plasma iron turnover were calculated. To determine the percentage of the dose of iron-59 in the total of the rat's erythrocytes, the volume of blood was calculated from the plasma volume and the hæmatocrit. The results in the unknown and control rats were submitted to statistical treatment of the significance between averages, with the distribution of t for $N_1 + N_2 - 2$ degrees of freedom.

The action of the rennin-type renal extract did not become significant ($P < 0·1$; $t = 2·32$ for 7 degrees

Table 1. TISSUE EXTRACTS

Exp. No.	Material injected	No. of rats	Wt. of rats (gm.)	Per cent dose of ^{59}Fe 3 hr. after injection: Total plasma	Total erythrocytes	Liver	*K* per cent hr.	Plasma iron μgm./ml.	Turnover μgm/hr.	Hr. of starvation
79	Rennin-type renal extract (equivalent to 750 U Bs.As. of rennin)	5	223	7·4	17·2 $P<0·1$	3·9	89	0·8	5 7	110
	Control 4 ml. of normal dog plasma	4	224	19·6	3·2	6·2	54	1·9	7·5	
86	Rennin-type spleen extract. Total dose . 7·5 mgm. proteins	5	181	19 5	11·1 $P<0·01$	4·9	56	2·1	10·3	79
	Alcohol-boiled kidney extract. Total dose : 7·5 mgm. proteins	6	179	16 1	9·6 $P<0 01$	7·0	62	2·1	11·0	
	Rennin-type liver extract. Total dose · 7·9 mgm. proteins	6	178	20 1	4·8 $P<0·05$	7·4	55	2·1	8·1	
	Control 0 9 per cent NaCl solution	4	176	38 7	2·3	—	31	2·3	6·0	
100	Alcohol-boiled liver extract. Total dose : 12·1 mgm. proteins	5	178	8 9	11·0 $P<0·05$	3·4	85	0·8	4·5	72
	Alcohol-boiled spleen extract. Total dose : 10·4 mgm. proteins	5	182	11·2	8·1 $P<0·01$	3·5	74	1·1	5 8	
	Control Normal plasma alcohol-boiled extract. Total dose · 9 0 mgm. proteins	5	185	22·4	3·1	4·5	51	1·4	4 9	

of freedom), in spite of the noticeable difference of the average with the control group. This might be due to great dispersion of the values (between 7·4 and 35·8 per cent) observed in this group, attributable to an exaggerated period of starvation. In this connexion, the control group injected with 4 ml. of native whole plasma, which normally raises the erythropoiesis of these starved animals, has low values of incorporation of iron-59 in the erythrocytes, similar to that of the control group injected with only 9 mgm. of proteins and with only 72 hr. of fasting. This observation seems to be confirmed by the results of the injection of renal extract boiled in alcohol, of a high statistical significance (Exp. 86) $P < 0{\cdot}01$.

The splenic and hepatic extracts show statistically significant results. The incorporation of small amounts of iron-59 in the erythrocytes, in the case of hepatic extract of Exp. 86, appreciably increases when the dose of this extract goes up to 12 mgm. of proteins (Exp. 100).

The results referring to the percentage dose of iron-59 in the plasma confirm those of the erythrocytes. As the dose of the iron-59 which remains in the plasma lessens at the end of 3 hr. after injection, so much greater is the uptake of iron-59 by the erythrocytes and greater is the time-constant of disappearance from plasma of iron-59. Thus we see in the active groups that a lower proportion of iron-59 goes to the liver—one of the storage organs.

All these results indicate an erythropoietic stimulation of the groups injected with different types of extracts when compared with the control groups. The results of plasma iron turnover, except in Exp. 86, are not a good index of erythropoiesis since the values of plasma iron were less than 2 µgm./ml. (ref. 11).

The hæmatocrit values in the experimental and control groups (48·4 and 48·7 respectively) support the idea that the erythropoietic stimulus must be ascribed directly to the extracts, and not to a secondary effect due to hæmolytic action.

In Exp. 100, both the control and the active groups had received approximately the same quantity of proteins and in Exp. 72 the controls had received several times more. Therefore, the erythropoietic stimulus cannot be ascribed to the quantity of injected proteins.

Like erythropoietin, the active substance of the different extracts showed that it was heat-stable[4,13] and precipitated at pH 4·5 with 4 volumes of ethanol[5,14]. On the other hand, the strongly active extract boiled in alcohol was proved to be free of rennin-type substances.

The substance obtained from normal pig kidney is substantiated by the results which Lagrue *et al.*[14] obtained with normal rabbit kidneys, though they failed when using pig's kidneys. Their method of extraction differed from ours in that they used successive freezing and de-freezing. We believe that our success lies principally in the stage of incubation for 20 hr. with a 6 per cent sodium chloride solution at room temperature without oxygenation.

ROLE OF THE PITUITARY GLAND IN KETOGENESIS

By DR. P. A. MAYES

Division of Biochemistry, Royal Veterinary College,
London, N.W.1

IN previous experiments an increased production of ketone bodies was found to be most closely associated with a shortage of utilizable fuel and the need for an additional source of energy[1]. The ketonæmia of rats consuming a completely fat diet persisted in animals fed sub-calorific amounts but became reduced or absent when sufficient fat was consumed to satisfy the calorific requirement.

Evidence may be drawn from several sources to account for the promotion of ketogenesis by a shortage of utilizable fuel and for the antiketogenic effect of calorie sufficiency. Ketogenesis *in vivo* is invariably accompanied and sustained by the mobilization of fat from the fat depots in the form of unesterified fatty acids. The release of unesterified fatty acids from the depots of fasting subjects is inhibited after administration of glucose[2], amino-acids[2] and fats[3], which is strongly indicative of an underlying mechanism sensitive to the availability of calorigenic substrates. Furthermore, the unesterified fatty acids released may stimulate 'latent' adenosine triphosphatase activity in the liver, making more adenosine diphosphate available for the acceptance of high-energy phosphate and allowing hepatic fatty acid oxidation to proceed at an accelerated rate[4]. Consequently, the production of acetyl-coenzyme A would exceed the capacity of the liver to oxidize it and ketogenesis would ensue. However, elevation of serum unesterified fatty acids resulting from the administration of the pituitary fraction H of Rudman *et al.* does not lead to acetonæmia in fed rabbits[5], a finding which suggests that there may be an additional hepatic effect of calorie deficiency or starvation which facilitates the conversion of mobilized unesterified fatty acids to ketone bodies in the liver. It appears that a basic mechanism could exist for the control of ketosis which does not necessarily require the active participation of hormones.

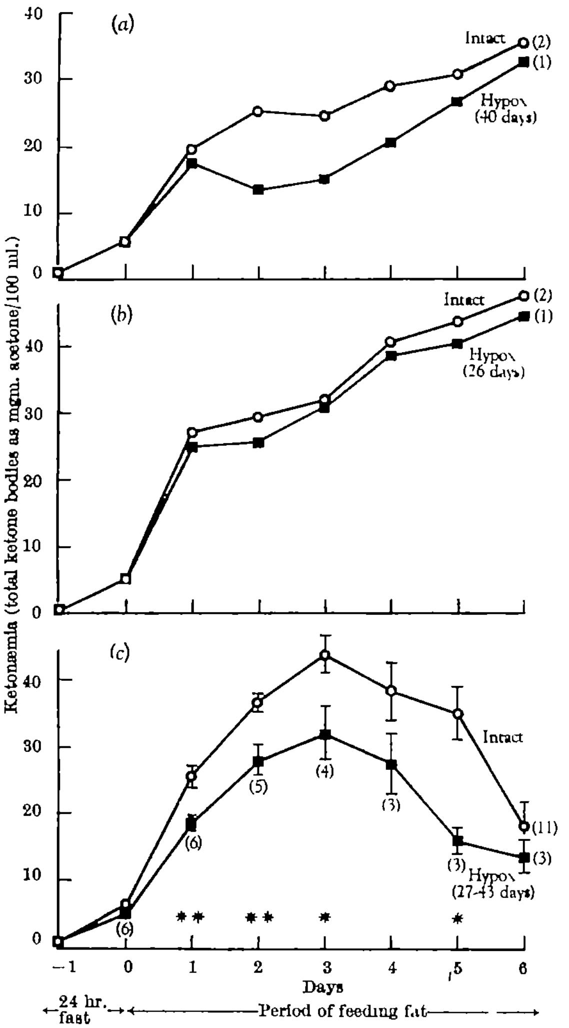

Fig. 1. Ketonæmia in hypophysectomized (hypox.) and intact rats fasted for 24 hr. and then force-fed (*a*) 2 gm., (*b*) 4 gm. and (*c*) 6 gm. butter fat/day. Average initial body-weight was 184 gm. and 187 gm. for the hypophysectomized and intact groups respectively. Temperature was held at 26–27° C. Numbers of animals are shown in parentheses. The bars indicate the *S.E.* and asterisks show where differences between operated and intact rats are significant; *, $P = 0 \cdot 05$–$0 \cdot 01$; **, $P = 0 \cdot 01$–$0 \cdot 001$

There is also much experimental work which suggests an active role for the pituitary gland in ketogenesis[6]. It is possible to envisage the secretion of the pituitary gland responding to the stimulus of calorie deficiency by promoting the mobilization of fat and ketogenesis, its effect being additive to that of the mechanism outlined here. Certain pituitary gland extracts have adipokinetic and ketogenic activity[7,8] and substances having one or both of these properties have been found in the urine of fasting rabbits[9], and in the urine of fasting humans provided a functional pituitary gland is present[10]. Removal of the pituitary gland reduces the ketonuria of phlorhizinized or pancreatectomized dogs[11]. Oastler and Anderson[12] fed hypophysectomized rats a high fat diet and found that ketonuria was abolished while ketonæmia was still present, but they did not consider their results as necessarily contradicting the hypothesis of a pituitary 'ketogenic factor'. However, the calorie intake was not controlled, a factor now considered in this laboratory to be of importance in regulating ketogenesis[1].

The experiments reported here were carried out to assess the part played by the pituitary gland in the promotion of ketosis in rats on a fat diet. A comparison was made of the ketonæmia of hypophysectomized female rats fed on an all-fat diet with that of intact controls, the calorie intake being regulated as in previous experiments[1]. Force-feeding of both groups was adopted because of the depressed appetite of hypophysectomized animals. All rats were fasted for 24 hr. and were then force-fed butter fat (2, 4 or 6 gm./day) in two equal portions given at 10 a.m. and 10 p.m. The diet contained 3 per cent salts and kaolin to reduce the incidence of diarrhœa. No results have been used where the alimentary absorption of fat was less than 98 per cent of the amount fed. Other experimental procedures have been described elsewhere[1].

The ketonæmia of the intact rats force-fed butter fat rose to approximately double the concentration found previously in intact animals consuming a corresponding amount of fat by free-feeding[1]. Qualitatively, however, the ketonæmia was similar, a reduction in ketonæmia being observed only in those rats fed 6 gm. of butter fat per day the calorie requirement of which was being satisfied from the diet (Fig. 1). These results suggest that the underlying mechanism controlling ketogenesis was the same with both methods of feeding. Force-fed intact rats were considered, therefore, to be suitable controls for force-fed hypophysectomized animals.

Comparison of hypophysectomized rats with controls showed that removal of the pituitary gland did not have any marked effect on the pattern of the ketonæmic responses of rats fed all fat diets. In hypophysectomized rats force-fed butter fat in subcalorific amounts there was an ensuing and persistent ketonæmia, similar to that of intact animals (Fig. 1*a*, *b*). In those fed 6 gm. of fat daily, thereby satisfying calorie requirements, there was a reduction of ketonæmia in the operated animals, the response again being similar to the controls (Fig. 1*c*). Nevertheless, the magnitude of the ketonæmia tended to be lower as a result of hypophysectomy, and significantly so in the case of the rats fed 6 gm. of butter fat per day. Whether this reduction in ketonæmia can be attributed to the removal of a ketogenic hormone of pituitary origin is doubtful. If such a hormone is directly involved, the smallness of the reduction suggests that it is of little physiological significance. The lesser ketonæmia of the hypophysectomized rats is more probably accounted for by their known hypothyroid condition causing a reduction in energy requirement, a situation where a diminution in ketogenesis is to be expected[1]. Confirming the hypothyroid condition of the hypophysectomized rats was their reduced requirement for metabolic fuel. This is shown by the finding that during the period of feeding fat the operated rats fed on 6 gm. fat a day gained an averge of 5·3 gm. per rat body-weight, whereas the intact controls lost 0·5 gm. per rat during the same period. The lesser ketonæmia following hypophysectomy may also result in part from reduced activity of the adrenal cortex, as an adequate level of circulating adrenal cortical hormone is necessary to permit a maximal response to many stimuli which promote fat mobilization[13]. These results are in keeping with those of other workers who have observed that hypophysectomy does not abolish either the rise in plasma unesterified fatty acids[14] or the increase in ketonæmia[6] of the fasting rat.

The failure of hypophysectomy to alter qualitatively the difference in the pattern of the ketonæmia resulting from feeding fat diets of differing calorific value to rats demonstrates that both the ketogenesis resulting from calorie deficiency, and the antiketogenic effect of feeding a sufficiency of calories in the form of fat, are not likely to be caused by variations in the hormonal secretion of the pituitary gland. Provided the secretion of a ketogenic hormone of extra-hypophyseal origin is not being stimulated, available experimental evidence suggests that one of the main sites of action of the stimulus of calorie insufficiency in promoting ketosis is to be found in the mechanism of release of unesterified fatty acids from the fat depots. In turn, the unesterified fatty acids passed into the plasma provide the principal substrate for the production of ketone bodies in the liver.

'ADAPTATION' OF A LINE OF MOUSE BONE MARROW TO AN INCOMPATIBLE STRAIN

By DR. P. L. T. ILBERY and S. M. WINN

Department of Preventive Medicine, University of Sydney

TRANSPLANTATION of hæmopoietic tissue to an incompatible mouse strain following lethal whole-body irradiation usually results in the appearance of secondary radiation disease; but when fœtal hæmopoietic tissue is used in preference to adult bone marrow in the graft the disease may occur only mildly or may be avoided[1,2]. Retransplantation of bone marrow from radiation chimæras made from homografts of incompatible fœtal hæmopoietic tissue to further lethally irradiated test animals has shown a propensity for the marrow to 'take' without death ensuing from homologous disease. We have used the term adaptation without implication as to the mechanism involved at the cellular level to describe this phenomenon[3]. Koller *et al.*[4], transplanting marrow from radiation chimæras, where adult tissue had been given to effect resuscitation from the lethal effects of radiation, observed a similar phenomenon. Rubin[5] has described a related occurrence in parabiosis.

Transplantation of the adapted bone marrow to further lethally irradiated test animals of host and donor type strains has shown persistence of the phenomenon as judged by the results of genetic transplantation tests. However, as emphasized by Urso *et al.*[6], it has been necessary to exclude the possibility of reversion to host-type marrow in the primary or subsequent radiation chimæras giving a false impression of adaptation or the carrying over of a syngeneic graft with transplanted marrow. Accordingly, we have labelled the donor cells with a marker chromosome and examined cytogenetically the hæmopoietic tissues of the test animals into the second and third passage of bone marrow for its continued presence.

CBA mice were given 1,050 rads cobalt-60γ lethal irradiation. Twenty were given adult bone marrow from (*C57BL* × *T6*)F_1 hybrids and all succumbed to secondary radiation disease between the twenty-first and sixtieth days post-irradiation. In the particular line to be described, five lethally irradiated *CBA* received 1·2 × 10^7 embryo liver cells from a (*C57BL* × *T6*)F_1 litter of approximately 17 days gestation. This transplantation is considered as the initiation of the line of hæmopoietic tissue and two *CBA* were well nourished, greyed animals without evidence of diarrhœa at death 215 days later. Macroscopically, their hæmopoietic and lymphoid organs appeared normal. Bone marrow, thymus, spleen and lymph node were taken for cytogenetic examination, and passage 1 of the hæmopoietic tissue, in this case, bone marrow from the two radiation chimæras, was made to six lethally irradiated *CBA* and four lethally irradiated (950 rads) *C57BL*. Our usual dosage and method of administration of bone marrow[3] was used. Two *CBA* and two *C57BL* survived the period of secondary disease appearing greyed, well nourished and without evidence of diarrhœa after 90 days. The results of the cytogenetic investigation of the two *CBA* are shown in Table 1 as line 1*a* and 1*b*.

Table 1. CYTOGENETIC ANALYSIS OF *CBA* CHIMÆRAS

Passage	Bone-marrow *T6+*	Bone-marrow *T6−*	Spleen *T6+*	Spleen *T6−*	Thymus *T6+*	Thymus *T6−*	Lymph node *T6+*	Lymph node *T6−*
1*a*	72/1	−/1	12		—		—	
1*b*	113		10		7		11	1
2*c*	120		68		41		25	
2*d*	55	/1	16		8		14	
3*e*	16		52		—		—	
3*f*	—		49		5		5	
3*g*	53	−/1	38	−/4	—		—	

Figure to right of stroke indicates less than 40 chromosomes, that is, probably a broken cell.

The two-passage 1 *CBA* chimæras from sub-line 1*b* were killed 127 and 134 days respectively from the inception of chimærism, their tissues examined cytogenetically (Table 1, 2*c* and *d*) as before and transplantation made of bone marrow (passage 2) to eight *CBA* and seven *C57BL* lethally irradiated mice. Four *CBA* and two *C57BL* survived longer than 90 days and near the ninetieth day the *CBA* chimæras were grafted with *CBA* and *C57BL* skin on the left and right flanks respectively. One mouse died during the grafting procedure, the *C57BL* graft failed in one animal and both grafts were accepted by two. The animal with the failed *C57BL* skin graft was regrafted successfully. Transplantation of bone marrow (passage 3) was made from two-passage 2 *CBA* chimæras 166 days and 270 days respectively from the inception of chimærism to further lethally irradiated *CBA* and *C57BL* mice. Both these chimæras, the cytogenetic details of which are recorded as 3*f* and *g* in Table 1, had carried *C57BL* skin grafts for 93 days and 146 days respectively to the time of their death. The passage-2 *CBA* chimæra 3*e* from 2*d* was killed earlier (105 days) without further passage simply for confirmation of the presence of the marker chromosome.

The results show that cells carrying the marker chromosome, and those cells only, are present in this line as judged by our ability to recognize the marker in the dividing tissues examined. The marker has been followed in an unbroken line (1*b*, 2*d*, 3*e* and *f*) through three transplant generations of $(C57BL \times T6)F^1$ hæmopoietic tissue to the incompatible strain *CBA* hosts (also 1*b*, 2*c* and 3*g*) and the line will be maintained, if possible[7], at approximately six-monthly passages. In other marked lines we had previously shown the propensity for adapted marrow to take in host and donor type lethally irradiated hosts[8]; but it is felt that these serial transplantation results strengthen our hypothesis that adaptation, whether of a selective or instructive nature, does occur in recovery from or avoidance of secondary disease. Somatic mutation of the cells to enable proliferation in either host or donor type environment as an explanation is unlikely as passage of the line through donor type lethally irradiated mice abolishes their propensity to resuscitate lethally irradiated host type test animals. The similarity to the predictions of clonal selection[9] in acquired tolerance is remarkable.

RECOVERY EFFECT OF HIGHLY POLYMERIZED HOMOLOGOUS LIVER DEOXYRIBONUCLEIC ACID INJECTED INTO LETHALLY IRRADIATED RATS: HISTOLOGICAL EXAMINATION OF THE SPLEEN AND BONE MARROW

By V. PANTIĆ and N. STOŠIĆ

Institute of Histology and Embryology, University of Belgrade

AND

DR. D. KANAZIR, A. BEĆAREVIĆ and G. JOVICKI

Laboratory of Radiobiology, Institute of Nuclear Sciences,
"Boris Kidrich", Belgrade

OUR previous work has shown that the homologous highly polymerized (native) nucleic acids from the liver and spleen of young donors may reduce mortality due to radiation[1-3]. In the course of this work on the recovery of the irradiated rats by means of nucleic acids, we showed significant thirtieth-day survival of the irradiated rats ($LD_{100/30}$) (refs. 1, 2 and 3); recovery of the metabolic functions concerning the incorporation of formate labelled with carbon-14 and phosphorus-32 in the nucleic acids of the irradiated treated recipients[4]. In addition, a recovery of the processes leading to the synthesis of the antibodies in the irradiated rats was obtained by means of native nucleic acids[5]. Our histological investigations, however, have demonstrated that the irradiated rats treated with deoxyribonucleic acid (DNA) show less-evident damage in the structure of the adrenal glands and some organs of the digestive system, that is, the structure of these organs was less altered after DNA treatment[6,7]. On the basis of these results, we are inclined to believe that the animals treated with DNA have a greater capacity for recovery from the injury caused by X-rays than the controls.

In our attempts to understand the mechanism of this recovery from injury caused by radiation, it was of interest to ascertain whether a similar recovery of the bone marrow and the spleen can be obtained after DNA treatment of the irradiated rats ($LD_{100/30}$). The present article is concerned with a histological examination of the modification of radiation-induced changes in the spleen and bone marrow of the rats exposed to a $LD_{100/30}$ of X-rays, and treated with homologous native liver DNA.

Adult albino rats, bred at our animal farm, were used. The experimental conditions and mode of treatment have already been described[1-3]. The animals treated with DNA and their respective con-

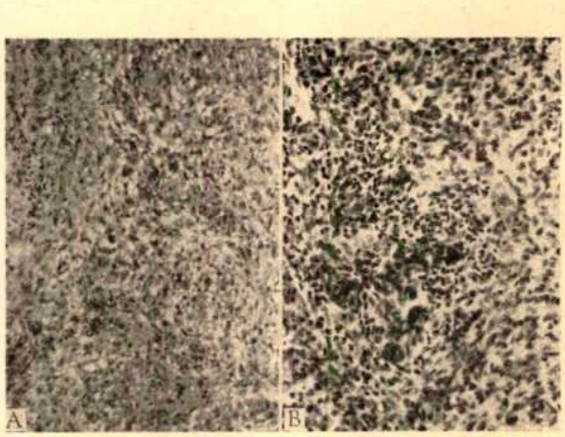

Fig. 1. Spleen of irradiated rats. *A*, untreated; *B*, DNA-treated with fairly well preserved Malpighian body

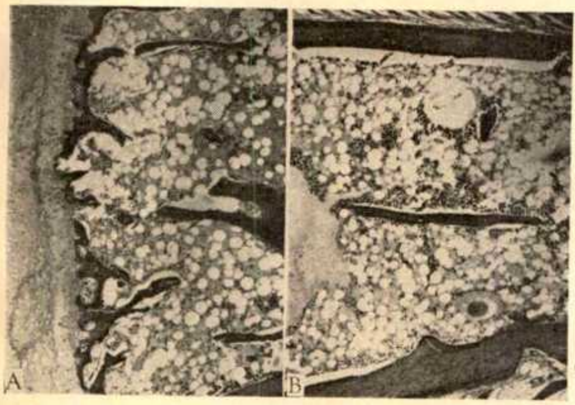

Fig. 3. Bone marrow of irradiated rats. *A*, untreated; *B*, DNA-treated

trols were killed on the fourth or ninth day after irradiation.

The microscopic specimens were fixed in 10 per cent neutral formol, Bouin and Serra fixative and 1 per cent of isotonic osmic acid. Decalcification was carried out by Ebner's method. The sections were stained with hæmatoxylin–eosine and according to Azan and Brachet.

Spleen. In the spleen of the lethally irradiated rats, as already known, only closely packed reticular cells and fibres, macrophages and some lymphocytes can be seen (Figs. 1*A* and 2*A*).

In the spleen of the animals treated with DNA the changes are, however, considerably less marked: the venous sinuses in the red pulp are less dilated and hæmorrhage is less frequent. The reticular cells are less damaged and, in addition, cells in the blast stage are found. In the cytoplasm of fixed macrophages there are many particles of pigment granules and erythrocytes in various stages of digestion. Among these cells the lymphocytes are diffusely scattered. In the spleen of the animals treated with DNA there are lymphoblasts and lymphocytes around the v. centralis in the form of small-size irregular Malpighian bodies. Some lymphoblasts in these bodies are dividing; the peripheral part of the white pulp consists mostly of altered reticular cells, macrophages and some lymphocytes (Figs. 1*B* and 2*B*).

Despite the pronounced reduction of the lymphopoietic elements in the spleen of the irradiated rats treated with DNA, the number and the structure of the lymphoblasts and lymphocytes seem to indicate a favourable recovery effect produced by the homologous liver DNA on the spleen of the irradiated animals.

Bone marrow. Injury to the bone marrow of the sternum in all the lethally irradiated rats is very great. In most of the investigated regions only the reticulocytes and fat cells were observed (Fig. 3*A*). Hyperæmia and hæmorrhage are expressed to a considerable degree. Alterations in the form, size and structure of the nuclei and cytoplasm of the reticular cells vary from cell to cell. Among these cells there is a small number of myelopoietic and erythropoietic lines formed, and occasional megakaryocytes. These forms usually appear along the compact parts of the sternum. In some areas an increased number of eosinophils is found. Closely packed, more or less altered, leucocytes are found also (Fig. 4*A*).

It has been noticed that in the bone marrow of the rats treated with DNA hyperæmia is less evident, whereas hæmorrhage is less frequent. The structure of the bone marrow gives the impression of being less damaged judging by the number and a more uniform numerical relationship of the formed elements in it (Fig. 3*B*). The number of the megakaryocytes is greater and the nucleoli are more numerous and of

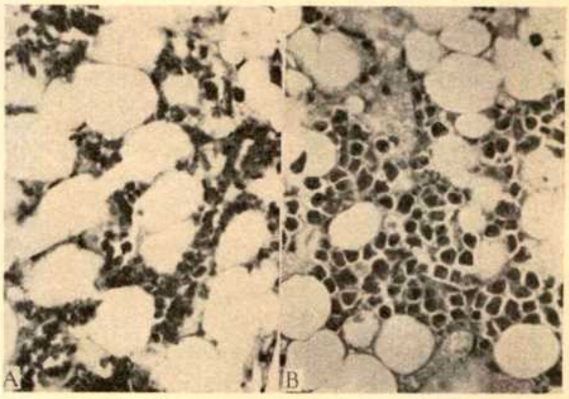

Fig. 4. Myelopoietic and erythropoietic elements in bone marrow of irradiated rats. *A*, untreated; *B*, DNA-treated

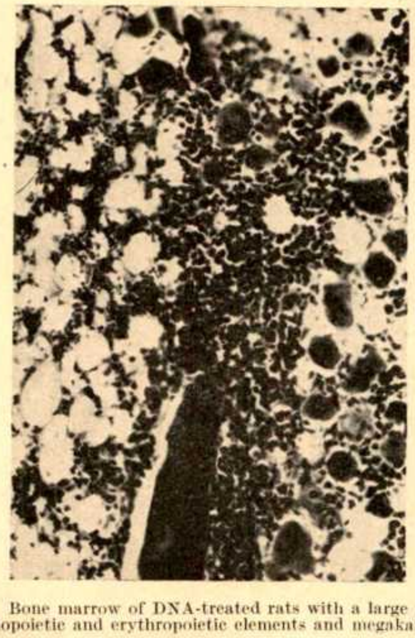

Fig. 5. Bone marrow of DNA-treated rats with a large number of myelopoietic and erythropoietic elements and megakariocytes

larger size (Figs. 4*B* and 5). The blood elements and the evolutionary forms of the blasts of the myelopoietic and erythropoietic line are distributed in groups, most frequently along the trabeculæ. The division of the cells is more numerous in the bone marrow of the rats treated with DNA. Groups of eosinophilic granulocytes in all phases of development are also found in the bone marrow of these animals.

On the basis of these preliminary results, we consider that the spleen and the bone marrow of the lethally irradiated rats treated with DNA are less damaged than the controls. The reticular cells are not so much altered and there are more lymphopoietic elements in the spleen and myelopoietic and erythropoietic elements in the bone marrow.

ANTAGONISM OF PENTOBARBITONE ANÆSTHESIA IN HAMSTERS BY 5,5-DIPHENYLHYDANTOIN MODIFIED BY SALICYLATE

By Dr. PETER H. STAPLE and Dr. DAVID J. NUTTER

Department of Pharmacology, University of Alabama Medical Center, Birmingham, 3, Alabama

DURING work[1] concerned with the action of salicylate[2,3] on periodontal effects of 5,5-diphenylhydantoin (phenytoin, B.P.), it was noted that some hamsters receiving phenytoin could not be satisfactorily anæsthetized with amounts of pentobarbitone adequate for the same animals before treatment. With satisfactory anæsthesia the required dental impressions could be taken during a 15-min. period without eliciting reflex movements. In contrast, in animals treated with phenytoin, impression-taking was often accompanied by alternate depression and elevation of the mandible; apparently touching the hard palate elicited a combination of linguomaxillary (mandibular) and palatomaxillary reflexes similar to that previously noted in other animals[4]. These reflex movements ceased on removing the impression tray from the mouth, but in order to complete the dental procedure unhindered additional pentobarbitone had to be administered. Nevertheless, despite such supplementation, the duration of anæsthesia appeared to be no longer than in the controls.

Further periodontal studies have now provided the opportunity to confirm our preliminary observations. Forty-eight young (40–80 gm.) male hamsters were assigned among four groups so as to give a balanced distribution of body-weights. The animals were housed singly in wire mesh cages with hay bedding and fed, as previously[1], a powdered high carbohydrate diet, the physical properties of which induce marginal gingivitis[5]. Eleven days later they were anæsthetized with a standard dose (65 mgm./kgm., intraperitoneal) of pentobarbitone sodium in order to take dental impressions. Table 1 shows the duration of 'sleeping time'[6] and the abolition of jaw reflexes in response to lightly touching the hard palate. For 65 mgm./kgm. pentobarbitone, analysis shows that the variance of group means for both parameters is not significantly different from that of individuals. Unlike our previous experience with older animals[1], in this series of young animals three required supplements of pentobarbitone for satisfactory anæsthesia. On experimental day 1, the following group treatments were started and continued as indicated in Figs. 1 and 2: (*a*) controls, sodium carbonate (intraperitoneal) and/or sodium chloride (subcutaneous) to match the pH of the phenytoin solution and provide sodium equivalent to phenytoin and/or salicylate; (*b*) phenytoin sodium 25 mgm./kgm. (intraperitoneal); (*c*) sodium salicylate 60 mgm./kgm. (subcutaneous); (*d*) both phenytoin and salicylate as in (*b* and *c*). At intervals during this regimen the hamsters were

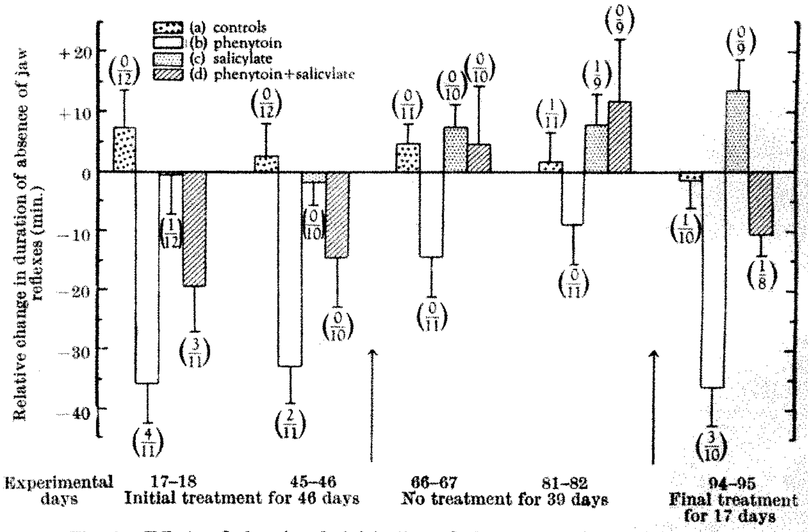

Fig. 1. Effects of chronic administration of phenytoin and salicylate on the duration of abolition of mandibular reflexes by pentobarbitone, 65 mgm./kgm. (intraperitoneal). The bars represent the means of the individual differences, calculated with reference to the duration the reflexes were absent before treatment began, each animal serving as its own control throughout the experiment. The number of animals and the proportion requiring supplements of pentobarbitone to complete dental procedures are indicated in parentheses by the fractions accompanying the measure of the standard error

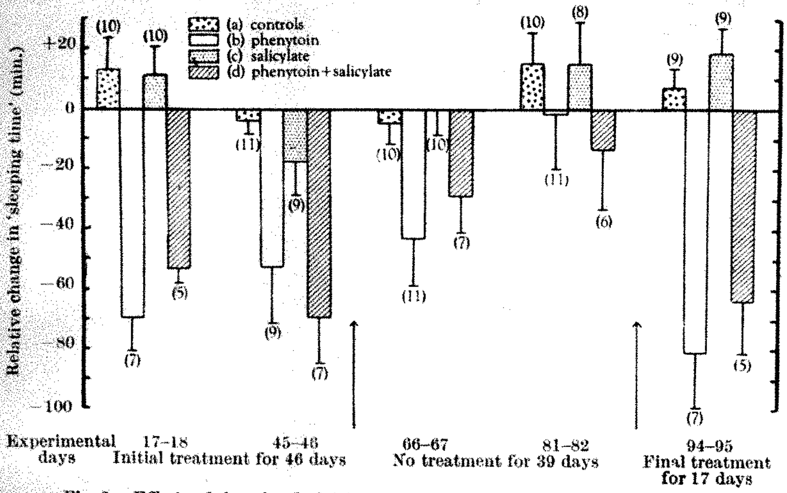

Fig. 2. Effects of chronic administration of phenytoin and salicylate on 'sleeping time' following pentobarbitone, 65 mgm./kgm. (intraperitoneal). As in Fig. 1, the bars represent means of the individual differences calculated with reference to the pre-treatment period. The number of animals is shown in parentheses accompanying the measure of the standard error

anæsthetized with pentobarbitone, 65 mgm./kgm. and tested as already described, 24–30 hr. following the previous daily treatment.

In Figs. 1 and 2 the duration of the absence of jaw reflexes and 'sleeping time' are compared with the initial values (cf. Table 1) for the same individuals before treatment. Clearly, chronic treatment with phenytoin reduced both the duration of the absence of mandibular reflexes and 'sleeping time', which is reflected by the increased number of animals requiring supplements of pentobarbitone for the completion of the dental procedure. These supplements did not increase 'sleeping time', as was the case for the control group (*a*) and for some animals in groups (*c* and *d*) before treatment (Table 1). Factorial analysis of variance for data on jaw reflexes revealed some interaction between phenytoin and salicylate, but this was not significant ($F_{1\cdot 39} = 3\cdot 43$, $0\cdot 05 < P$); furthermore salicylate treatment did not have a significant effect. Data for days 38–39, not shown in Figs. 1 and 2, confirmed these findings. In contrast, during the second treatment period (experimental days 94–95), when interaction between the two drugs was negligible, salicylate was shown to have a highly significant effect ($F_{1\cdot 33} = 8\cdot 82$, $0\cdot 01 > P$). Thus in group (*d*) salicylate counteracted the effect of phenytoin; similarly it prolonged the action of pentobarbitone in group (*c*). No interaction was found in the data for 'sleeping time', and it was clear that salicylate did not affect the action of phenytoin in group (*d*), nor that of pentobarbitone in group (*c*).

Table 1. PENTOBARBITONE ANÆSTHESIA IN HAMSTERS BEFORE TREATMENT

	(*a*) Controls*	(*b*) Phenytoin*	(*c*) Salicylate*	(*d*) Phenytoin salicylate*
Duration (min.)† jaw reflexes absent after pentobarbitone, 65 mgm./kgm.	25·7 ± 4·2 (12)	39·5 ± 4·2 (12)	27·1 ± 3·8 (12)	24·0 ± 7·5 (12)
Proportion of animals needing supplements of pentobarbitone to abolish jaw reflexes	0/12	0/12	1/12	2/12
'Sleeping time' (min.)† (i) animals receiving pentobarbitone, 65 mgm./kgm.	81·1 ± 7·7 (11)	110·9 ± 10·6 (12)	91·3 ± 12·2 (11)	95·8 ± 11·6 (9)
(ii) All animals including those receiving supplements of pentobarbitone	as (i)	as (i)	106·3 ± 18·7 (12)	117·2 ± 17·2 (11)

* Treatment subsequently administered.
† Mean ± *S.E.*, number of animals in parentheses.

In the interval between treatments (for example, experimental days 66–67 and 81–82), 65 mgm./kgm. pentobarbitone again gave satisfactory anæsthesia, but residual effects of phenytoin seemed to be present in group (*b*), as shown by the short period when jaw reflexes were absent and by the reduced 'sleeping time' on experimental days 66–67 ($0\cdot 05 > P > 0\cdot 02$). This accords with previous reports of the persistent action of a single[7], or chronic[8,9], administration of phenytoin.

Our experiments in hamsters show that phenytoin can antagonize some depressant actions of pentobarbitone, which seems paradoxical in view of the use of phenytoin and barbiturates in combination to suppress experimentally induced convulsions and treat grand mal epilepsy. In line with our findings, however, is an earlier report[10] that, in dogs, a single intravenous administration of phenytoin, 50 mgm./kgm., restored the knee jerk reflex previously depressed by pentobarbitone, 70 mgm./kgm.; conversely, phenytoin enhanced the depression of this reflex by ether. Moreover, while phenytoin suppresses the tonic phase of electroshock convulsions in rats it prolongs the clonic phase[7], and in low doses (< 100 mgm./kgm.) enhances carbon dioxide-induced spontaneous and withdrawal seizures[11]. Apart from the central nervous system, however, antagonism between phenytoin and pentobarbitone might possibly arise from adaptive increases in barbiturate-metabolizing enzymes, as recently reported[12] for a number of substances of widely differing chemical composition. Previous findings[2,3] would support the concept that phenytoin can enhance the central excitatory action of salicylate; but this is not a satisfactory explanation of our results, particularly as regards jaw reflexes on experimental days 94–95 (Fig. 1).

Since epileptics receiving phenytoin therapy may well try self-medication with salicylates, further examination of phenytoin–salicylate interaction seems desirable.

This work was supported by an Institutional Grant from the American Cancer Society. We thank Dr. Graham Chen of Parke, Davis and Co. for supplies of phenytoin as 'Dilantin' sodium.

CYTOLOGY OF COLLEMBOLA

By DR. OVIDIO NÚÑEZ

Instituto de Edafología e Hidrología, Universidad Nacional del Sur, Bahía Blanca, Argentina

UNTIL 1956 the chromosome numbers of only three species of Collembola (Insecta : Apterygota) were known[1-3]. Since then, data for eighteen other species have been published[4-6]. Table 1 gives chromosome numbers for twenty additional species from Bahía Blanca. The material was fixed in Clarke's solution[7]—glacial acetic acid previously saturated with ferrous hydroxide. The gonads were dissected out and squashed in acetic hæmatoxylin.

Table 1

Dicyrtominae			
Dicyrtomina sp.	5		9

Hypogastrura manubrialis and *Ceratophysella armata* var. *communis* have normally n♀ = 6, but now and then females turn up with 1–3 supernumerary chromosomes.

Saure and Brummer-Korvenkontio[5] found $n = 6$ in *Isotomurus palustris* and observed oocytes with a small additional chromosome. In the two forms of this species I have studied all the oocytes had seven bivalents (Fig. 1).

Tuzet and Manier[4] have determined $2n$♂ $= 8 + X$ in 3 species of *Entomobrya*, but my findings in 4 species of this genus show $2n$♂ $= 11$ (Fig. 3). It is noteworthy that one male of *E. pseudodecora* exhibited a spermatogonial metaphase with $2n = 12$ (Fig. 4) and another with $2n = 14$; other abnormal numbers appeared also to be present in this specimen. Moreover, I have found in this species a chromosome with differential behaviour, at the very early meiotic prophases, where a heteropycnotic element shows up by the nuclear membrane.

As the diploid set of males of two species of *Katianna* and *Dicyrtomina* exhibited also one chromosome less than that of the females, one should accordingly ascribe to Collembola, or at least to the families *Entomobryidae* and *Sminthuridae*, the XX♀ : XO♂ type of sexual determination.

No evidence has been found supporting Tuzet and Manier[4] to the effect that the diploid spermatogonia originate from polyploid.

Saure and Brummer-Korvenkontio[5] observed chromosome bridges in polyploid anaphases of young individuals of *Tomocerus vulgaris*. In most species I have studied, these so-called bridges are a regular feature of mitotic and second spermatocyte anaphases as a result of the distal ends of the longest chromosomes remaining in contact when the other chromosomes have already moved apart (Fig. 2).

Available results show a decrease of the basic chromosome number parallel to phylogenetic advance to reach a striking constancy within each of the more evolved families. It is not possible to advance as yet a sound opinion on the mechanism of this decrease because the nature of the material at hand and the limitations of the technique prevent a satisfactory analysis of the caryotypes.

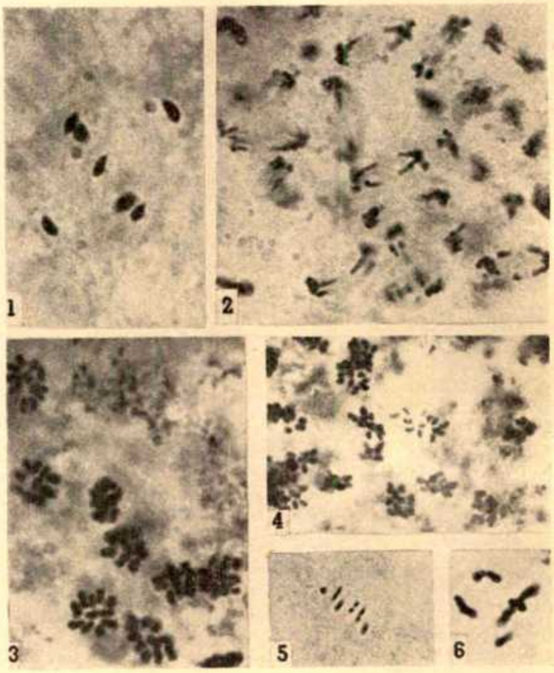

Fig. 1. Photomicrographs of chromosome behaviour in Collembola from temporary acetic hæmatoxylin squashes. All the plates have been pressed to spread out the chromosomes. (1) *Isotomurus palustris*, oocyte late diakinesis, $n = 7$ (× *c.* 1320); (2) *Hypogastrura manubrialis*, second spermatocyte anaphases (× *c.* 870); (3) *Entomobrya pseudodecora*, spermatogonial metaphases, $2n = 11$ (× *c.* 1320); (4) *E. pseudodecora*, same gonad as 3, $2n = 12$ (× *c.* 660); (5) *E. lanuginosa olivacea*, oocyte metaphase, $n = 6$ (× *c.* 600); (6) *Brachystomella parvula*, oocyte diakinesis, $n = 4$ (× *c.* 1320)

Collembola support Mather's[8] views on the connexion between a life-cycle with several generations per annum and low chromosome numbers (see also ref. 9).

I thank Prof. Eduardo H. Rapoport for identifying the species examined and for advice. I also thank Dr. John R. Baker for information regarding the dye used, and Prof. Dr. A. L. M. Lelong for the English translation of this article

UPTAKE OF AMINO-ACIDS BY THE FUNGUS *BOTRYTIS FABAE*

By O. T. G. JONES and W. A. WATSON

Chesterford Park Research Station, Saffron Walden

THE active accumulation of amino-acids has been intensively studied in bacteria[1–3] and animal cells[4,5]. Active transport of amino-acids in yeasts has been described[6,7]; but in the fungi generally information on the mechanism of action and specificity of the uptake process is slight. A study of this transport process in the fungi, with particular reference to the plant parasitic fungus *Botrytis fabae*, has now been made and is the subject of this report.

Botrytis fabae was grown in liquid culture 20° C. with constant shaking. The density of the spore inoculum greatly affected the diameter of the mycelial pellets and it was found most convenient to inoculate heavily to induce the growth of small pellets. The spheres were gathered by filtration, washed well with distilled water and then suspended in a 10^{-4} *M* solution of the amino-acid the uptake of which was being measured. The uptake of amino-acid from the suspending liquid was measured over periods of up to 40 min. by determining the amino-acid remaining in aliquots of the supernatant by a ninhydrin assay[8]. Recovery experiments were carried out by washing the pellets after incubation in the amino-acid, extracting in 70 per cent ethanol and assaying the ninhydrin-positive material in the alcoholic extract. The identity of the recovered amino-acid was checked by two-dimensional paper chromatography in butanol/acetic acid/water (4 : 1 : 5) and saturated phenol–water systems.

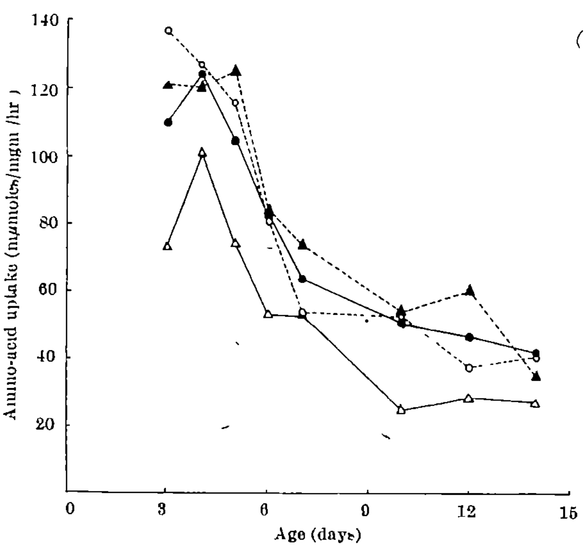

Fig 1 Change with age in rate of uptake of amino-acids by mycelium of *Botrytis fabae*
○, L-Glutamic acid; ▲, L-lysine, ●, L-methionine, △, L-tyrosine

It was found that the age of the fungus preparation greatly affected its activity (Fig. 1) and 4–5-day-old cultures were generally used in order to gain near maximal activity. The nitrogen content of the growth medium also profoundly affected the rate of amino-acid accumulation. When grown on a normal nitrogen-level medium (1 gm. nitrogen per litre as peptone) a high level of endogenous amino-acid was produced in the cells and the resulting outward diffusion of amino-acids masked any uptake. Growth at 0·1 gm. nitrogen per litre overcame this problem. Uptakes of amino-acid were found to be proportional to the dry weight of mycelium taken, which enabled comparisons of uptake rates of different amino-acids to be made (Table 1).

Table 1. UPTAKE OF AMINO-ACIDS BY *Botrytis fabae* FROM 10^{-4} *M* SOLUTION AT *p*H 5

Amino-acid	Uptake of L form (mμ*M*/mgm./hr.)	Uptake of D form (mμ*M*/mgm./hr.)
Glycine	135	—
Lysine	126	130
Glutamine	125	—
Valine	123	105
Serine	118	121
Methionine	116	107
Threonine	116	110
Glutamic acid	108	100
Isoleucine	106	45
Phenylalanine	104	140
Leucine	100	88
Histidine	100	129
Citrulline	100	94
Aspartic acid	97	—
γNH_2butyric acid	96	—
Alanine	96	150
Tyrosine	64	—
Di-OH phenylalanine	63	—
Tryptophan	38	45 (DL)

The most interesting feature of the results in Table 1 is the small difference in rates of uptake between different amino-acids, unlike the rates found in bacteria[2], and the lack of any marked stereoisomer specificity. Tyrosine, dihydroxyphenylalanine and tryptophan gave consistently low results. The rates of uptake appeared independent of the amino-acid recovery, which varied from 35 to 100 per cent for different amino-acids. Amino-acids may be concentrated up to a cellular concentration approaching 10^{-2}–10^{-4} *M* external concentration, with no marked differences between amino-acids.

Similar experiments, using a limited number of amino-acids, were carried out on a range of fungi (Table 2). In general, it appears that although the absolute rate of uptake of each amino-acid varies

Table 2. RATES OF UPTAKE OF FIVE DIFFERENT AMINO-ACIDS FROM 10^{-4} *M* SOLUTION BY A RANGE OF FUNGI

Fungus	Rate of amino-acid uptake in mμ*M*/mgm./hr. Phenyl-alanine	Glutamic acid	Lysine	Leucine	Meth-ionine
Botrytis fabae	112	89	108	115	105
Aspergillus niger	18·8	21·7	—	—	25·6
Pythium ultimum	4·0	7·0	10·7	12·6	12·4
Phytophthora palmivora	Any uptake masked by outward diffusion				
Fusarium culmorum	190	182	182	190	210
Cladosporium herbarum	26·3	25·2	42·3	51·6	48·5
Helminthosporium gramineum	10·4	4·1	20·3	9·4	13·2
Alternaria solani	40·5	28·1	39·8	50·7	49·1

widely in different fungi the ratio of rate of uptake of one amino-acid compared with another tends to be the same in different fungi, suggesting a common means of uptake.

The specificity of the accumulatory process was investigated by measuring the uptake of a labelled 10^{-4} *M* amino-acid labelled with carbon-14 in the presence of other unlabelled amino-acids at 10^{-3} *M*. The results of such an experiment with L-histidine given in Table 3 are typical. It is found that there is competition for accumulation between all the amino-acids tested, suggesting a common uptake process of perhaps varying substrate affinity. However, some degree of specificity is suggested by the greater effect of L-arginine and L-lysine on L-histidine accumulation and the similar more effective competition between L-glutamic acid and L-aspartic acid, L-alanine and L-valine.

The accumulation of an L-amino-acid is unaffected by the presence of its corresponding keto acid or by peptides, and only slightly by short straight-chain aliphatic amines. When *N* substituted derivatives of glycine were used as competitors of L-histidine uptake it was found that *N* acetyl glycine, hippuric acid, sarcosine, *N* : *N* dimethyl glycine and betaine were completely inactive, as was glycine hydroxamic acid.

Table 3. INHIBITION BY 10^{-3} *M* AMINO-ACIDS OF UPTAKE OF 10^{-4} *M* L-HISTIDINE

Competing amino-acid	Inhibition of uptake of L-histidine (per cent)
L-Glutamic acid	50
L-Phenylalanine	63
L-Valine	43
L-Arginine	83
L-Leucine	50
L-Lysine	84
L-Citrulline	44
L-Isoleucine	42
DL-Ornithine	75
γ-Aminobutyric	27
L-Methionine	65
L-Alanine	56
β-Alanine	10
L-Tryptophan	17
L-Glutamine	48
L-Serine	53
Glycine	31
L-Threonine	35
L-Aspartic acid	56
L-Asparagine	66
L-Proline	38

It is concluded that this accumulatory process is specific for α-amino-acids in which the carboxyl and amino-groups are unsubstituted. The competition between amino-acids for a transport system may help to explain results where high concentrations of added amino-acids have increased plant resistance to fungus attack[9,10]. Such added amino-acids may compete for uptake with an amino-acid which is essential for fungal growth.

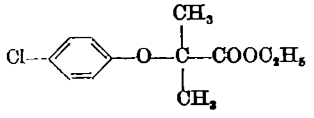
MODIFICATION OF METABOLISM AND DISTRIBUTION OF LIPIDS BY ETHYL CHLOROPHENOXYISOBUTYRATE

By J. M. THORP and W. S. WARING

Imperial Chemical Industries, Ltd., Pharmaceuticals Division, Alderley Park, Macclesfield

IN a screening test in rats on a normal diet it was found that a series of aryloxyisobutyric acids and related compounds showed marked activity in reducing total lipid and cholesterol concentration in blood and liver[1]. The compound, which combined maximum activity with minimum toxicity, was ethyl α-(4-chlorophenoxy)isobutyrate (I). The corresponding free acid, to which (I) is metabolized[1,2], was found to be equally active:



(I)

(I) was effective at levels of 0·15–0·3 per cent in the diet, or at 100–200 mgm./kgm. daily by oral or subcutaneous administration. At these doses no interference with growth of the animals occurred. Although active in both intact and gonadectomized rats, (I) enhanced the reduction of blood cholesterol induced by subcutaneously implanted œstradiol or testosterone. *In vitro* conversion of acetate labelled with carbon-14 into cholesterol by liver slices from rats treated with (I) was reduced by 30–50 per cent compared with controls[2]. In contrast to 2-(4-biphenylyl)-Δ^4-hexenoic acid[3], and similar branched-chain acids, which have been used clinically for the reduction of serum cholesterol, (I) caused no inhibition of the acute hyperlipæmia and hypercholesterolæmia induced in rats by intravenous administration of the surface-active polymer 'Triton *WR*-1339'.

The effects of (I) were also examined in other species. In the dog intravenous doses up to 100 mgm./kgm. did not alter cardiac or respiratory function, nor have any choleretic action. In the rabbit there was no significant inhibition of the aortic atheroma resulting from cholesterol feeding. The rise in serum cholesterol induced by atherogenic diets in the monkey and chicken was increased by treatment with (I). In the monkey, aortic atheroma was exacerbated in proportion to the rise in serum cholesterol, whereas in the chicken[4] there was no alteration of the degree of aortic or coronary atherosclerosis. Renal hypertrophy which was noted in the chicken was found to be due to inhibition by (I) of the tubular secretion of uric acid. In other species uric acid excretion was increased by (I), without renal hypertrophy.

The mode of action of (I) in the rat became clearer when it was found that it potentiated the metabolic and other actions of exogenous steroids, and that its activity in reducing the serum cholesterol varied in phase with a variation in serum cholesterol in control animals (Table 1).

Table 1. Seasonal Variation of Serum Cholesterol in Control Rats and in the Response to Treatment with (I)

Mid-point of observations	Control rats* No. of expts.	Control rats* Mean serum cholesterol (mgm./100 ml.)	*S.E.*	(I)-treated rats† Mean serum cholesterol (mgm./100 ml.)	(I)-treated rats† Percentage reduction of serum cholesterol
January	10	77 8	1·95	62	20
February–March	9	71·5‡	1·7	38	47
April	13	80·5‡	1·65	56	30
June	9	76·2	1·7	51	33
August	14	70·0‡	1·65	35	50
October	9	70·2	1·65	47	32
November–December	5	81‡	1·9	68	15

* Groups of 4–12 ovariectomized 130–160 gm. rats in each experiment.

† Treatment with 0 25 per cent (I) in diet for two weeks. Average values interpolated from results of 14 experiments.

‡ Mean significantly ($P < 0·05$) different from preceding value in column.

The seasonal variation of cholesterol in control rats was similar in amplitude and frequency to a variation in adrenal weight and adrenal ascorbic acid content[5], and was also correlated with a variation in morphological indices of adrenal and thyroid function[6]. As the periods of maximum activity of (I) corresponded with those of maximum thyroid and adrenocortical function, it seemed that (I) might be acting by potentiating the metabolic effects of adrenal steroids, the secretion and metabolic fate of which are known to be influenced by thyroxine. (I) was therefore tested in combination with exogenous steroids. Androsterone, on oral administration with (I), proved the most effective in reducing both liver and serum lipids at times of the year when (I) alone was relatively ineffective[7]. The results of a typical experiment are shown in Table 2, giving the average values found in groups of three male rats treated for 11 days. When administered orally, androsterone alone was devoid of significant action, nor did it increase the action of (I) at times when this compound alone was showing maximum activity.

Table 2. Effects of Treatment with (I) and Androsterone in the Rat

Group	Body-wt. (gm.) Initial	Body-wt. (gm.) Final	Serum cholesterol (mgm./100 ml.)	Liver composition (per cent fresh wt.) Water	Protein	Total lipid	Phospholipid	Cholesterol
Control	128	164	60	70·3	19·0	10·0	3·2	0 235
Treated*	133	157	34	70·3	22 9	6·8	3 5	0·200

* Administration of (I) (0·25 per cent) and androsterone (0·01 per cent) in the diet for 11 days.

Despite its marked effects on lipids, androsterone administered in combination with (I) showed as little androgenic activity as when administered orally alone. In castrated male rats (170 gm.) treatment with 0·5 mgm. adrosterone subcutaneously daily for 9 days increased ventral prostate weight by 81 mgm./100 gm. body-weight. At a dose of 2 mgm. androsterone orally, with or without 50 mgm. of (I) per rat daily, the increase in weight of the prostate was 11 mgm./100 gm. body-weight. The possible reasons for this dissociation of action are discussed elsewhere[10].

The discrepancy of the lipid responses in the rat and monkey to treatment with (I) alone may depend on differences in adrenocortical function. It is known that the ratio of hydrocortisone to corticosterone secreted by adrenals of monkey and man differs markedly from that of the rat and it is possible that this may be associated with differing levels of androsterone. In man the rate of secretion of adrenal steroids, their state of oxidation, and the amount of androsterone formed are largely dependent on thyroid function[8,9]. It has been gratifying to find that the combination of (I) with androsterone reduces serum cholesterol and triglycerides, without apparent effect on thyroid function, in the monkey[10], and in man[11], as in the rat. The results of these studies suggest that androsterone may function primarily as a regulator of metabolism rather than as an androgen.

PTYCTODONTID FISHES AND THE ANCESTRY OF HOLOCEPHALI

By Prof T. S. WESTOLL, F.R.S.

Department of Geology, King's College, Newcastle upon Tyne, 1

DR. T. ØRVIG has recently[1] described, as *Ctenurella gladbachensis*, n.g., n.sp., a most interesting fossil fish from the Oberer Plattenkalk (top-most Middle Devonian) of the Bergisch Gladbach area east of Cologne. This is clearly a member of the group of placoderm fishes known as Ptyctodontida, and *Ctenurella* shows a number of features of very great significance to work on comparative anatomy and phylogeny. The deep, strongly built palatoquadrate has three large articulation-areas which imply extremely firm attachment to the cranium, and the new material adds much to descriptions of this element in *Rhynchodus*[2]. Ørvig's account has very greatly strengthened the case for regarding the Ptyctodontida as ancestors of the Holocephali, with their autostylic suspensorium. The rostral structures described by Ørvig are equally significant.

The post-cranial skeleton also shows new features of great interest. Hitherto the only Ptyctodontida in which substantial remains are known have been *Rhamphodontus eximius* Jaekel (syn. *Rhynchodus tetrodon* Jaekel) from the Upper Devonian of Wildungen[2,3] and *Rhamphodopsis* Watson[3-8] from the Middle Old Red Sandstone of Scotland. Both genera are characterized by well-developed spinalia representing at least part of the pectoral fin-structures[9]; and *Rhamphodopsis* has a large median spine, inserted in a slot in the median dorsal, which was presumed to form a 'cutwater' in front of an anterior dorsal fin, a basal element of which is also preserved. *Ctenurella* has a large mobile pectoral fin, but the spinale is apparently completely absent, and the anterior dorsal fin-skeleton is well developed, with no spine (though a low crista is present on the median dorsal). The pectoral fin is reconstructed as a tribasal fin on what seems very reasonable evidence. The pelvic fins are remarkable in that they appear to show sexual dimorphism (as seems likely also in the case of *Rhamphodopsis* Watson[4] where the evidence has been less complete). The presumed males, with long basipterygia, have also a small 'spine' anterior to the pelvic fin, identified by Ørvig as homologous with the tenaculum of Holocephali. It is interesting that a small 'spine' also precedes the main structures of the posterior dorsal fin.

This new material clearly adds very greatly to the probability that Ptyctodontida include the ancestors of Holocephali, as long ago suggested in refs. 5–8 and 10. There are two matters of considerable interest in Ørvig's account that call for immediate comment.

The first concerns the interpretation of the skull-roof and cheek, which Ørvig found very puzzling. It would seem that the difficulties may arise from the incompleteness of his material and from errors in the identification of the bones. Watson's reconstruction of *Rhamphodopsis*, with a few modifications and some corrections in homology as compared with more normal Arthrodira, can be confirmed on additional material collected by me, by Dr. R. Denison and by Mr. R. Miles, which is now under active investigation. I have already (ref. 6) ventured a re-interpretation of Watson's reconstruction (in which the hyoid arch was shown in front of the orbit) by adding a post-marginal and by re-interpreting Watson's 'suborbital' and 'bone *X*' as marginal and suborbital respectively. The new specimens confirm this structural pattern, which is shown diagrammatically in text-figure 1*a*. The structure of *Rhamphodopsis* has been reviewed in refs. 5 and 8, and Ørvig[1] gives yet another version.

The homologies used by several authors for the same element in *Rhamphodopsis* are shown in Table 1.

Table 1

Rhamphodopsis Watson 1938	 Stensio 1948	 Ørvig 1960	 Westoll 1945, 1962	*Ctenurella* Ørvig, 1960 *A*	 *B*
MB	*N*	*Nu*	*Nu*	—	—
ExB	*Pan*	*M*	*PNu*	*Pan*	*M*
C	*C*	*Cl*	*C*	*CNu*	*Pan*
PrO	*PrO*	*C.Pro*	*PrO*	*C.Pro*	*C.PrO*
'*Y*'	*Pp*	*Cm*	*PP*	—	*CNu*
PtO	*Cl*	*Pto*	*PtO*	*Pto*	*Pto*
—	—	—	*PM*	*M*	—
SO	*Pto + M*	*So*	*M*	*SO*	*SO*
'*X*'	*SO*	*X*	*SO*	—	—

In Table 1 the abbreviation-letters are as given in the original works, and indicate the use of well-established arthrodiran bone names: *N* or *Nu* (nuchale) ≡ *MB* (median basal); *PNu* = *Pan* (paranuchale) ≡ *ExB* (external basal), *C* = centrale; *PrO* = *Pro* (pre-orbitale); *PP* (post-pineale) = '*Y*' = *Pp*; *PtO* = *Pto* (post-orbitale); *M* = marginale; *Pm* = post-marginale; *SO* (sub-orbitale). In the text these names are anglicized. Stensio's 'lateral central' (*Cl*) and '*Pto* + *M*' and Ørvig's 'centro-nuchal' (*CNu*), 'centro-preorbital' (*C.Pro*), 'lateral central' (*Cl*) and 'median central' (*Cm*) represent versions of the usual view of the Swedish school that differences in bone-patterns frequently involve redistribution and differential fusion of a number of separate elements rather than the results of differential growth.

In brief justification of some of the homologies implied by the terminology for *Rhamphodopsis* used in the present account, it should first be pointed out that the bone called 'suborbital' (*SO*) by Watson and by Ørvig is suturally united to more dorsal elements, a condition not known in other arthrodires, and that the true suborbital is always associated with the outside of that part of the palatoquadrate that supports the posterior supragnathal, the homologue of the 'upper tooth-plate' of ptyctodonts. Furthermore, the backward movement or enlargement of the orbit so that the marginal enters the orbital margin between *PtO* and *SO* is exactly paralleled in many euarthrodiran genera from the Upper Devonian of Wildungen[11], where there is no doubt of the homologies (for example, *Pachyosteus*, *Rhinosteus*, *Enseosteus*, *Brachydirus*, etc.). In the skull-roof, a post-pineal fontanelle in the dermal bones is found in several Wildungen genera (for example, *Belosteus*, *Trematosteus*), and may be partly filled by a median post-pineal bone, comparable directly with Watson's bone '*Y*'. 'Scissors-and-paste' homologies are unnecessary.

Ctenurella, as interpreted by Ørvig, shows some remarkable anatomical inconsistencies as compared with its nearest relatives and with other arthrodires. The most obvious are: (*a*) that the bone identified as paranuchal, which normally would be expected to articulate with a condylar trochlea on the anterior dorso-lateral, is shown with a posterior process lying far admesial to that trochlea; (*b*) that the articulation with the trochlea is said to be on the posterior surface of the bone called marginal, in both *Ctenurella* and *Rhamphodopsis*, a condition quite unknown in normal arthrodires. It seems clear that a drastic re-interpretation is necessary, and fortunately *Rhamphodopsis* allows this to be done.

Ørvig thought that the posterior process of his 'paranuchal' may have passed beneath the median dorsal and prevented excessive downward movement of the head. Examination of his Pl 26, Figs. 1–2 suggests that there is a flanged area at the back of this bone. Two possibilities may be considered:

(*A*) The best specimen figured by Ørvig (Pl. 26, Figs. 1–2) is clearly somewhat damaged and incomplete. If Ørvig's 'paranuchal' is correctly identified, then its posterior process in life should have adjoined the trochlea on the anterior-dorso-lateral. Com-

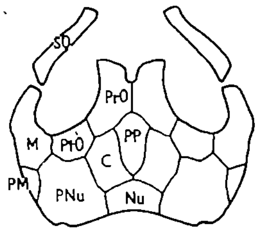

Fig. 1. *Rhamphodopsis trispinatus*, flattened skull-roof modified after Watson from new material

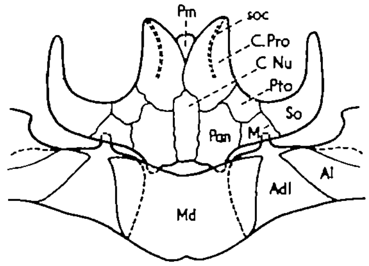

Fig 2. *Ctenurella gladbachensis*, redrawn from Ørvig, that author's interpretation

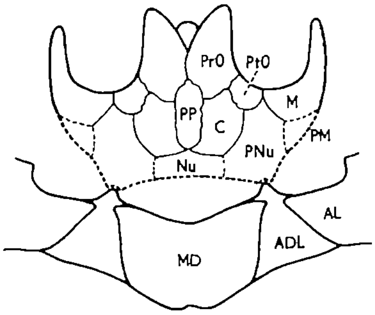

Fig. 3. Same as Fig. 2, re-interpreted and restored where necessary (broken lines)

parison with the diagram of *Rhamphodopsis* would then suggest the equivalences shown under *Ctenurella*, *A* in Table 1.

In other words, the bone taken by Ørvig as a median 'centro-nuchal' is not median; two important median elements are not preserved in the figured fossil material, and the articulation with the body-armour could be adjusted to this. Such an arrangement, however, is found on trial to require a very broad set of median elements, and if Ørvig's recognition of the median line between the bones he labels '*C.PrO*' is correct, leads to a number of serious inconsistencies of shape. Furthermore it requires the homologues of the postorbital and postmarginal to meet so as to separate the *PNu* and *M*; while perhaps not impossible, this would be very unusual. A possible point in favour of this view, however, is that Ørvig's 'centro-nuchal' becomes the normal paired central, on which sensory-canal grooves would in fact be expected to occur. On the whole, however, this interpretation leads to more difficulties.

(*B*) The second, and certainly the more acceptable, comparison is of the simplest and most direct kind, in that every element in *Ctenurella* has a one-to-one equivalence to one of *Rhamphodopsis*, the major difference being the absence or loss of the nuchal element in the former The homologies are then those shown under *Ctenurella*, *B*. in Table 1 and Fig. 3.

It was noted above that the posterior process of Ørvig's 'paranuchal' seems to have flanges developed, which could well represent overlap-surfaces for a median nuchal (*Nu*) and for an admesial extension of the existing 'marginal', which on this comparison, and on the evidence of its articulation with *ADL*, must be a paranuchal. The centrale of *Rhamphodopsis* (according to our material) has a precisely similar posterior process and flanged surface. The simplest interpretation is that the posterior margin of the skull-roof of Ørvig's best specimen has been damaged and that *Nu* and part of the *PNu* have been lost. There would then be no difference from the pattern seen in *Rhamphodopsis*. The alternative, that *PNu* has suffered true reduction and that *Nu* was not developed, is of course possible; but *Nu* has important functions in the arthrodiran occipital region and its failure to develop is *a priori* unlikely.

It seems rather likely that more complete material of this most remarkable fossil will demonstrate the presence of a true *Nu* and of a more extensive true *PNu*.

It is important to make these points since there is now every reason to believe that *Ctenurella* and *Rhamphodopsis* are closely related members of the Ptyctodontida, a highly distinctive sub-group of the Arthrodira (cf. classification used by Westoll[6]), derived almost certainly from primitive Euarthodira with well-developed spinalia. *Rhamphodopsis* has a large spinale, while *Ctenurella* has a mobile tribasal pectoral fin and has no spinale. In the terminology of Stensiö[8], one is merosomactidial and spinothoracic, the other holosomactidial and aspinothoracic. Stensiö[8,12], has used such morphological differences to set up a new classification and evolutionary configuration for placoderms that is opposed by many other considerations (cf. refs. 9 and 13) The importance of *Ctenurella* for me is that it seems to give striking evidence of the rapid development of one condition from the other in a single specialized group. In every reasonably well-defined lineage the evidence points firmly to the spinothoracic condition being earlier. Mr. R. S. Miles and I hope to present further convincing proof that the sequence *Coccosteus*–*Plourdosteus*–*Dinichthys* is such a narrowly defined lineage, in which the spinale is rapidly reduced, and Miles[14] has described the Lower Devonian *Coccosteus angustus* Traquair, and has shown how clearly it bridges the gap between *Coccosteus* and Arctolepida.

Ctenurella thus appears to demonstrate a rapid development in its fin structures, from a *Rhamphodopsis*-like condition to one highly suitable as an ancestor for the Holocephali. Its structure is also of great importance in assessing the interpretation of the paired fins of placoderms recently made by Prof. Stensio[8] and used by him as a major factor in a new classification of these forms. There now seems to be a very strong case for regarding the mobile pectoral fins of several groups of placoderms as independent phylogenetic derivatives from an essentially arctolepid condition, in which these fins are represented largely, or even in some cases wholly, by the bone-jacketed spinalia (cf. Westoll[6,9]).

Since the foregoing was written I have visited Stockholm and Dr. Ørvig has kindly shown me material of *Ctenurella* and a new reconstruction of that genus soon to be published. Some of the points already noted are clarified, and others raised, by this new work Briefly, Dr. Ørvig now agrees that the

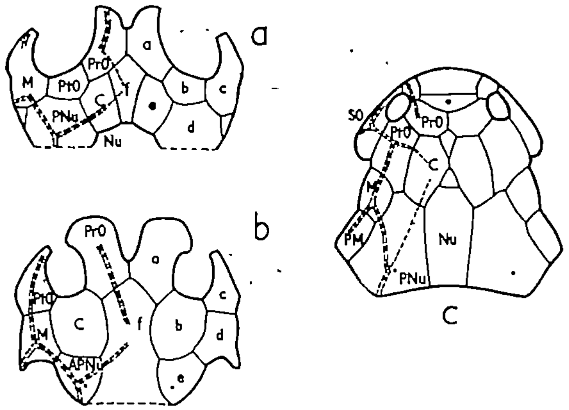

Fig. 4. Homœomorphy in orbital regions of some Arthrodira. *a*, *Rhamphodopsis*, posterior part cut off along broken line; *b*, the petalichthyid *Lunaspis*, posterior part cut off along broken line; *c*, an arctolepid, semi-diagrammatic. In *a* and *b* the right-hand side has topologically similar bones similarly labelled, *a–f*; true homologies, independently determined on left; and latero-sensory system indicated on left by double row (deep canals) or single row (pit-lines) of broken line. In *c*, the position of median (? anamestic) bones, occasionally and separately present, is shown in front of *Nu*, behind *P*. *PPNu* omitted in *b*

bone previously labelled 'marginal' by him is the paranuchal, and his new reconstruction avoids the more obvious anatomical inconsistencies of the first. Only in one specimen does he find a median bone of the skull-roof behind his "*ONu*", and there is no indication of a post-marginal bone (which may not be present in all specimens of *Rhamphodopsis*).

He also demonstrates that the latero-sensory lines of the head are largely enclosed in canals in the dermal bones, opening by pores. An important feature is the meeting of the supraorbital and "posterior pit-line" canals in a median X-shaped anastomosis at the centre of his "*O.Nu*" (my *PP*). This arrangement is paralleled in *Rhamphodopsis*, where, however, only surface grooves represent the "posterior pit-line" (as may also be the case in some *Ctenurella*). There can no longer be any residual doubt that the bone-pattern in the two genera is exactly comparable, with the exception that *Nu* and *PM* (my notation) may be lost in *Ctenurella*.

Dr. Ørvig compares this pattern with that of petalichthyid arthrodires, mainly on the basis of the median X-junction of latero-sensory lines. In order to do so he must 'suppress' the structurally very important posterior part of the petalichthyid skull. If this is done, there is a most remarkable resemblance in the pattern of the dermal bones in the two groups, so long as the mere topographic relations to one another and to the orbit are concerned (cf. right-hand side of Fig. 4*a*, *b*). The only real difference is that bone *a* meets *c* in ptyctodonts and not in petalichthyids, where they are separated by the junction of *b* and *f*. Such alternative junctions are common in euarthrodires, and are explicable by slight differences in proportional growth of bones. There is in fact an almost perfect topological correspondence between the bones labelled *a–b*; yet it can easily be shown to do violence to every other principle of comparative anatomy, and represents a very instructive example of convergent homœomorphy.

This is made clear by the true homologies as determined by other factors (cf. left-hand side of Fig. 4). *PNu* in the ptyctodonts is obviously correctly so named in comparison with normal euarthrodires, since it is concerned in the dermal cranio-thoracic articulation, and shows the characteristic Y-shaped latero-sensory lines; in euarthrodires it also transmits the endolymphatic duct. In petalichthyids the bone is represented by two elements, *APNu* and *PPNu*. The former shows the characteristic relations to the endocranium, latero-sensory lines and endolymphatic duct of *PNu* of Euarthrodira; *PPNu* (and the long posterior part of *Nu*) may best be understood as reflexions of the great relative elongation of the occipito-spinal region in petalichthyids, *PPNu* being a special development for the more remote exoskeletal cranio-thoracic articulation. The elements *M* are clearly homologous because of their latero-sensory lines. The petalichthyid *PtO* is recognized as such by its relations to *M* and the latero-sensory-lines; its position lateral to the orbit is paralleled in *Homosteus*. Though *C* in petalichthyids does not receive the 'central latero-sensory line' from *PtO* as in euarthrodires, its true nature is revealed by its relation to a similar endocranial region in both; again comparison with *Homosteus* is instructive. In the ptyctodonts *PtO* and *C* have been compared above with other well-known euarthrodires. Thus the bones lying lateral and postero-lateral to the orbits in ptyctodonts and petalichthyids are not severally homologous in spite of their remarkable superficial similarity. It should be noted that a very similar pattern is seen in such typical euarthrodires as *Coccosteus*, and that the bone lying lateral to the orbit in those forms is the suborbital *SO*, not homologous with the positionally corresponding bone in either petalichthyids or ptyctodonts (Fig. 4*c*). This 'topographical' similarity has caused great confusion in the past, and is due to the fact that the orbit has relatively 'migrated' in different directions; in ptyctodonts it has, so to speak, pushed back between *SO* and *PtO* and indented *M*, so that the last is now moulded to the orbit, and in petalichthyids it has moved postero-medially to meet *C* (as in *Homosteus*), separating *PtO* and *PrO* and causing the latter to be so moulded.

The only remaining resemblance between petalichthyid and ptyctodont skull-patterns is in fact the X-shaped median junction of latero-sensory lines. In primitive Euarthrodira the supraorbital canal has a short and variable posterior extent. If a 'fontanelle' in the dermal roof existed between the paired *PrO* and *C* elements the supraorbital lines and posterior pit-lines could easily continue into it, and a bone developing in such a position (PP in ptyctodonts) could 'capture' these portions. The conditions in ptyctodonts and petalichthyids thus have almost certainly been acquired independently.

Dr. Ørvig has also further prepared the cranial fragments described as *Epipetalichthys minor* Gross, and I am now convinced (against my previous opinion) that it is probably a ptyctodont. I appreciate his discussion of these matters with me.

POTASSIUM–ARGON AGES ON ROCKS FROM EASTERN GREENLAND

By Prof. J. L. KULP and Dr. R. KOLOGRIVOV
Geochemical Laboratory, Lamont Geological Observatory and Geology Department, Columbia University, New York

Dr. J. HALLER
Mineralogical-Petrographical Institute, University of Basle

AND

Dr. L. KOCH
East Greenland Expeditions, Ministry of Greenland, Copenhagen

THE geological expeditions to the northern and eastern sides of Greenland over the past thirty years have developed a body of information in an area of profound geological complexity. With the development of quantitative methods of geochronometry in the past few years it appeared that the geological history in eastern Greenland might be placed on an absolute basis so that correlation from North American to Scandinavia and thus to Britain would be possible. As a preliminary step in this direction, the available petrographic collections of the Danish East Greenland Expeditions at the University of Basle were surveyed, and the most suitable samples selected for analysis by the potassium–argon method of geochronometry. In virtually all cases of igneous or metamorphic rocks, this method gives a reliable minimum absolute age. If the rock or mineral being analysed has remained a closed mineral system subsequent to its formation, the calculated isotopic age will be the actual time of formation.

The laboratory techniques are described elsewhere[1], and yield an analytical error of the isotopic age of less than 3 per cent. The location of the samples is given in Fig. 1. The analytical results are given in Table 1.

The detailed description of the geological studies carried on by the East Greenland Expedition under the sponsorship of the Danish Government are published in a special series, which now runs to more than 100 volumes. A more comprehensive discussion of the samples and dates reported here with complete petrographic descriptions of the rock types will be published in one of the above series[2].

The geological history in north-eastern Greenland is long and complex. The oldest observable rocks constitute a complex metamorphic plutonic basement of unknown age which may have undergone multiple cycles of metamorphism prior to its stabilization on the platform on which a thick pile of clastic sediments and basaltic sills, dykes and flows were deposited. This latter sequence, called the "Groenlandian" by Koch, includes an earlier (Thule group) series and later (Hagen Fjord group in north-east Greenland, Eleonore Bay group with Tillite group at top in central East Greenland) series which are separated by the Carolinidian orogeny in north-east Greenland. All these events happened in Pre-Cambrian times since Cambrian and Ordovician sedimentary rocks were deposited on top of the Groenlandian strata with distinct unconformity. In the geosyncline of central East Greenland, deposition ceased in Middle Ordovician time followed by a great orogeny (Caledonian). Deposition recommenced in the early Middle Devonian and continued intermittently through the rest of the Palæozoic, interrupted locally by folding, late orogenic granite intrusion and volcanism. Finally, after some Mesozoic deposition and Tertiary plateau basalts, a series of superficial Cainozoic disturbances occurred in northern Greenland.

The samples for this survey were grouped according to the problem. An attempt was made to determine the age of the ancient basement, the time of the deposition of the Thule group, the Carolinidian mountain building, the end of the main Caledonian orogony and duration of related post-orogenic events. The attempt was only successful in part but is reported for the interest of other workers in North Atlantic geology and as a guide to further more adequate collection of material when the opportunity presents itself.

Sample *GAA*-135 from the basement exposed on the western edge of the fold belt in the Scoresby Sound area was selected since it showed no petrographic evidence of having been affected by the Caledonian metamorphism which affected most of eastern Greenland and was at least 20 km. from the

Table 1. Isotopic Ages Grouped by Structural Period

Sample No.	Rock type	Mineral	Isotopic age (m.y.)	K (per cent)	^{40}Ar s c.c./gm.	Location
I. Pre-Cambrian basement						
GAA-135	Alkali granite	Biotite	1,900 ± 50	6·74	$6·98 \times 10^{-4}$	70° 20′ N./29° 47′ W.
HN-89	Migmatite	Biotite	490 ± 12	4·80	$1·07 \times 10^{-4}$	75° 00′ N./21° 50′ W.
II. Pre-Palæozoic supracrustal rocks						
BNW-44	Quartz-dolerite	Whole rock	375 ± 10	0·48	$7·98 \times 10^{-6}$	77° 10′ N./24° 00′ W.
GW-59	Phyllite	Whole rock	410 ± 10	4·23	$7·74 \times 10^{-5}$	73° 10′ N./28° 30′ W.
JH-560	Phyllite	Whole rock	425 ± 10	5·02	$9·53 \times 10^{-5}$	73° 11′ N./28° 35′ W
III. 'Caledonian' infrastructural rocks (Pre-Middle Devonian)						
JH-105*B*	Schist	Phlogopite	400 ± 10	7·95	$1·44 \times 10^{-4}$	73° 20′ N./26° 35′ W.
HN-202*A*	Pegmatite	Biotite	405 ± 10	5·14	$9·34 \times 10^{-5}$	79° 20′ N./19° 40′ W.
IV. Late orogenic intrusives						
HN-7*b*	Pegmatite	Muscovite	395 ± 10	8 90	$1·57 \times 10^{-4}$	75° 41′ N./22° 15′ W
KF-11-1 180-182	Granite	Biotite + muscovite	395 ± 15	7·87	$1·37 \times 10^{-4}$	73° 15′ N./22° 10′ W.

nearest aureole. The potassium–argon date of 1,900 ± 50 m.y. demonstrates the great antiquity of this basement. Since there is no guarantee, until more extensive geochronometric investigations are made, that this rock was not mildly affected by the Caledonian event or by deep burial for a prolonged period, the actual time of the last metamorphism of the basement complex could be much older than 1,900 m.y.

Fig. 1. Sketch map of eastern Greenland showing sample locations

It is significant that the isotopic age came out 1,900 m.y., since the biotites in the Karelian and Svecofennian belts in Scandinavia and north-eastern U.S.S.R. all give 1,650–1,780 m.y. Thus it may be concluded that: (1) this basement in eastern Greenland formed earlier than the time of the Karelian and Svecofennian orogenies; (2) that the basement in this area was not affected by these major tectonic events of north-eastern Europe.

Sample *HN*-89 is a polygenetic migmatite from the old basement that was affected to some extent by Caledonian orogeny. The isotopic age of 490 m.y. indicates that all the accumulated argon was not released during this Silurian event.

Three attempts were made to identify the time of deposition of the Groenlandian Pre-Cambrian supracrustal rocks. Samples *GW*-59 and *JH*-560 are phyllites which may have been generated during a Pre-Cambrian metamorphism or the Carolinidian orogeny. Whole rock analyses can give correct ages for phyllite. The isotopic ages on these samples fall in the range of time of the Caledonian orogeny. Thus, it is not possible from the isotopic ages to identify the time of formation since the Caledonian event could have produced a temperature increase with consequent loss of the argon yet without causing the phyllite to be re-crystallized. *BNW*-44 was a basalt boulder of presumed Thule age, but it also appears to have been outgassed in Caledonian time.

More definitive results were obtained from samples *JH*-105*B* and *HN*-202*A*. *HN*-202*A* represents a late-tectonic pegmatite which intruded the latest shearing pattern in the coast area of Lambert Land. The emplacement of this pegmatite dates the relaxation of Caledonian activity in north-east Greenland. Since there was no further metamorphic activity in this area and no proximate igneous intrusions, the isotopic age of 405 ± 10 is probably an absolute age and represents the end of the main Caledonian orogeny. *JH*-105*B* is geologically from an early state of the main orogeny derived from one of the earliest upwarpings of the infrastructure in central East Greenland. The age, in conjunction with that of *HN*-202*A*, suggests either that the total length of the major orogeny was only about 10 m.y. or, more likely, that the schist containing *JH*-105*B* was sufficiently warm until the end of the main orogeny that it could not retain argon.

The post-orogenic but pre-clastic deposition granite pegmatite *HN*-7*b* gives an age of 395 ± 10 m.y., while a pre-mid Middle Devonian granite which cuts lowermost Middle Devonian clastics gives 395 ± 15 m.y. The analytical uncertainties in these results are sufficiently great so that they could be considered 20 m.y. apart without further data.

It is interesting to see how these results relate to the absolute geological time-scale[3] and the Caledonian of Britain, where extensive analyses have been made[4]

First, deposition ceased in the geosyncline of eastern Greenland in the Middle Ordovician. Based on a number of excellent measurements on rocks of Trenton Time (basal Upper Ordovician) and lower Upper Carodocian[4], it appears that deposition in eastern Greenland ceased about 440 m.y. ago. The beginning of the Silurian is estimated as 425 m.y. and the end, 405 m.y.[4]. Thus it appears from the above dates that in eastern Greenland the climax of the main orogeny occurred just at the Silurian–Devonian boundary or slightly into the Lower Devonian. This leaves almost 40 m.y. for the Caledonian orogeny to take place, but from data in Nova Scotia and Britain, as well as northern Greenland, where Silurian sedimentary rocks are involved in the orogeny, the actual time interval may be much shorter, possible 10–20 m.y.

Finally, it is noted that the oldest post-tectonic granites in east Greenland occur in the middle or late part of the Lower Devonian. This is precisely the time of the early post-tectonic granites in Britain and Ireland[4].

With the superb exposures and the excellence of the geological investigations which are already completed, the region of eastern Greenland presents an unusual challenge for geochronometric study.

ANOMALOUS LORENZ PARAMETER IN SPECIMENS OF HIGH-PURITY COPPER AT LOW TEMPERATURES

By DR. M. S. R. CHARI

Low Temperature Section, National Physical Laboratory, New Delhi, 12

FROM investigations of the low-temperature transport properties of high-purity copper, annealed as well as cold-drawn, Powell, Roder and Hall[1] have shown an unusual behaviour of the (electronic) Lorenz parameter L. For the annealed specimen, they have given the value of L, extrapolated to 0° K., as $1·9 \times 10^{-8}$ and, for the 26 per cent drawn specimen, the value $2·1 \times 10^{-8}$ W.-ohm-deg.$^{-2}$. On the other hand, for a copper specimen of the same nominal purity (99·999 per cent), obtained from the same source (Central Research Laboratories, American Smelting and Refining Co.), White and Tainsh[2] derive a Lorenz parameter which, at the lowest temperatures, does not deviate more than 2 per cent from the normal Sommerfeld value ($L_n = 2·45 \times 10^{-8}$).

Attention is directed to the facts that, for the Boulder annealed specimen and the Sydney specimen, respectively . (1) the residual electrical resistivity is 1·01 and $0·87 \times 10^{-9}$ ohm-cm. ; (2) the impurity thermal resistivity coefficient B (the electronic thermal resistivity due to impurities and imperfections, at temperature T° K., being given by B/T) is 0·059 and 0·035 cm.-deg.^{2}/W. ; (3) the maximum value of thermal conductivity is 135 and 190 W./cm.-deg. These suggest that the Boulder annealed specimen contains some contamination compared with the Sydney specimen.

A close scrutiny of the experimental points (as distinguished from the extrapolated curves), in the case of the Boulder annealed specimen (ref. 1, Fig. 8) shows that the trend of the L-T curve between 20° and 8° K. is such as to attain the normal value L_n at temperatures close to 0° K. However, at about 8° K., the curve starts flattening ; and, below 5° K., it shows a tendency to fall with temperature. Similarly, in the case of the cold-drawn specimen, the L-T curve between 30° and 10° K. suggests that L would rise to the value L_n at temperatures close to 0° K. Actually, L presents a maximum (of about 2·16) at 9° K., falling to (what looks a minimum) 2·09 at 4° K. These authors mention that the L-T curves for very dilute alloys containing silver also gave similar results[3], either flattening out or bending over significantly For the annealed high-purity copper sample, they give $1·9 \times 10^{-8}$ as the extrapolated value of L at 0° K., unless the curve changes its behaviour again below about 4° K.

It appears to me that this change in behaviour could indeed be the case if the contamination referred to here is, for example, iron. For, in the case of some alloys of silver with small amounts of a transitional metal, manganese, in random solid solution, it has been found[4] that the electronic Lorenz parameter L_e, at liquid helium temperatures: (1) dipped below the normal Sommerfeld value L_n ; (2) attained a minimum ; (3) rose to the value L_n at the lowest temperatures, below about 1° K. This fall in L_e has been interpreted as follows : the transition of these alloys to antiferro/ferro-magnetism[5] removes the spin degeneracy of the ground-state of the impurity (manganese) ion. The scattering of the conduction electrons by these impurity centres, each of which can occupy one or the other of the energy states, could be inelastic. Since inelastic scattering makes a much larger contribution to thermal resistivity than to the electrical resistivity, the electronic Lorenz parameter dips below L_n. The approach of L_e towards L_n at temperatures close to 0° K is due to the cessation of this inelastic scattering.

Fig. 1 gives a plot of the electronic Lorenz parameters in the above-mentioned cases, with respect to temperature. Curves 1, 2 and 3 refer to the three silver–manganese alloy specimens (containing respec-

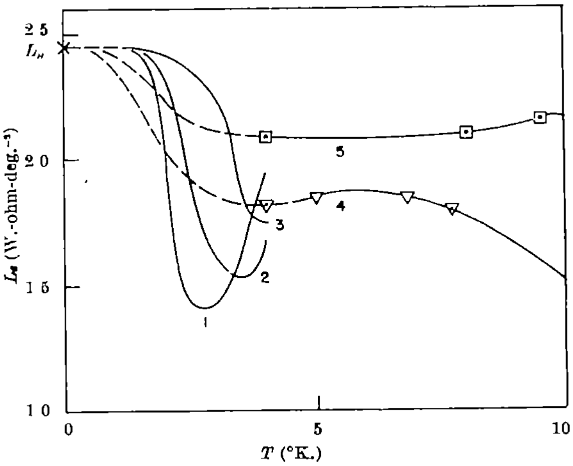

Fig 1. Anomalous (electronic) Lorenz parameter (W.-ohm-deg.$^{-2}$) against temperature (°K.). Curves 1, 2 and 3 are for the dilute silver–manganese alloys, in the order of increasing manganese content. Curves 4 and 5 are, respectively, for the annealed and the 26 per cent drawn specimens of high-purity copper

tively 0·14, 0·32 and 0·55 atoms per cent of manganese in random solid solution). Curves 4 and 5 are for the high-purity copper specimens (annealed and cold-drawn, respectively) reported in ref. 1. The dashed lines at the lowest temperatures are my extrapolations, presuming that L_e would attain the value L_n at 0° K., owing to the cessation of the inelastic scattering of the conduction electrons.

In cases 1, 2 and 3, there is not much surprise in their departure from the requirements of the law of Wiedemann–Franz–Lorenz (namely, that in the 'impurity scattering' region, L_e should have the value L_n and L_e should be independent of temperature), since the electrical and thermal conductivities are themselves anomalous. In cases 4 and 5, the electrical and thermal conductivities do not show noticeable anomalous behaviour, at any rate, down to 4° K. Plots of wT against T^3, however, show an anomalous rise above rectilinearity, at temperatures below about 14° K. in the case of the 26 per cent drawn specimen, and a less marked rise below about 10° K. in the annealed specimen. The temperatures at which these wT–T^3 curves have their maximum rise above the rectilinearity are found broadly to correspond to the temperatures at which L exhibits the minimum value (w being the thermal resistivity).

After a series of experiments to determine the effects of minute amounts of various elements in copper, it has been concluded by investigators[6] at Ottawa that anomalous thermo-electric powers and electrical resistivity minima can ultimately be traced to small amounts of iron contamination in solid solution. In fact, they find large anomalous thermo-electric powers even in cases where the amount of iron is so small (around about 0·0001 per cent) that the residual electrical resistivity does not present a noticeable anomaly. This is because the size of the electrical resistance minimum depends on the total (not the relative) iron concentration.

It is thus possible that the Boulder high-purity copper specimens (and their dilute alloys with silver) contain a small contamination of iron which does not show up vividly in the residual electrical resistivity measurements down to 4° K., but is sufficient to affect the Lorenz parameter in the temperature region where the electrical conductivity is limited primarily by the impurity scattering. The Sydney specimen has apparently too small (if at all) an iron content even to affect the Lorenz parameter. This view is supported by the disparity between the Sydney specimen and the Boulder annealed specimen as regards the residual electrical resistivity, the impurity thermal resistivity coefficient B and the maximum value of thermal conductivity.

The depression of L below L_n would be a measure of what fraction inelastic scattering of the conduction electrons constitutes, out of the total impurity scattering (which includes elastic scattering from chemical as well as from physical imperfections). In the Boulder 26 per cent drawn specimen, cold-work has introduced a considerable number of physical imperfections in the form of lattice defects. The interaction of the conduction electrons with the magnetic impurity centres would now constitute a smaller fraction (than in the case of the annealed specimen) of the total impurity/imperfection scattering. Thus, for the cold-drawn specimen (as can be seen from curve 5, Fig. 1), the Lorenz parameter is less depressed below the value L_n, just as the large anomalous (negative) thermo-electric power is considerably reduced[1,6–8] on cold-working.

RADIAL DISTRIBUTION OF THE RANDOM CLOSE PACKING OF EQUAL SPHERES

RANDOMLY packed equal spheres can provide a useful model for simple liquids. In previous experiments[1] with steel balls packing densities were found to be between 0·60(1) and 0·63(7). The arrangement corresponding to the upper limit 0·63(7) is referred to as random close packing and probably it is related to the configuration of the atoms in liquids such as those of the rare gases. Bernal and Mason[2] have used a special marking technique to obtain the physical co-ordination of random close packing and found it to be somewhat more than 8·5. They also refer to the fact that the fractional difference between the densities of regular close packing and random close packing is nearly the same as the percentage increase in volume which occurs in the melting of argon.

To extend the available data concerning the random packing of equal spheres, and in particular to determine the radial distribution in random close packing, a method was devised for determining the positions of a reasonably large number of randomly packed ⅛-in. steel balls. A standard optical comparator was modified so as to be suitable for making measurements of the three cartesian co-ordinates over a space approximately 5 × 5 × 10 cm. About 4,000 balls were poured into a cylindrical container 4·5 cm in diameter and 15 cm. long, the walls of which were dimpled as previously described[1], and which could be split open lengthwise. The balls were shaken down to give random close packing[1] and then after the container was warmed to about 65° C., molten paraffin wax was poured in and the whole allowed to cool. One side of the container was taken off and the outside layers of balls and wax were removed. Under the comparator the co-ordinates of the balls in a roughly spherical cluster were determined. The top surface of each ball in turn was cleared of wax and then polished. The image of the filament of a small incandescent lamp reflected in the top surface of the ball was used as a reference for making the settings. After the measurement the surrounding wax was scraped away and the ball was removed. The readings were reproducible within ±0·03 mm. in the vertical direction and to better than ±0·01 mm. in the two horizontal directions. Such precision is adequate for the purpose since it means that the balls

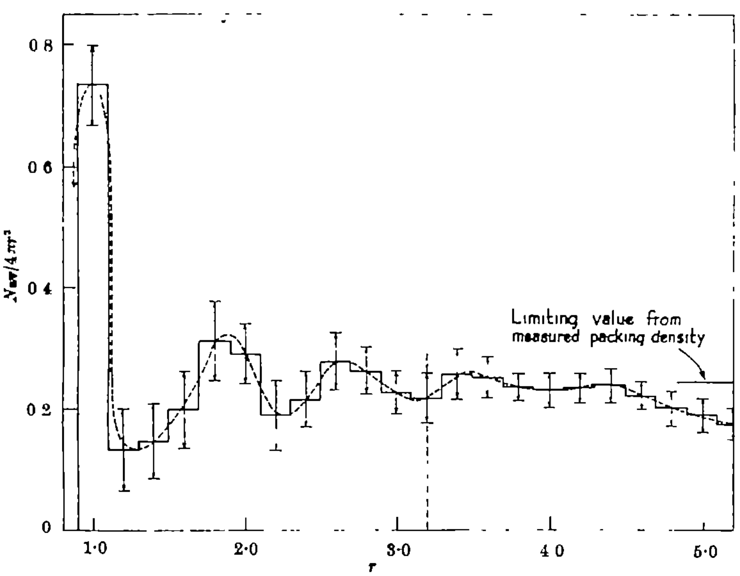

Fig. 1. Histogram of $N_{av}/4\pi r^2$ versus r. N_{av} is average number of spheres in intervals of 0 2 of sphere diameter averages with standard deviations for 25 centres. r, Distance from centre in units of sphere diameter

are located to better than 1 per cent of their diameter whereas the increment used for the radial distribution was 20 per cent of the diameter.

A preliminary set of measurements was made on a cluster of about 200 balls in order to develop both the technique of making the measurements and the computational methods required for the results. A final set of measurements was made for a cluster of approximately 1,000 balls.

The computations were carried out with the aid of the IBM 650 of the University of Toronto Computation Centre. An arbitrarily selected ball near the middle of the cluster was used as origin, and the distances to all the other balls were found. The radial distribution was then determined for intervals of one-fifth of the ball diameter. The distributions were computed first for a group of five origins and later for a group of twenty-five origins. The averages and standard deviations at each interval were then calculated for the group. The fact that the deviations were approximately the same for both the five and twenty-five centre groups suggests that they are characteristic of the random packing.

A histogram showing the results for the group of twenty-five centres in the 1,000 ball cluster is given in Fig. 1. The plot is made for the average number N_{av} per interval divided by $4\pi r^2$ so that the distribution function will become constant for large r. For the 1,000 ball cluster and twenty-five centres the distribution cannot be taken beyond 3·2 diameters without having this distance fall outside the cluster in some direction for at least one of the centres. However, reasonable significance appears to be maintained well beyond the 3·2 limits, although by 4·6 the expected falling off of the function is quite marked. The distribution function appears to be consistent with the previously measured packing density of 0·63(7), as indicated by the value of $N_{av}/4\pi r^2$ for large r corresponding to the density of 0·63(7), which is shown by the horizontal line at the right of the graph.

The first peak in the distribution function, although shown for the interval 0·9–1·1, corresponds in fact to the interval 1·0–1·1 since the balls are essentially rigid. The number of nearest neighbours determined from the average number of balls in this first interval is 9·3 ± 0·8, which is consistent with the estimate of the co-ordination number made by Bernal and Mason and mentioned above.

From neutron diffraction experiments Henshaw[3–5] has determined the radial distributions of the atoms in liquid helium, neon and argon. Henshaw estimates the number of nearest neighbours as 8·5–9·7 for helium, depending on the method of analysis, 8·8 for neon and 8·0–8·5 for argon, although the value by X-rays is rather higher. The figure of 9·3 ± 0·8 obtained from random close packing of balls can be considered in agreement with the experimental results for the liquefied rare gases.

The relative positions of the peaks in the radial distributions for liquid helium, neon and argon were taken from Henshaw's graphs. They are compared in Table 1 with the relative positions of the peaks found for the random close packing of balls.

Table 1. RELATIVE POSITION OF PEAKS IN THE RADIAL DISTRIBUTION

	Second	Third	Fourth
By neutron diffraction			
Liquid Helium	1·8(7)	2·6(6)	3·5(8)
Neon	1 8(5)	2 7(7)	3·5(7)
Argon	1·8(1)	2·6(4)	3 4(4)
Random close packing of balls	1 8(3)	2 6(4)	3·4(5)

In each case the radial distances of the second, third and fourth peaks are expressed in terms of the distance to the first peak. The agreement is surprisingly good; certainly it is well within the expected errors.

As mentioned by Bernal and Mason, the fractional change of volume on the melting of argon is the same as the fractional difference between the densities of regular close packing and random close packing. From the data given by A. C. Hollis Hallett[6] the ratio of solid and liquid densities at the triple points for neon, argon, krypton and xenon are 1·15(8), 1·15(2), 1·15(8), 1·14(8) respectively, whereas the ratio of the regular to random packing densities of balls was found to be 1·16(3). Again the results agree within experimental error.

I acknowledge the assistance of Mr. A. M. Charlesworth in making the measurements and in carrying out the computations.

Dr. Scott and Mr. Charlesworth are to be congratulated on carrying out the careful and tedious measurements of co-ordinates of random close-packed spheres. We are in a position to realize this, as one of us has recently carried out a similar set of measurements with a thousand ballbearings of larger size

(¼ in.), prepared in the manner already described[1] and using a mechanical three-point contact device for measurement.

Although this is an apparent duplication, the object of our investigation was different. We were not concerned so much with radial distribution function as with the neighbourhood number distribution function for which rough measurements had been obtained in previous work[1]. However, computation based on our results so far as they go $(r \ngtr 2r_0)$ are in close agreement with Dr Scott's results. We have now exchanged our co-ordinate data and it would be interesting to see how far, if at all, they are statistically distinguishable from each other. Dr. Scott will be able to carry out radial distribution function calculations on our sample and we will be able to carry out neighbourhood distribution function measurements on his.

We attach particular value to the latter because we believe that, from the point of view of a physical theory of liquids, the distribution of numbers of neighbours is a more important criterion than the shape of the radial distribution curve. Dr. Furth has already made use of this idea for deriving a very interesting and radically new statistical-mechanical theory of liquids which should be published as soon as the measurements become available.

DYNAMIC YIELD STRESS OF 'PERSPEX'

In a recent communication Roberts[1] presented values of the "dynamic yield stress" in compression for 'Perspex' (poly(methyl methacrylate)); the stresses were calculated, by the theory of Hertz, from estimates of the maximum contact area arising on impact between a metal sphere and a plane 'Perspex' surface. Using the same theory and observed times of contact, the dynamic modulus of 'Perspex' was also calculated.

The experimental technique was based on the fact that electrostatic charge is generated on the surface of the insulator as the strain develops in it; charge-sharing between the sphere and the surface produced observable potential changes on the sphere. The residual charge on the 'Perspex' was revealed by lycopodium powder attracted to the surface and the area of contact was assumed to be that covered by the powder.

It is clear from the data of Ely[2] and of Hoff[3] that Roberts's values of yield stress are much too low and that their apparent dependence on strain-rate is much too great.

Values of compressive yield stress obtained at low rates of strain $\dot{\varepsilon}$ by various workers are given in Table 1. Some measurements we have made recently are also given for comparison.

Table 1. Effect of Strain-Rate and Temperature on the Compressive Yield Stress of Poly(methyl Methacrylate)

Temp. (°C.)	Compressive yield stress (dyne/cm.$^2 \times 10^{-8}$) $\dot{\varepsilon}$, Strain-rate—sec^{-1} (approx.)						
	(*a*)	(*b*)	(*c*)	(*b*)	(*d*)	(*d*)	(*e*)
$\dot{\varepsilon}$	$1 \cdot 6 \times 10^{-4}$	$3 \cdot 2 \times 10^{-4}$	1×10^{-2}	3×10^{-1}	4×10^{5}	6×10^{5}	10^{6}
0	12	18	17·7	22			
20	9	—	15	—	3·2	6·8	17
50	5·6	6·3	10	12·5			

(*a*) Hoff (ref. 3), (*b*) Ely (ref. 2), (*c*) present authors, (*d*) Roberts (ref. 1), (*e*) Hunter and Davies (see ref. 1).

The stresses determined at low rates are nearly all greater than Roberts's, irrespective of temperature; and in Fig. 1 it can be seen how improbably large is the dependence on rate he has calculated for his yield stress. We also show in Fig. 1 some yield stresses determined in tension at similar rates of strain; these give a somewhat lower dependence on rate of yield stress than the compressive work; but the magnitudes both of stress values and of their rate dependence are vastly different from Roberts's values. We suppose, incidentally, that the tensile yield stress, defined at the peak (mathematical maximum) of the load versus extension curve, is not necessarily a material constant; a peak in the load may merely be an indication of mechanical instability preceding the formation of a neck; analogous effects were observed by Hoff[3] when he investigated the compression of hollow 'Perspex' cylinders; buckling of the cylinders was accompanied by 'peaking' of the load. In our own measurements the slenderness ratio (height/diameter) of the solid cylinders was made small (~ 0·5) to eliminate buckling; no load peak occurred but plastic deformation at constant (true) stress was observed.

Roberts chose to extrapolate his yield stresses on a linear scale to short times (higher strain-rates) and attached significance to the fact that an unpublished value of Hunter and Davies lay on this line; it is certain that this value was a brittle failure stress,

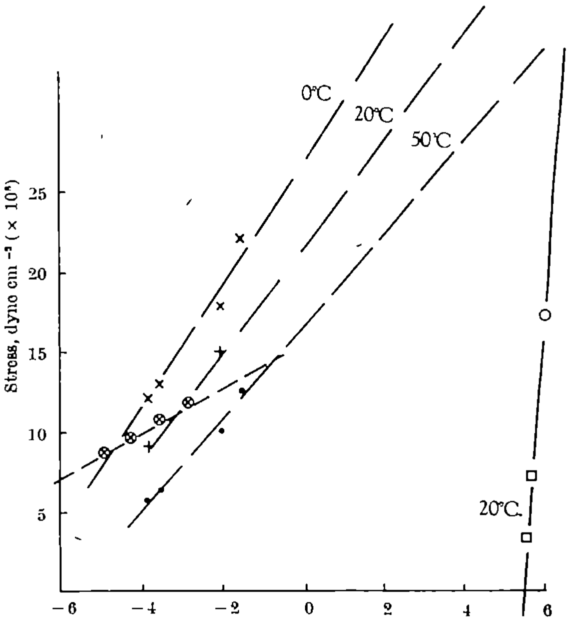

Fig. 1 Effect of strain-rate on the compressive yield stress of poly(methyl methacrylate). ○, Hunter and Davis (ref. 1), □, Roberts (ref 1). ⊗, Tensile yield, 20° C. (present authors), ×, + and ●, from Table 1

as was that of Kolsky[4], well below the yield point. We would estimate from the trend of the various compressive results that the yield point at 20° C. is near 40 × 10^{8} dynes/cm.$^{-2}$ at a strain-rate of 10^{5} sec.$^{-1}$; at − 50° C. we found the yield stress to be 35 × 10^{8} dynes/cm.$^{-2}$ for $\dot{\varepsilon} \simeq 10^{-2}$.

The discrepancies which exist between the various measurements we have quoted and those of Roberts can probably be explained by a critical examination of his theoretical and practical assumptions. We have not attempted an exhaustive inquiry, but one point requires immediate comment. Charge generation at an interface may occur simply by separation of two bodies; it is not necessary for extensive or permanent shear deformation, which is involved in compressive yielding, to occur. Roberts, however, has assumed without justification that yielding has taken place throughout a considerable volume near the area of contact between the steel sphere and the 'Perspex'.

[4] Kolsky, H., *Proc. Phys. Soc.*, **62**, B, 676 (1949)

THE first point made by Sandiford and Vincent concerns the magnitude of the stresses compared. The yield stress which I have attempted to estimate[1] is the stress giving rise to slight initial yielding. A convenient mathematical description of this yield stress is given by the Guest–Mohr hypothesis[2]. This hypothesis was tentatively adopted as a starting point as it has been useful with metals although it is fully realized that there are many criticisms which may be brought against its use. In what follows the above yield stress will be referred to as the initial yield stress.

The compressive yield stresses of Hoff[3] and Ely[4] appear to correspond to maximum load points[3] and may be termed yield strengths[5] as distinct from initial yield stresses. It seems reasonable to assume that these quantities are not identical, the yield strength being greater than the initial yield stress.

Unfortunately neither Hoff nor Ely give actual stress–strain curves from which initial yield stresses might be estimated. So far as is known the only result available is that of Kolsky[6], whose curve suggests an initial yield of approximately 1·2 × 10^{8} dynes/cm.^{2}, assuming that the purely elastic behaviour of 'Perspex' is Hookean. This result was taken to indicate that the estimated yield stresses[1] were possibly of the correct order.

Kolsky's[6] dynamic curve does not, however, show a very distinct linear region, but an inspection of his experimental points might suggest a value of 2·7 × 10^{8} dynes/cm.^{2}. This seemed rather low, so later information was sought leading to Hunter's[7] stress–strain curve, which is linear up to an initial yield of the order of 16·9 × 10^{8} dynes/cm.^{2}.

A second point concerns the linear extrapolation and plot used in comparing the results for various rates[1]. This was merely the simplest empirical presentation. The broken line was supposed to indicate this very limited significance. It is probable that the functions between rate and (1) initial yield, and (2) yield strength are not identical.

Thirdly, the question concerning charge generation at an interface. In the present case it is possible that charge generation on separation is restricted to charge being induced on the steel ball since it is near the charged polymer surface. The charge generated at the interface is associated with the discharge of the charge induced on the ball during its approach to the polymer surface and possibly the additional process of charge transfer usually occurring when a conductor and non-conductor are in contact[8]. Both these processes may occur most efficiently where really good contact is made, and it was assumed, in view of the results obtained[1], that good contact is associated with initial yielding. The charge transfer aspect is being considered in more detail at the moment so that the above is only a tentative view. Problems associated with physical contact of surfaces are also involved.

A final point is concerned with the yielding which has occurred in the volume near the area of contact. In view of the above it was assumed that the stresses throughout a volume near the area of contact exceed an initial yield stress but probably do not exceed the yield strength of the material since no permanent indentation is easily discernible.

By its very nature the original preliminary communication[1] posed more problems than it solved and discussion at this stage is valuable.

ACCURACY IN THERMOGRAVIMETRIC ANALYSIS

By G. M. LUKASZEWSKI*

Crystallography Section, Battersea College of Technology, London, S W.11

VARIOUS factors limiting the accuracy obtainable in thermogravimetric analysis have recently been discussed[1,2]

The main sources of error appear to be due to: (1) air buoyancy and convection effects, (2) measurement of temperature; (3) atmosphere in the furnace; (4) heating-rate; (5) heat of the reaction studied.

---

* From June 1962 at the Research Laboratories, Mineral Division, C S I.R O , Melbourne, Australia

These sources of error can result in considerable inaccuracies in the records, of the temperature and the weight loss (or gain) functions, obtained in the course of thermogravimetric investigations. These properties are generally interrelated and thus cannot be considered separately, although they may vary in importance with instruments of differing design. Full consideration must be given to all these factors in the operation of thermobalances.

Accurate thermogravimetric analysis requires that a correction be applied for the buoyancy of the sample holder and its support. This buoyancy effect appears as a progressively changing non-linear weight function which is related to the heating-rate.

Air buoyancy introduces an appreciable error if the density of the object being weighed differs greatly from that of the weights used to counterpoise it. The importance of such a correction is often not realized, and its application is neglected. Large errors may thus be introduced into the terminal loss in weight at the completion of reactions, and the overall shape of the weight-loss curve may be affected resulting in the misinterpretation of reaction kinetics[3].

The spurious gains in weight observed may be attributed to three main causes: (*a*) a decrease in air buoyancy with increasing temperature; (*b*) increasing convection with increasing temperature; (*c*) effect of heat on the balance mechanism.

However, further effects may be superimposed on the above three, namely, (*d*) thermal turbulence in the hot-zone of the furnace; (*e*) random fluctuations in the recording mechanisms; (*f*) furnace induction effects; (*g*) electrostatic effects; (*h*) the environment of the thermobalance.

All these factors result in an extremely complex non-linear buoyancy function in the temperature-range : Ambient to 1,500° C., which is subject to the heating-rate employed.

A further complication is introduced by the effect of a dynamically altering load, in the course of a reaction involving weight loss (or gain) of the sample. The effective load is compound, consisting of the crucible with support assembly and a sample capable of sudden weight changes. Large changes will modify the buoyancy function.

Considerable thermal turbulence can occur in the hot-zone of the furnace owing to convection currents. Expansion of the air in the hot-zone produces changes in volume which exert a pressure on the column of air in the furnace, and hence on the crucible and its support. This pressure is proportional to the heating-rate and the effective volume occupied by the crucible and support. Non-linearity in the heating-rate and turbulent heat-flow conditions produce fluctuating pressures which tend to modify the buoyancy function in an asymmetric manner, and hence affect the weight record.

The volume of the crucible, its shape and load have a considerable effect on the streaming of turbulent air or other gas. This also applies to the supporting assembly. Under turbulent conditions, therefore, it is highly desirable that the crucible and its support be streamlined so as to decrease interactions. Furthermore, the control of the heating-rate should be as linear as possible, in order to minimize thermal fluctuations in the hot-zone.

The present discussion refers to observations made during the operation of a Stanton thermobalance (model *HT–D*), under various conditions.

An automatic electric weight-loading servomechanism enables the instrument to follow a change of weight up to 0·1 gm. ± 0·05 mgm., in a manner unlimited by the effective width of the rectilinear chart, or the range of a single beam deflexion. This arrangement allows the full weight-range to be covered in ten increments of 10 mgm., each of which represents the full width of the recording chart. The maximum rate of change in weight per minute that can be recorded is 40 mgm., and when correctly adjusted, the instrument will record such variations with a reproducibility better than ± 0·05 mgm.

The sensitivity of the instrument is such that it will tend to record accurately all the phenomena described here as they occur in the hot-zone of the furnace.

The true loss in weight characteristic of a sample is difficult to evaluate in the presence of these large, spurious, non-linear contributions to the weight record. It is therefore necessary to minimize them so far as possible in order that the fine detail of the thermogravimetric curves may be resolved.

Good design in the Stanton thermobalance permits factors (*c*), (*f*) and (*g*) to be neglected. No appreciable contributions from these have been observed.

Factor (*h*) is within the control of the operator, and adequate precautions should be taken to ensure a suitable environment for the thermobalance.

The main modifications of the weight function result from (*a*), (*b*) and (*d*), which are subject to the hot-zone parameters of the furnace. In the *HT–D* model, the hot-zone is cylindrical (1·5 in. in diameter and 1·5 in. high), and is located at the mid-position of the furnace, which is mounted vertically, being closed at the top by means of a ceramic plug filled with powdered alumina (Fig. 1).

Under these conditions, the maximum decrease in the air buoyancy occurs in the region: Ambient to 50° C., and results in a rapid relative increase in

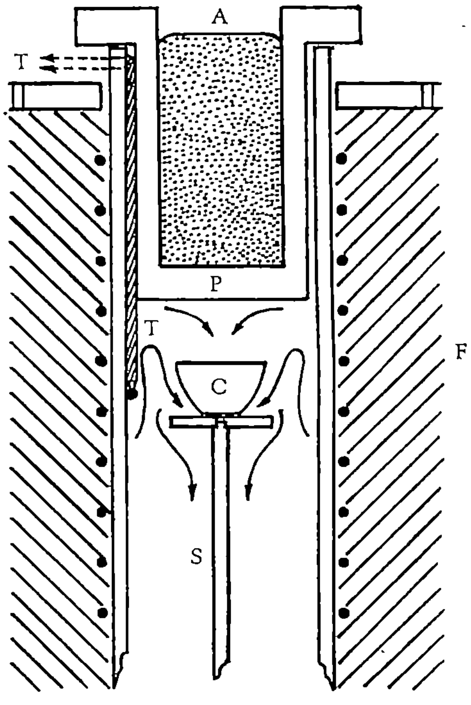

Fig. 1. The hot-zone of a standard thermobalance furnace. *A*, alumina powder; *P*, refractory ceramic plug; *T*, thermocouple; *F*, furnace wall; *C*, crucible; *S*, support assembly

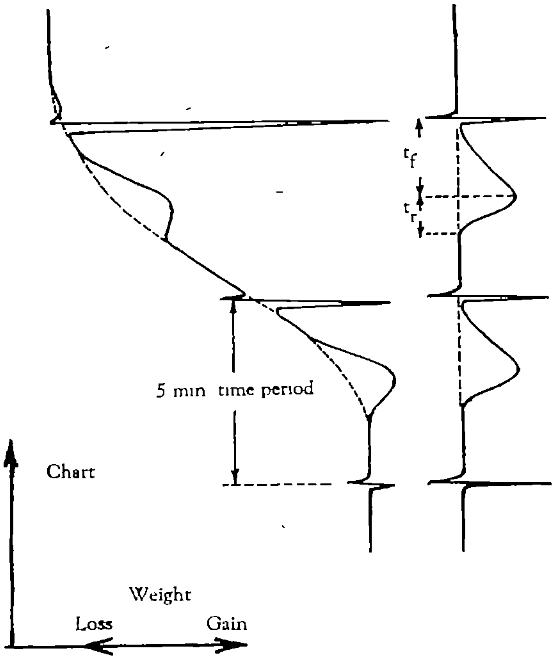

Fig. 2. A thermogravimetric record (diagrammatic), showing the effect of thermal pulsing in the furnace. t_r, rise time; t_f, fall time

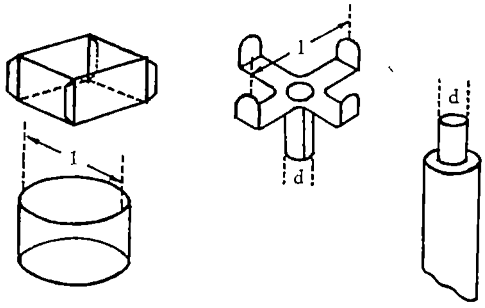

Fig. 3. Recommended crucible and support assembly. $l \simeq 0{\cdot}5 - 0{\cdot}75$ cm.

weight (a shift of original weight 'zero' position) when the furnace is first switched on.

In the enclosed hot-zone of the furnace, transference of heat occurs mainly by natural convection and radiation, with the latter predominating at elevated temperatures, that is, above 400° C. The buoyancy curve shows extreme susceptibility to thermal fluctuations in the region: Ambient to 400° C. The rapidly changing resistance of platinum furnace windings with temperature makes a full continuous control of input power impossible, so that to advance the temperature and maintain a desired heating-rate, increases must be made incrementally according to a pre-set programme. The periodic application of relatively large power increments to the furnace windings aggravates the thermal turbulence in the hot-zone and produces thermal pulsing effects. This is particularly noticeable in the range quoted here, where appreciable transference of heat occurs by convection. The weight record then depicts a series of periodic pulses which assume a 'saw-tooth' appearance and define a positive weight contribution (Fig. 2).

It has been claimed[1] that the magnitude of the various buoyancy effects can be considerably reduced by appropriate venting at the top of the furnace. This amounts to critical damping of the hot-zone volume, and in general, may introduce further non-linearity in the buoyancy curve. The response to venting will vary with the hot-zone parameters and the heating-rate, and appears to be advantageous where gas streaming techniques are utilized and the maintenance of linear non-turbulent flow rates is desired.

In view of the situation, various types of crucible assemblies were investigated in order to minimize the interactions discussed above.

A vast improvement was obtained with the assembly shown in Fig. 3, for which data are presented in Table 1. It is possible to utilize alumina or platinum crucibles in this arrangement. Crucible parameters may also be varied without detrimental results, if the following general conditions are observed:

Table 1. RESULTS OBTAINED WITH A PLATINUM BOAT CRUCIBLE (Fig. 3); DIMENSIONS: 0·7 CM. SQUARE × 0·5 CM. DEEP, WEIGHING 1·6 GM.

(a) *Buoyancy correction*:

Temperature-range	Heating-rate	Increase in weight (mgm.)
Ambient (plus)	1–3° C. per min.	+0·4 ± 0·1* (gain in 5 min.)
Ambient–350° C.	,,	+0·3 ± 0·05
350° C.–1,400° C.	,,	+0·2 ± 0·05

* The initial deviation may be neglected, since it occurs so quickly and only amounts to a change of relative 'zero' position on the weight record.

The total significant buoyancy correction over the range Ambient to 1,400° C. is then +0·5 ± 0·1 mgm. for a sample weight of 100 mgm.

(b) *Spurious effects*.

Effect	Temperature-range	Contribution (mgm.)	Time of effect. (min.)	
			Rise time	Fall time
(i) Thermal pulsing ± 5° C.	Ambient–400° C.	+0·2	1	5
	400° C.–1,400° C.	+0·1	2	7·5
(ii) Change of heating-rate: 1° per min. to 40° per min.	100° C.–400° C.	+0·2 ± 0·1	1	5
	400° C.–1,000° C.	+0·1 ± 0·05	2	10
(iii) Noise	Ambient–1,400° C.	± 0·05 mgm. Superimposed on pulsing.		

(1) That symmetrical crucibles of minimal volume are used, together with support assemblies which are as small and as streamlined as possible.

(2) Well-controlled, linear heating-rates of the order 1°–2° per min. (or less) should be used.

(3) The use of small quantities of sample material, with crucible to sample weight ratios of the order 20 : 1.

(4) Initial trial buoyancy determinations should be made with the crucible, at each relevant heating-rate. Comparison of the buoyancy effects obtained for the empty crucible with those for the crucible filled with inert material.

(5) The maintenance of constancy in experimental technique. All experimental conditions and precautions should be reported and the technique described.

(6) Consideration should be given to the nature of any reaction to be studied.

The information provided should allow appreciable control over the various factors governing the buoyancy effects.

LETTERS TO THE EDITOR

RADIOPHYSICS

Very Low Frequency Noise at Brisbane

MEASUREMENTS of the broad-band component of ionospherics in the 5 kc./s. region, 'very low frequency noise', have been reported by Aarons, Ellis and Dowden[1-3].

This type of noise has now been recorded at Brisbane using equipment consisting of a loop of 1,440 sq. metres effective cross-section oriented for north–south directivity, a high-gain audio-amplifier and an asymmetric integrator of the type described by Ellis[2]. This method of recording makes use of the period between impulsive disturbances whether atmospheric or man-made to measure the wanted signal, and the ability of the apparatus used in Brisbane to do this was enhanced by carefully adjusted 'limiting' at several stages in the amplifier. Limiting occurred for an input signal of 0·9 μV. at 4·6 kc./s. corresponding to a noise-field of at least 0·09 μV./mc./s.$^{-1/2}$ for a source in the direction of maximum sensitivity.

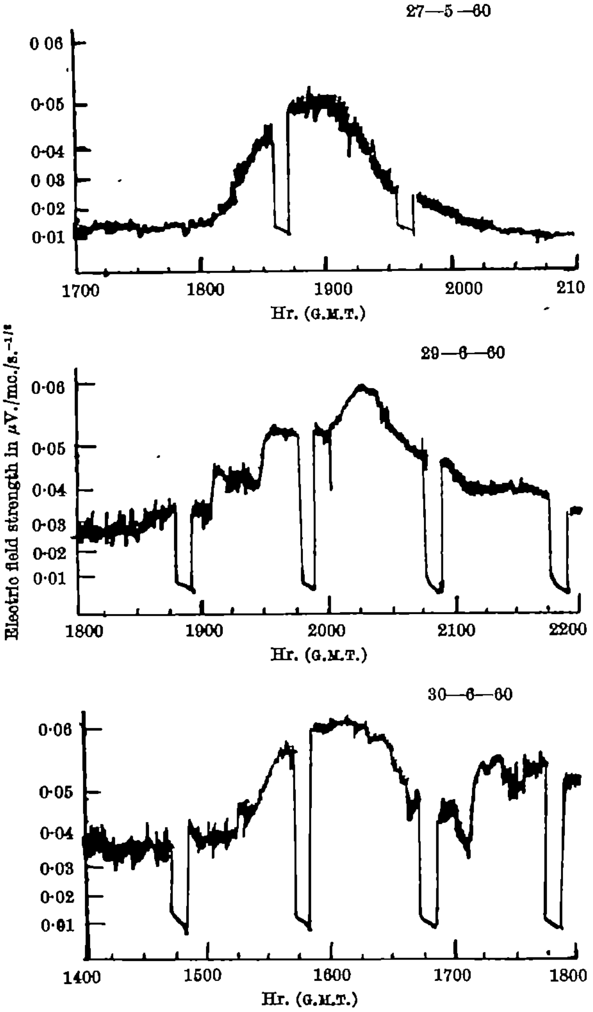

Fig. 1. Very low frequency noise at 4·6 kc./s. at Brisbane for a band-width of 800 c./s.

Unambiguous records of noise-bursts were obtained on three occasions during the winter months of 1960, each occurrence being coincident with a magnetic disturbance. These noise-bursts were recorded also at Camden and Hobart by Prof. G. R. A. Ellis (private communication), and close agreement in the time variation within the bursts was found for these observing points. The maximum noise-signal recorded at Brisbane corresponds to a field-strength of approximately 0·05 μV./mc./s.$^{-1/2}$ for a band-width of 800 c./s. to 6 db. points (Fig. 1). This is about 10 db. less than the measurement made at Camden.

No definite broad-band component could be distinguished during magnetic disturbances other than the three mentioned, although bursts were recorded at Hobart and Camden during many of them. The records made at Brisbane on these occasions were greatly disturbed by atmospherics, the time between large impulses received at Brisbane being negligible.

Brisbane at 27·5° S., 149° E. and 35·7° S. geomagnetic is believed to be the lowest latitude location at which very low frequency noise has so far been recorded.

ASTROPHYSICS

Cosmic Magnetic Fields

MAGNETIC energy appears to be as widespread as matter itself and perhaps of comparable basic significance in cosmology. Its origin poses one of the outstanding problems in astrophysics.

The magnetic fields of the Sun and its planets and of other stars may be explained in terms of dynamo action[1] on the galactic field. The latter appears to result from a similar winding up of a much weaker intergalactic field[2]. However far this process may be effective we must eventually face the problem of explaining the original 'seed' field.

In the 'explosion' theory of the universe the difficulty may be insurmountable. Going backwards in time the intergalactic field must increase as R^{-2}, where R is the radius of the sphere of matter. The magnetic pressure and energy density will increase as R^{-4} and the total magnetic energy as R^{-1}. Before R is reduced sufficiently these quantities may become prohibitively high.

In the 'steady-state' theory[3] an intergalactic field, if present, must always have been present and we need only explain its maintenance. There are objections to the hypothesis of maintenance by turbulent motion of the gas, even if the particles created are neutrons rather than hydrogen atoms[4]. The statistical accumulation of momentum in limited regions would appear to be strongly inhibited by any significant intergalactic field. It is the object of the present communication to suggest an alternative origin of such a field resulting from neutron creation—a hypothesis which already has several attractive features[4].

If some or all of the particles created are neutrons then one would anticipate a slight excess of neutrons to appear with their spin axis and magnetic axis aligned with the intergalactic magnetic field. The reason is that this satisfies the condition of minimum energy, and even though the energy difference is minute it may be significant. Aligned neutrons will remain aligned for their brief lifetime and, on decay, non-conservation of parity will ensure an excess of electrons ejected along the field lines. These constitute newly created electric current and newly created magnetic field.

In a first approximation the resulting magnetic field is force free (see, for example, ref. 5), having the form curl $B = \alpha B$, where α is a scalar function of space co-ordinates. Simple force-free fields show a periodic variation in the direction of B, rather like a series of onion skins of thickness $2\pi/\alpha$. Since curl $B = 4\pi j$, where j is the current density, the 'wave-length' of a force-free field is $\lambda = B/2j$.

In a second approximation the field is not force-free. The decay electrons, whether aligned or not, comprise a gas at a temperature of about 2×10^9 °K. which is trapped within a magnetic onion skin. The gas expands the skin and thereby transfers momentum to the proton gas by the medium of the Lorentz force $j' \times B$ due to a current j' flowing across the field lines. The protons are accelerated to a velocity of about 3×10^8 cm. sec.$^{-1}$, at which time they have their share of the energy of neutron decay.

If the intergalactic density[4] is 10^{-6} protons cm.$^{-3}$, then the magnetic field strength needed to explain the galactic field in terms of condensation is less than 10^{-8} gauss and the corresponding magnetic energy density less than 10^{-5} the gas energy density. Thus only a small proportion of the neutron decay energy is needed to create the field.

The field wave-length λ is found by identifying the above proton recession velocity of 3×10^8 cm. sec.$^{-1}$ with the observed recession velocity $3\lambda H$, where H is Hubble's constant. This gives λ as about 30 mpc., a dimension already suggested[6] as a likely size of the regions from which families of galaxies are formed. The significance of this dimension is now enhanced by the concept of regions within which the gas may condense but which are magnetically isolated from similar external regions.

The importance of the magnetic field in the partition of energy between the proton and electron gases is now evident because the collision distance of the β-decay electrons is about 300 mpc., an order of magnitude larger than the condensation regions. The field may also be important in causing hydromagnetic instability which may involve variations in space and time of the rate of creation of aligned neutrons.

It is of interest to compare the aligned-neutron hypothesis with a possible mechanism for the creation of magnetic fields in some cosmic radio sources. There can be little doubt that the field in the Crab Nebula was created long after the supernova explosion and that the process may be continuing to-day at a rate corresponding to about 10^4 times the Sun's power output[7]. The field is remarkably ordered and seems to have a force-free form[5]. The only suitable source of energy (already invoked to explain the light emission[5,8]) seems the decay of unstable isotopes, probably silicon-32 and argon-39, formed during the explosion and having half-lives of 200–300 years. These nuclei, with magnetic moments greatly increased by orbiting electrons, tend to align themselves in the existing field and to strengthen that field as they suffer β-decay. A difficulty is met, however, in the very long relaxation time of unaligned nuclei and some alignment mechanism must be sought.

The creation of magnetic field from radioactive energy, either by aligned nuclei or by a 'spinning' process[7], would also explain the vast concentrations of magnetic energy in the radio galaxies[9] and why these galaxies appear to be exploding[10].

In conclusion, a laboratory experiment is suggested using the principle of aligned radioactive ions. With a field perpendicular to two insulated metal plates, electric charge is developed on one plate and a high-voltage generator is provided.

Star Formation in Elliptical Galaxies and Intense Radio Sources

G. R. BURBIDGE has recently reviewed the problem of the energy sources required to give the non-thermal radio emission from intense extragalactic sources[1]. The intrinsically strongest sources appear to be mostly associated with giant elliptical galaxies, and to be radiating at power-levels up to 10^7 times that of our own Galaxy. Burbidge argues convincingly that the high-energy particles responsible for the radio emission must be accelerated in supernova explosions. A typical strong radio source would require the explosion of 10^7 or 10^8 supernovæ in a period of 10^7 or 10^8 years. This is a considerably greater supernova-rate than normally occurs in a galaxy.

Burbidge suggests that a Type I supernova chain-reaction can provide the necessary explosive frequency. He requires an unusually close-packed cluster of old stars, not much more massive than the Sun, to be detonated by the blast waves from their exploding neighbours. This requires that a significant fraction of the explosive energy of a supernova be emitted into space in a small fraction of a second, that when incident on a stellar surface the energy can propagate into the interior as an intense shock, and that it will commonly encounter a degenerate core which can be exploded (since non-degenerate matter is resistant to thermonuclear excursions[2]). The conditions are singly and collectively implausible.

However, because of the force of Burbidge's arguments concerning the energy sources, we should see if periods of intense supernova activity can arise in some other way. Let us consider the process of star formation in a giant elliptical galaxy.

From the virial theorem we can write the condition for a cloud of gas to become gravitationally unstable as:

$$2U + \mathfrak{M} + \Omega < 0$$

where U is the internal thermal energy, $\mathfrak{M}$ is the magnetic energy inside the cloud, and Ω is the gravitational potential energy of the cloud. We neglect turbulent energy, rotational energy, and external pressure. For a spherical cloud of solar composition, the above relation may be written as:

$$M^{2/3} > 17{\cdot}8\, T n_{\mathrm{H}}{}^{-1/3} + 1{\cdot}11 \times 10^{15} H^2 n_{\mathrm{H}}{}^{-4/3}$$

where M is the mass of the cloud in solar units, T is the temperature, H is the magnetic field in gauss, and n_{H} is the number density of hydrogen atoms.

As an illustration that may not be inappropriate for a giant elliptical galaxy with small gas content, suppose $T = 100°$ K., $H = 10^{-6}$ gauss, and $n_{\mathrm{H}} = 0{\cdot}01$ cm.$^{-3}$. Then, for gravitational instability, $M > 3 \times 10^8 M_{\odot}$. The significance of this result lies in the large mass of gas required for gravitational instability, and the fact that the magnetic energy term contributes overwhelmingly to the right-hand side of the above expression.

I have recently discussed the conditions for star formation in our own Galaxy[3]. The probable sequence of events is as follows: A gas cloud becomes gravitationally unstable and collapses with fragmentation until the fragments become optically thick. There follows a period of Kelvin–Helmholtz contraction, to be followed by a further period of gravitational collapse when hydrogen molecules become dissociated and hydrogen and helium atoms become ionized. However, in the present instance, fragmentation is not possible, owing to the fact that the gravitational and magnetic energies increase in proportion during the collapse, and the virial theorem cannot be satisfied for a smaller fragment. For such a large cloud, the collapse will not stop short of the ionization stage[4], but will continue until rotational instability produces a flattened disk.

The subsequent formation of stars can be presumed to take place by subcondensations occurring along the lines of force in the disk, either due to gravitational flattening or owing to magnetic friction opposing differential rotation. There is no reason for supposing that this should take more than a few million years. We have no way of knowing what the luminosity function of the new stars may be; stars of small mass may well be prevented from formation by the strong magnetic field.

The more massive stars contract quickly and all spend about 3×10^6 years on the main sequence[5]. Subsequent evolution should be rapid and should lead invariably to Type II supernova explosions[3]. Thus, it appears likely that star formation in giant elliptical galaxies will lead invariably to a period of intense supernova activity and hence to the formation of a strong radio source.

There are some interesting consequences of this analysis. The magnetic field is greatly strengthened and pinched at the place where star formation occurs. Ordinarily the energetic particles from the supernovæ will escape from the constriction and fill the confines of the galactic magnetic field. However, if there is a twist in the magnetic field which will lead to the formation of magnetic mirrors on either side of the constriction, then the particles should produce visible synchrotron radiation with three regions of greatest intensity. This seems to be the situation in the luminous jet of the strong radio source $M87$ (refs. 6 and 7). The large energy density in the particles should lead to a rapid expansion and short lifetime for such jets.

The magnetic field in the galaxy may be part of a general intergalactic field, since it is difficult to understand its formation if it is not primordial[8]. When the galactic field is filled with energetic particles, a rapid expansion will follow that will propagate out into the intergalatic region. Thus two magnetic mirrors will travel outwards. The energetic particles will tend to concentrate near the mirrors. This may account for the double nature of many strong radio sources. If this is the case, such double sources should have interesting intensity and polarization properties.

The history of both star formation and magnetic field configuration can be a very complicated function of galactic age. Hence one should be very cautious in drawing cosmological conclusions from the observed number-intensity relation of the intense radio sources.

I thank Wolfgang Priester and Harlan J. Smith for discussions which led to the development of these ideas.

CAMERON[1] considers that the mechanism which I have proposed to explain radio emission from elliptical galaxies[2] is implausible. Since I have been looking into this question rather carefully, I do not agree; but the discussion of this problem is of great complexity and nothing can be gained by making general assertions. Let us concentrate therefore on a discussion of the mechanism of energy generation put forward in Cameron's communication with the view of deciding whether it provides a reasonable alternative to the mechanism proposed by me.

It should first be emphasized that this idea, that stars form and evolve rapidly to the supernova stage giving rise to radio emission in external galaxies, was first put forward by Shklovsky[3] and is discussed in my communication. However, if we are to explain the appearance of large sources of radio emission centred on seemingly normal elliptical galaxies, the comparatively short time-scale for radio emission which is indicated by the synchrotron mechanism and for other reasons described in my paper means that we must choose between the following two hypotheses:

(1) That the elliptical galaxies which we see now as sources of radio emission condensed into stars a very short time ($\leqslant 10^8$ years) ago and that some stars have

evolved and exploded, giving the energetic particles responsible for the radio emission.

(2) That some stars have very recently condensed, evolved, and exploded in elliptical galaxies which are old in evolutionary terms with ages $\sim 10^{10}$ years or greater.

The first hypothesis, which demands that some elliptical galaxies are exceedingly young, appears to be completely at variance with the observational evidence on the stellar populations and the structures of such galaxies. That an age of only about 10^9 years may be compatible with the observations in some cases (though not necessarily in those elliptical galaxies which are radio sources) was mentioned by me in one of the summarizing lectures at the Santa Barbara Conference on Extragalactic Astronomy[4] Although some astronomers have mentioned this possibility, it is not generally accepted, and certainly a much shorter time-scale would appear to be out of the question.

It seems best to adopt the second hypothesis at present since most astronomers still accept the conventional view that elliptical galaxies in general have ages $\sim 10^{10}$ years or greater. Let us consider the criteria developed by Cameron as applied to this model. He has written down the condition for gravitational instability, and having neglected the turbulent energy, rotational energy, and external pressure, he has put in values $T = 100°$ K., $H = 10^{-6}$ gauss, $n_{\mathrm{H}} = 0{\cdot}01$ cm.$^{-3}$ for the gas in order to obtain the critical mass for contraction.

However, Osterbrock[5] has shown, from the profile of the [O II]λ 3,727 doublet, that the turbulent velocity of the gas in the centres of some elliptical galaxies is of the order of 400 km./sec. There is also evidence for considerable rotation in the gas in some cases. These high turbulent velocities are comparable to the values of the random velocities of the stars in similar galaxies[6,7]. Thus, contrary to what has been assumed by Cameron, the turbulent velocity in the gas cannot be neglected in deriving the condition for gravitational instability. In fact, this term dominates. For an assumed turbulent velocity of 400 km./sec., the turbulent energy is of the order of 10^5 times the internal energy of the gas at 100° K., and of the order of 100 times the magnetic energy if $H = 10^{-6}$ gauss. The criterion for gravitational instability in a turbulent medium was derived by Chandrasekhar[8] and the above result follows immediately from his work. Thus the critical mass is very much greater than the value of $3 \times 10^8 M_{\odot}$ obtained by Cameron. It may be added that even this low value for the critical mass is much larger than the total amount of gas known to be present in an elliptical galaxy (Osterbrock obtains values ranging from 6×10^3 to $12 \times 10^6 M_{\odot}$ depending on the assumed degree of ionization in the case he discussed in detail).

Finally, we must consider the effect of the stars already present in the elliptical on the condensation of new stars. The radius of the sphere containing a critical mass of $3 \times 10^8 M_{\odot}$ as derived by Cameron is about 10^4 parsecs. This is of the same order as the radius of the elliptical so far as its stellar population is concerned. Thus we may ask whether this approach of applying the virial theorem for the gas alone to a gas mass which co-exists with a stellar galaxy is valid. Even if the conditions were such that the critical mass could be reduced so that it was initially contained within a radius of 1,000 parsecs (and in view of the general dynamical conditions described earlier this appears to be exceedingly difficult), it is not clear that further contraction and fragmentation into stars can go on unimpeded. The problem is that of considering further contraction of a gas cloud in a deep potential well, which is continuously being stirred by the hundreds of millions of stars which lie within it, and are moving with velocities of several hundred kilometres a second.

This discussion has brought out some of the difficulties associated with postulating that the formation and rapid evolution of stars in an elliptical galaxy will provide a source of radio emission. This is one of the reasons why I attempted to develop the model described in my earlier communication[2].

PHYSICS

Hydrodynamic Lubrication of 'Perspex'

In recent experimental investigations of the lubrication at heavily stressed contacts, particular attention has been paid to measurements of the thickness of the lubricant film which, between gear teeth, is typically about 1μ. Using steel cylinders nominally in line or point contact the thickness of the film has been deduced from measurements of electrical capacity[1,2] or from determination of the penetration through the gap of a well-collimated and carefully aligned beam of X-rays[3]. The purpose of this communication is to direct attention to the advantages of direct observation of the contact using transparent specimens when the thickness of the lubricant film can be deduced from the examination of white light fringes; these techniques are illustrated by a description of some preliminary observations of a point contact between crossed cylinders[3] of 'Perspex'.

The lower cylinder, *C* (Fig. 1), of 2-in. diameter was rotated with surface speed 21 cm./s., while the upper cylinder, *B*, of 1-in. diameter rotated at less than 1 cm./s. and was loaded against cylinder *C*; this arrangement created an elliptical area of contact with the resolved velocity, *V*, effectively along the major axis of the ellipse. The polished surfaces were flooded with a plain mineral oil having viscosity 1·5 poise at 25° C., and the contact area, *A*, was viewed by the microscope, *M*, through the 'Perspex' rider, *R*, which was designed to reduce distortion. The source of white light was at *S*.

Fig. 2 is an impression of the contact area at a load of 2·1 kgm. (mean pressure 490 kgm./cm.^{2}); unfortunately, intense reflexion from the air bubble at recess prevents observation of fringes close to this edge, but over the rest of the contact the coloured fringes can be interpreted to give values of film thickness. The order of colours given by Newton[4], for white light fringes formed by reflexion, is used for identification; since the refractive index of the

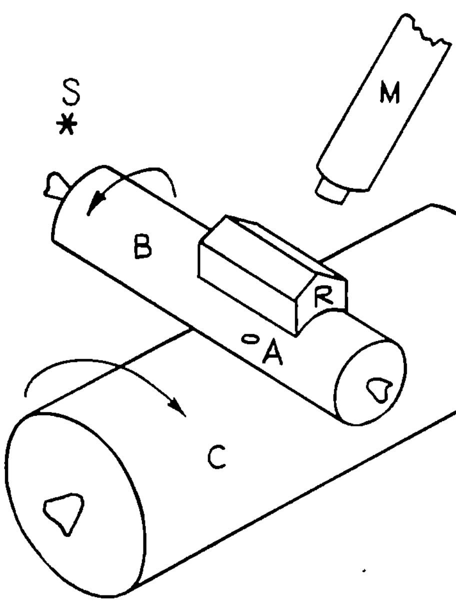

Fig. 1. Optical arrangement for viewing contact *A*

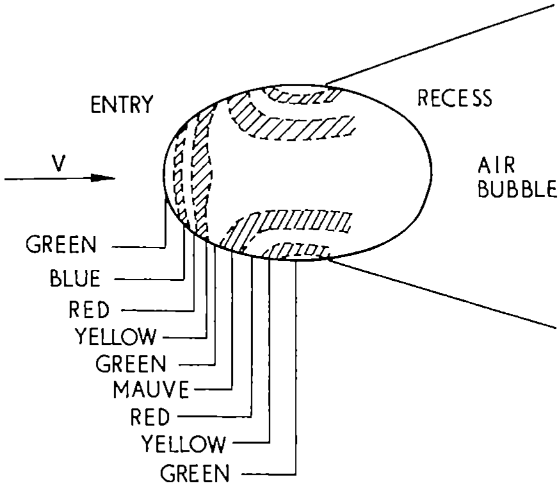

Fig. 2. Distribution of white light fringes in the contact

oil used is very close to that of glass, the film thickness for each colour can then be taken directly from Newton's table of values for glass. The effect of pressure on the density of the oil, and hence on its refractive index, is negligible in this experiment. After making a small correction for the angle of observation, in Fig. 2 the thickness of the oil film at the centre of the contact is then $4{\cdot}8 \times 10^{-5}$ cm., at entry $6{\cdot}6 \times 10^{-5}$ cm., and at the sides $2{\cdot}8 \times 10^{-5}$ cm. It is apparent that if monochromatic fringes were used not only would the absolute thicknesses be unobtainable but also the variations of thickness would be visible in far less detail.

Confirmation that the lubrication is indeed by a fluid film is obtained in two ways; first, from the fact that the fringes move steadily through the contact as the speed of cylinder *C* is varied, and secondly, from the extremely low value of the coefficient of friction, which is about 0·005. This value of the friction in a concentrated contact is in itself surprising only while the film thickness is unknown; in fact, simple calculations in respect of Fig. 2, assuming the friction is that of either a parallel-plate viscometer or a tilting-pad bearing, give coefficients of this order. There is a marked contrast between this behaviour of 'Perspex' and that of steel cylinders, where the higher pressures cause the viscosity of the oil to increase exponentially and the friction, therefore, to be very much higher[3]. Further results of experiments on the lubrication of 'Perspex' will be published elsewhere.

Epitaxial Growth of Silicon by Vacuum Evaporation

Single crystal layers of silicon up to 50μ thick have been deposited on to a heated single crystal silicon substrate. Reflexion electron diffraction of the deposited layer showed Kikuchi lines indicating a high order of crystalline perfection. *PN* junctions with a maximum reverse breakdown of voltage in excess of 300 V. have been made. The conventional bevelling and staining techniques[1] showed a sharp junction between the deposited layer and the substrate. Maximum resistivities of 10 Ω-cm. for *P*-type and 3 Ω-cm. for *N*-type layers have been obtained.

The silicon was evaporated in a specially designed electron bombardment furnace which could be stabilized either for a constant power input or for operation at a constant evaporation temperature. The evaporations were performed in a vacuum of 10^{-5}–10^{-6} mm. of mercury. The layers were deposited uniformly over a 2-cm. diameter slice of single crystal silicon with a < 111 > orientation heated by radiation from a tungsten filament and held 5 cm. from the evaporating silicon. The maximum rate of deposition was 3 μ/min. It was possible to control the thickness of the deposited layer to within 1 per cent of its nominal value. A limited control of the resistivities was obtained by the choice of suitably doped evaporation material.

The temperature of the evaporating silicon was maintained between 1,600° C. and 1,800° C. according to the rate of evaporation wanted. The minimum temperature of the substrate for good single crystal layers was critical within a range of 1,100°–1,250° C., the exact value depending on the rate of deposition. The higher temperature was required for the faster rate of deposition.

To reduce the risk of contamination especially of the evaporating silicon: (1) the silicon was evaporated by focusing the electron beam into an area about 2 mm. in diameter in the centre of a 2-cm. diameter silicon rod which was held in a water-cooled copper pedestal; (2) both the evaporating silicon and the heated substrate were shielded[2] from direct line of sight of the tungsten cathode of the electron gun; (3) for evaporation at constant temperature a photoelectric feed-back loop could be used instead of a thermocouple: the light from the heated spot was reflected by a mirror of vacuum-deposited silicon into a photomultiplier the output of which controlled the bombardment power.

In spite of the high mobility of silicon at substrate temperatures of the order of 1,000° C., it was found possible to mask the deposited layer by means of a metal mask placed 2 mm. away from the substrate. The edge of a deposited layer 30μ thick reached full thickness in a distance of less than 10μ as measured by a Talysurf profile measuring machine.

The results obtained by this method of producing epitaxial films compare with those obtained by the hydrogen reduction of silicon halides[3], a method at present in general use by the semiconductor industry. In addition vacuum deposition seems to offer certain advantages over the chemical method such as cleanliness, the use of movable masking, the making of ohmic contacts and the possibility of the fabrication of complete devices in vacuum.

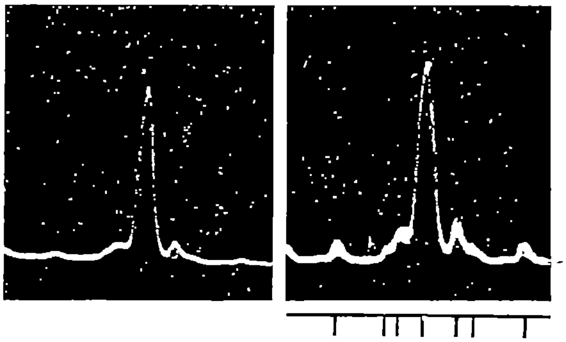
Anomalous Spectral Intensity Modification in a Hollow-Cathode Discharge

Hollow-cathode and high-frequency discharges are the light sources commonly used in optical spectral analysis of isotopic composition. Both these light sources have been used with an oscillating Fabry–Perot spectrometer in a determination of isotope abundance in mercury[1-3]. The hollow-cathode lamp appeared to exhibit anomalous variations in the spectral intensity of the odd isotope components, the magnitude of the variation depending on the discharge current strength, so a high-frequency discharge lamp was used exclusively in this work. Similar anomalous spectral intensity modifications have been reported by Schuler and Keystone[4], and by Murakawa[5], who used Fabry–Perot rings with photographic detection and consequently with less accuracy in spectral intensity measurement. The intensity variations have been further examined with an oscillating Fabry–Perot spectrometer with photomultiplier detection and oscilloscope recording.

The demountable hollow-cathode tube used consisted of a 'Pyrex' glass sleeve fitting into a 'Duralumin' base through an O-ring seal. The actual cathode was a hollow cylinder of diameter 1·4 cm. constructed of pure aluminium and fitting snugly into the 'Duralumin' base which was finned on the outside to facilitate cooling with liquid nitrogen. The nickel anode was also cylindrical in shape, being 2·5 cm. in diameter and 4 cm. long. Before use the electrodes were thoroughly outgassed.

A small blob of mercury inside the hollow cathode was sufficient to produce an intense discharge. Helium at a pressure of 1 mm. mercury was used as the carrier gas and was purified by continuous circulation through heated copper oxide and a liquid-nitrogen cooled charcoal trap. The stability of the high-voltage supply was tested by examining the spectral profile of several orders of λ5461 of a mercury-198 lamp, displayed both on an oscilloscope and on a pen-recorder function plotter. Spectral intensity variations were < 0·5 per cent.

On the oscilloscope trace spectral intensity variations in the light output of the hollow-cathode discharge were observed. The variations increase with discharge current, and at large discharge currents the anomalous intensity modifications of the odd isotope components become considerable. Fig. 1 shows two spectral profiles of λ5461 of mercury I for discharge currents of 200 m.amp. and 500 m.amp. respectively. The effective resolving power is 300,000, and mercury-199 *A*,*C* and mercury-201 *a*, *b*, *f*, *h* components are resolved. The interferometer scanning frequency is 7 c./s. corresponding to 20 m.sec. for one complete spectral profile. At a discharge current of 500 m.amp. the odd isotope components have increased in relative intensity by a factor of two while the central component, consisting mainly of the even isotope lines, has increased by only 20 per cent. The increase in half width and the change in shape of the main line can be explained by a doubling in intensity of the central odd isotope components, mercury-199 *B* being the strongest of these. Smaller magnitude rapid fluctuations in the intensity of the odd isotope components are also revealed by the 500 m.amp. spectral trace.



200 m.amp. 500 m.amp.

Fig. 1. λ 5461 mercury I; resolving power 300,000

Such anomalous intensity modification requires that the hollow-cathode discharge should be used with caution as a light source for the spectral analysis of isotopic composition and, at any event, limits the strength of the discharge current which can safely be used. On the other hand, the high-frequency discharge is more stable and controllable and increasing the discharge current to increase intensity does not affect stability nor lead to anomalous intensity changes so a greater precision in spectral intensity measurement is obtainable.

Use of an oscillating Fabry–Perot spectrometer enables the behaviour of a source under different discharge conditions to be easily and quickly examined to determine optimum operating conditions as well as permitting continuous monitoring of the spectral profile so that any anomalous behaviour is immediately detected.

RADIATION CHEMISTRY

Photochemistry of Cellulose in the Far Ultra-violet

It is known that hydrogen, carbon monoxide and carbon dioxide are evolved, and aldehyde and carboxyl groups formed[1], during the photolysis of cellulose with short-wave ultra-violet radiation in the absence of oxygen; but the complications produced by the presence of oxygen and water vapour are not fully understood. We have found that temperature markedly affects the nature of the results obtained in atmospheres of dry oxygen and dry nitrogen, and have obtained evidence which suggests that the type of reactions involved are different in oxygen-containing atmospheres in the presence and absence of water vapour. In our experiments we have exposed undyed bleached cotton yarn to the radiations from a low-pressure mercury-vapour lamp emitting mainly at 2537 Å. The yarn was contained in the inner compartment of a brass cell fitted with a quartz window. The cell was maintained at a constant temperature by circulating a suitable heating (or cooling) medium through the outer compartment. During the experiment a stream of gas heated to the required temperature was passed through the cell. The degradation of the cotton was assessed by measurements of tensile strength, fluidity (poise^{-1}) in cuprammonium[2], reducing power[3], and carboxyl content[4]. Various attempts[5] have been made to convert fluidity into degree of polymerization but the accuracy of these relations is doubtful where the cellulose has been subjected to breakdown of largely unknown character. Accordingly, the rise in fluidity of the cotton produced by irradiation has been used as a quantitative measure of the extent of chemical action. A large rise in fluidity corresponds to considerable breakdown of the cellulose molecule.

The effect of temperature on the degradation of cotton cellulose exposed in dry oxygen and dry nitrogen to 2537 Å. radiation is shown in Fig. 1. The degradation of the cellulose increases markedly as the temperature rises when oxygen is present; but in its absence the degradation seems to decrease at temperatures above 50° C. It is possible that in the absence of oxygen recombination of the free radicals produced by photolysis of the cellulose molecules is favoured at the higher temperatures. The results in oxygen presumably indicate the increasing importance of secondary thermal reactions as the temperature rises. Similar results to those shown in Fig. 1 were also obtained using the reducing power of the cellulose as the parameter of degradation. The carboxyl content of the cellulose increased steadily with rise in temperature on exposure in oxygen, but in nitrogen the value was largely independent of temperature.

The rate of degradation of cotton cellulose was also studied in air at 0 and 100 per cent relative humidity at temperatures of 15°–70° C. At all these temperatures the loss in tensile strength of the cotton yarn was always significantly greater in the absence of water vapour, the difference being greatest for short times of exposure. The reducing power of the cellulose was slightly greater in dry air than humid air for short times of exposure, but after longer periods the changes were greater in humid air. The changes in cuprammonium fluidity were greater for exposure in humid air than dry air, although for short periods of exposure the difference was negligible. As a consequence of the differences obtained using different parameters of degradation, the relation between rise in fluidity and loss in tensile strength of the irradiated yarn, as shown in Fig. 2, is different for exposures in dry and moist air. The comparable relation for dyed and undyed cotton yarn degraded by exposure to sunlight in dry and moist air[6], and also that for cotton yarn degraded by acid hydrolysis[7], are both represented by a straight line joining the origin with a point corresponding to a fluidity rise of 25 and a loss in strength of 50 per cent. Consequently, exposure of cotton yarn to 2537 Å. radiation in dry air produces a large loss in strength for quite a small change in fluidity (and hence in degree of polymerization). This seems to indicate highly localized degradation of the cellulose near the end of the chain.

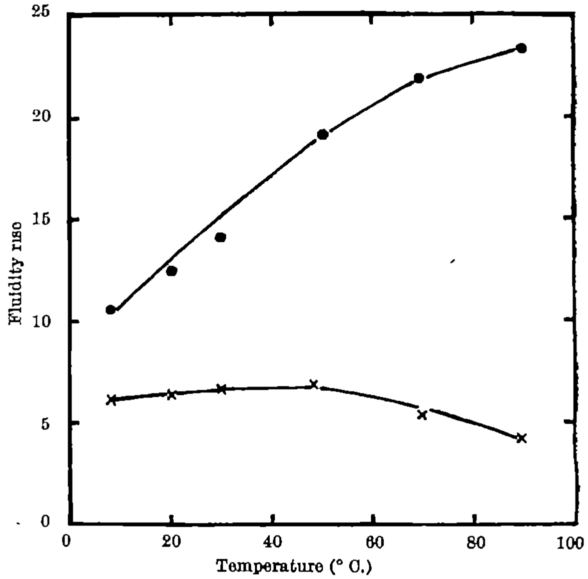

Fig. 1. Effect of temperature on degradation of undyed cotton exposed to low-pressure mercury-vapour lamp in dry oxygen (●) and dry nitrogen (×) for 20 hr.

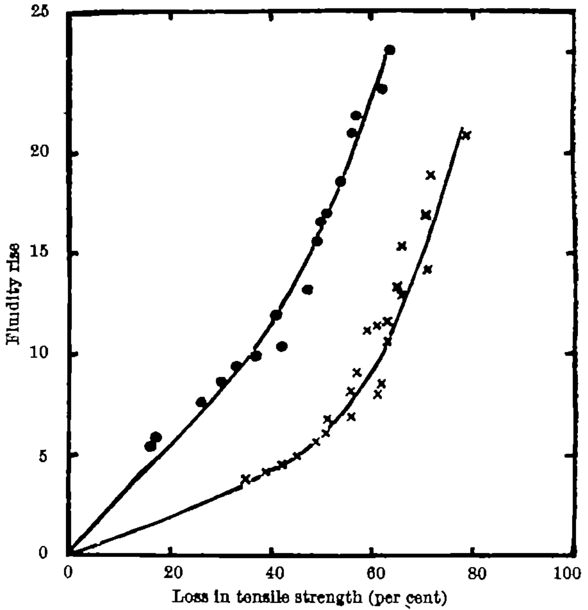

Fig. 2. Undyed cotton exposed to low-pressure mercury-vapour lamp in air at 0 per cent relative humidity (×) and 100 per cent relative humidity (●)

In the presence of moisture the degradation is not so localized, and it seems likely that the course of the reactions is significantly different. Launer and Wilson[8] have suggested that the effect of water vapour is the result of its fundamental chemical combination with cellulose. However, we have also found that the loss in tensile strength of nylon yarn after exposure to 2537 Å. radiation is markedly greater in dry air than in humid air. It is probable that the role of water vapour in these photochemical reactions is more complex than has hitherto been realized.

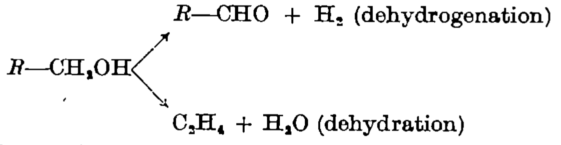
Radiation Effects on Zinc Oxide Catalyst in Dehydrogenation of Ethyl Alcohol

IT is well known that the activity of a solid catalyst may be affected by ionizing radiations, and the effects of nuclear radiations on heterogeneous catalysts have been investigated by various workers[1,2]. Recent work has shown the changes, due to irradiation, which are produced in the catalytic behaviour of some oxides[3]. These effects are due to the fact that catalytic activity is strongly dependent on the structure and energy condition of the material, and this structure may be modified under irradiation[4].

Consequently, the catalytic activity may be increased or decreased by the presence of impurities, nuclear radiations, or by illumination. Nuclear radiations may create new energetic-levels which shift the position of the Fermi-level in the solid catalyst and influence the paths for a given reaction.

In this case, I have examined the well-known reaction of the dissociation of ethyl alcohol, which proceeds along two paths:



$$R\text{—CH}_2\text{OH} \begin{cases} \nearrow R\text{—CHO} + \text{H}_2 \text{ (dehydrogenation)} \\ \searrow \text{C}_2\text{H}_4 + \text{H}_2\text{O} \text{ (dehydration)} \end{cases}$$

The particular reaction path taken is determined at the first stage of reaction, the adsorption of the alcohol molecule, and depends on the particular bond broken in adsorption: the O—H or the C—OH bond; this in turn depends on the nature of the catalyst. With zinc oxide catalysts, both reactions occur. In this case, the relative activity of the catalyst for dehydration or dehydrogenation, in the framework of the electronic theory of catalysis, depends on the position of the Fermi-level. It has been reported by Wolkenstein[5] that the lowering of the Fermi-level retards dehydrogenation and accelerates dehydration, and since Kon, Moore and Taylor[6] had shown that irradiation effects are relatively stable in refractory oxides, zinc oxide was chosen as the catalyst in the present investigation. Factors which affect the position of the Fermi-level are: acceptor impurity, donor impurity, nuclear radiation, etc.

This has been confirmed experimentally, using donor impurities, by Roginsky *et al.*[7]. This communication reports the results of irradiation effects on the catalytic behaviour of zinc oxide, prepared by ignition of zinc carbonate at 450° C. in air for 3 hr. The resulting coarse powder was pressed into pellets, and these were then crushed in order to have granules in the size range of 20–28 mesh. The amount of catalyst used in each test was 0·4 gm. The surface area was 23·7 m.^{2}/gm.

Several samples were irradiated in the Chalk River reactor and the maximum flux for catalyst sample II was $2 \cdot 3 \times 10^{13}$ n/cm.^{2}/sec. and for catalyst sample III, $3 \cdot 9 \times 10^{13}$ n/cm.^{2}/sec. (Sample I is an unirradiated sample.) The reaction has been examined in a flow system made of quartz. The specific radioactivity present in catalyst sample II was 20 mc./gm. and in catalyst sample III, 52·4 mc./gm.

Fig. 1 shows the reaction-rate at a fixed temperature of 390° C. for normal and irradiated catalysts. Fig. 2 compares the proportion of hydrogen and ethylene evolved for normal and irradiated catalysts, and it is evident that the irradiation significantly affects the reaction paths and that the effect increases with increasing irradiation time or specific radioactivity of the solid catalyst. For the temperature-range 330°–390° C. the reaction of dehydrogenation predominates in zinc oxide[8]. According to Wolkenstein[5] and Garner[9], the dehydrogenation of alcohol is an acceptor or n-type reaction; in other words, this is a reaction accelerated by the presence of free electrons and it proceeds more rapidly the higher is the Fermi-level (other conditions being equal). In contrast, the dehydration is a donor or p-type reaction.

It is evident that a higher Fermi-level is obtained in the irradiated catalysts compared with the non-irradiated ones, and this leads to an increase in the

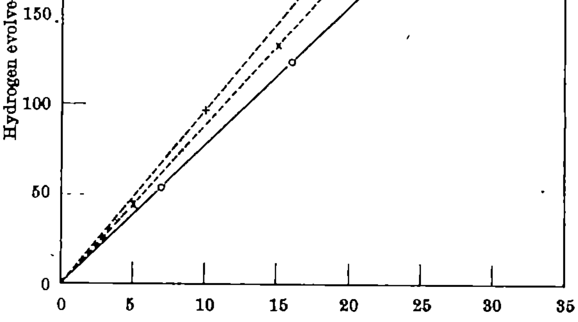


Fig. 1. Reaction-rates for different catalysts. Ethyl alcohol feed, 0 204 ml./min. I (○), Normal catalyst; II (×), radioactive, 20 mc./gm.; III (+), radioactive, 52·4 mc./gm.

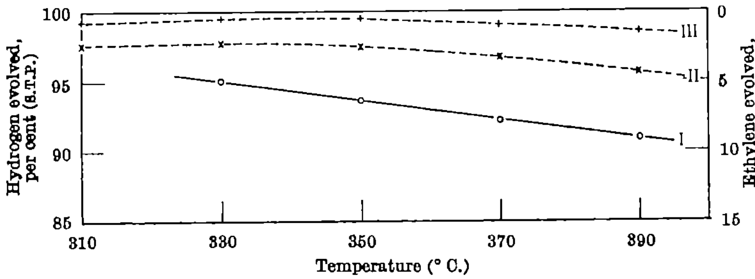

Fig. 2. Behaviour of zinc oxide catalysts. Ethyl alcohol feed, 0·204 ml./min. catalyst, zinc oxide type *A*, 0·4 gm. 20–28 mesh. I (○), Normal catalyst; II (×), radioactive, 20 mc./gm.; III (+), radioactive, 52·4 mc./gm.

hydrogen/ethylene ratio in the reaction products, which is a function of the radioactivity of the catalyst. Work is in progress to investigate the catalytic behaviour of different catalysts (*p*-type semiconductors) to see if it is possible by irradiation to introduce any Fermi-level shifting which may increase the dehydration reaction under similar reaction conditions.

CHEMISTRY

Structure and Retention Time in the Gas-liquid Chromatography of Unsaturated Fatty Acids on Polyester Substrates

It is generally accepted that plots of $\log_{10}$ retention time in the gas-liquid chromatography of the longer chain normal saturated fatty acid methyl esters against the number of carbon atoms in the fatty acid chain give a straight line with both non-polar and polar substrates. On the other hand, various simple plots of similar values obtained from unsaturated fatty acid esters with polar substrates, correlating chain length or number of double bonds, yield surprisingly little information[1–4]. In the course of gas-liquid chromatographic examination of the methyl esters of the fatty acids of marine oils the retention-time data of a number of identified unsaturated fatty acids examined by different workers[1,4–9], all using polyester substrates, were plotted on semilog paper against the number of carbon atoms in the fatty acid chain. Despite the fact that a number of differing polyester substrates were used, the resulting plots showed a surprising overall similarity. This suggested that the key to the relation of the plotted points lay in the structural position of the methylene-interrupted double bond systems in the fatty acid chains in the case of the polyethylenic fatty acids, and in the position of the isolated double bonds in the monoethylenic fatty acids, rather than in the type of polyester.

The following hypothesis is therefore advanced. In plots of $\log_{10}$ retention time of ethylenically unsaturated fatty acids versus number of carbon atoms, where polyester phases are used, parallel straight lines can be drawn between those points corresponding to fatty acids of the same number of methylene-interrupted double bonds, or of single double bonds, when the number of carbon atoms beyond the double bond farthest removed from the carboxyl group, including the terminal methyl group, is the same.

A corollary to this hypothesis is that the lines are parallel to that derived from certain of the commonly occurring monoethylenic fatty acids, namely, octadec-9-enoic, eicos-11-enoic, and docos-13-enoic, and not necessarily parallel to the plot of the saturated fatty acids. Since two or more of these are normally present in most natural lipids, the basis for plotting other materials is readily available. The general observation may also be made that the precise nature of the polyester is relatively unimportant (cf. ref. 6), facilitating comparison of data from various authors.

‡ Parentheses indicate hypothetical structures.

§ No. of carbon atoms after ultimate double bond including methyl group.

The data from Farquhar *et al.*[5], obtained on ethylene glycol-adipate polyester at 197° C., provide the most comprehensive test of this hypothesis, although similar data are available in part from other authors. Certain supplemental points were also plotted, using an equivalent chain-length system[7] (*ECL*) based on the plotted monoethylenic fatty acid lines. These are indicated in Table 1 in the reference author column, and are subject to some reservations as to accuracy as a result of the transfer. Of the various groups of fatty acids listed in Table 1, groups I–IV represent accurate correlation of plotted data with the hypothesis (Fig. 1). The two points of group V do not agree so well, but the retention times for the sixteen carbon fatty acids are possibly not as satisfactory as others since the retention times are shorter and the separation of isomers inadequate (cf. refs. 1, 2, 5). In group VI are listed plotted points which should not fall on any established line since either the number of double bonds or the end carbon chains do not match. These in fact do not fall on any line (see, however, group XII for a possible tetraenoate correlation) although the sixteen carbon chain data are subject to reservations. The validity of the necessity of the methylene-interrupted system in polyethylenic fatty acids is shown in group VII, where the plot of a diene not possessing this structure[10] falls remote from any diene line. In group VIII are listed three fatty acids, the plotted points of which fall on a straight line, although they should not. However, in addition to the doubts affecting the sixteen carbon chain acids, the plotting of any number of points will inevitably give some falling on a straight line through chance. With a revised plot, based on transferred data, as given in group IX, these three points are no longer linearly related, but in both plots there is reasonable agreement between hexadeca-9,12-dienoic acid and octadeca-11,14-dienoic acid[11]. The important negative correlation of data with theory is given in group X, where two points which should be fitted to a line on the basis of the given structures cannot be related in any way. However, comparison of octadecadienoic retention times[11] suggests that the relative retention time of octadeca-6,9-dienoic acid should be approximately 1·30, correlating with point 21. The eicosatetraenoic and docosahexaenoic acids, group XI, are unique, unless the approximate correlation of the latter with the unknowns (group XII) with relative retention times 4·11 and 4·38 could indicate the presence of an eicosahexaenoic acid of the same type, although this is improbable.

The validity of any structural determination depends on the number of bits of information pointing to that particular structure. Thus if the retention time is known, and other data indicate a twenty-two carbon diene acid[10], the assumption of the structure of the acid as docosa-10,13-dienoic acid (group XII) seems indicated by the plot coincidence with a line based on that diene structure type. However, owing to possible error in transferring the data a docosa-13,16-dienoic structure is also reasonable if the structure assigned to point 21 is correct. The identities suggested for the other unknowns of group XII are, however, highly speculative, since in two cases not even the chain length is known, but these are put forward as materials which could be used under controlled conditions to check the hypothesis advanced as the basis of this submission.

Separation of Low-boiling Hydrocarbons by Gas Chromatography using Packed Capillary Columns

BY modifying the method described by Desty *et al.*[1] for drawing glass capillaries, we have succeeded in making packed columns having an inner diameter comparable with that of capillary columns, which will be referred to here as 'packed capillaries'. A capillary packed with an adsorbant is particularly suited for

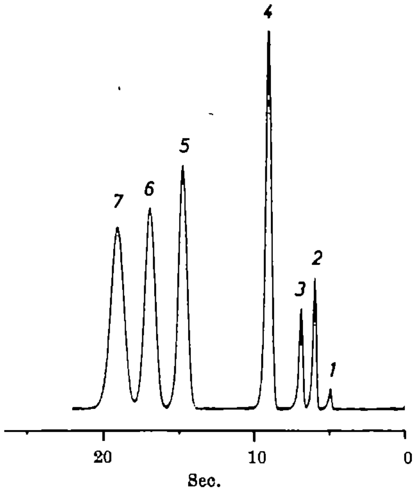

Fig. 1. Separation of (1) methane, (2) ethane, (3) ethylene, (4) propane, (5) propylene, (6) isobutane, (7) normal butane, in 20 sec. Col. length, 2 m.; temperature, 90° C.; carrier gas, hydrogen; inlet pressure, 2·0 atm.; flow-rate, 4 65 ml./min. (room temperature); sample size (syringe), 0 05 ml.; by-pass ratio, 1 : 700. Flame ionization detector with electrometer amplifier and high-speed ultra-violet galvanometer recorder

separating low-boiling hydrocarbons at room temperature, an operation requiring very low temperatures when carried out with a conventional capillary column. Filling the capillary with an adsorbant is performed thus: a carefully cleaned steel wire of 1 mm. diameter is pushed through a glass tube having an inner diameter of 2·2 mm. and the empty space between the wire and the tube wall filled with the adsorbant. Then placing the tube in a horizontal position and removing the wire carefully the glass is drawn to a capillary of 0·3 mm. inner diameter, using Desty's method. The adsorbant used in our experiments was alumina produced by calcining for 9 hr. at 400° C. hydragillite (CAMAG Chemie-Erzeugnisse und Adsorptionstechnik AG., Muttenz, Switzerland) [γ-$Al(OH)_3$], having a grain size of 0·10–0·15 mm. Afterwards the column was flushed for 24 hr. at 120° C. by a stream of dry hydrogen, in order to remove traces of water which might have been adsorbed by the alumina during the filling and drawing operation.

Fig. 1 shows the chromatogram of a high-speed analysis of a hydrocarbon mixture up to *n*-butane, obtained at a temperature of 90° C. with a packed capillary column 2 m. long. In addition, a flame ionization detector and an electrometer amplifier ('DC 60', Atlas-Weke AG., Bremen) combined with a high-speed ultra-violet galvanometer recorder ('Luminoscript', Hartmann und Braun AG., Frankfurt am Main) were used for registration. Owing to the high polarity of this alumina a complete separation of ethane–ethylene and propane–propylene in the order given could be obtained. Polarity, given as the ratio of the net retention volumes of propylene and propane, may be increased by lowering the temperature of the column. However, running in the same direction, retention times and duration of the analysis are increased, also.

Besides changes in temperature, de-activation with water is suitable for setting the activity (retention times) and the polarity at a chosen level[2]. The simplest method for impregnating the solid support with water is to pre-saturate the carrier gas with water vapour. A certain partial pressure of water vapour may be produced by passing the carrier gas through salt hydrates or through a layer of cotton-wool soaked with saturated aqueous solutions. Due to the relatively small quantity of alumina involved, equlibrium is reached within a few hours. The degree of de-activation attainable by applying a certain partial pressure of water vapour increases with decreasing column temperature. This method provides, by a suitable selection of retention volumes and polarity, a satisfactory separation of substances with very similar boiling points in an optimal time. To illustrate this, a mixture of 15 saturated and unsaturated low-boiling hydrocarbons was analysed (Fig. 2), with a packed capillary column, 10 m. long, de-activated by water released from crystalline sodium sulphate at room temperature (column temperature, 80° C.).

The packed capillary columns are suitable for high linear flow-rates like the conventional capillary columns, but they show the separation characteristics of the packed columns (4 mm. inner diameter) with active support[3] thus making possible the separation of low-boiling hydrocarbons even at elevated temperatures. Although such capillaries reveal an unevenly distributed packing, they have a good column performance. In Table 1 values of height equivalent to a theoretical plate (H.E.T.P.) are given for various flow-rates.

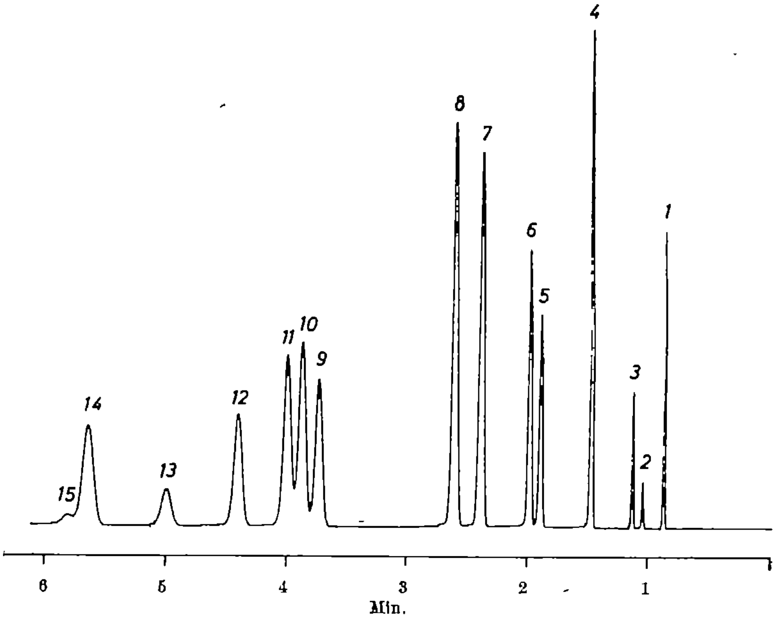

Fig. 2. Separation of (1) methane. (2) ethane, (3) ethylene, (4) propane, (5) propylene, (6) acetylene, (7) isobutane, (8) *n*-butane, (9) butene-1, (10) *trans*-butene-2, (11) isobutene, (12) *cis*-butene-2, (13) iso-pentane, (14) *n*-pentane, (15) butadiene. Col. length, 10 m.; temperature, 80° C.; deactivation, moistening of the carrier gas with crystalline sodium sulphate; carrier gas, hydrogen; inlet pressure, 4·4 atm.; flow-rate, 2·5 ml./min. (room temperature); sample size (syringe), 0·10 ml.; by-pass ratio, 1 : 600. Flame ionization detector with electrometer amplifier and 2 5 mV. compensation recorder

Table 1

Linear flow-rate (cm./sec.)	H.E.T.P. (mm.) Ethylene	H.E.T.P. (mm.) n-Butane
20	0·28	0·52
30	0·35	0·70
40	0·53	1·08

The optimal H.E.T.P. values are about 0·5 mm. for butane and 0·3 mm. for ethylene. As in conventional capillary columns H.E.T.P. values increase with increasing retention volumes. The good resolution may probably be explained by the fact that only a few grains of alumina can be located side by side, thus leaving but a few free passages to the flow of gas. The combination of narrow gas passages and empty spaces between the grains allows a quick mass transfer in the gaseous phase which, in the case of adsorption chromatography practised here, provides a short duration of analysis.

BIOCHEMISTRY

Essential Fatty Acids

Previous work[1] on the relationship between chemical structure and biological activity of fatty acids was based on the theory that either the 6-term. (that is, a double bond between the 6th and 7th carbon-atom counted from the terminal methyl group) or the 9-term. double bonds or both were fundamental for essential fatty acid activity. By means of a new quantitative bio-assay[1] a number of fatty acids were tested and the results were in favour of the theory that both the 6-term. and the 9-term. positions are essential.

Three new essential fatty acids were found: 6,9,12-octadecatrienoic acid (= γ-linolenic acid = 18 : 6,9,12-term.), 10,13-nonadecadienoic acid (19 : 6,9-term.) and 11,14-eicosadienoic acid (20 : 6,9-term.). These acids appeared to have divergent potencies. Consequently, the 6,9-term. structure is not an exclusive condition, and sub-hypotheses (on the influence of the presence of other double bonds and of the chain-length) were put forward.

In a later investigation[2] it was shown that fractions of C_{22}-fatty acids from human brain glycero-phosphatides were active. According to Klenk[3] these fatty acids have the 6,9-term. configuration.

The work on the relationship between chemical structure and essential fatty acid potency has now been continued. The previous observations with regard to the activities of 18 : 3,6,9-term., 18 : 6,9,12-term., 20 : 6,9-term. and 20 : 6,9,12,15-term. were confirmed.

In addition two new essential fatty acids were found, namely, 7,10,13-nonadecatrienoic acid (19 : 6, 9,12-term.) and 8,11,14-eicosatrienoic acid (20 : 6, 9, 12-term.). The activity of the former was low, but significant, while the C_{20}-acid appeared to have about the same potency as linoleic acid (18 : 6,9-term.).

The results obtained to date are summarized in Table 1. The data in this table regarding previous bio-assays have already been published elsewhere[1].

Table 1. Bio-Potencies of Essential Fatty Acids

Fatty acids tested: Chain-length	Fatty acids tested: Location of double bond (terminal numbering)	Bio-potencies (U./gm.)*: Previous bio-assays	Present bio-assays: I	Present bio-assays: II	Present bio-assays: III	Present bio-assays: IV	Average
18	6, 9		arbitrary				100
18	3, 6, 9	9		8			9
18	6, 9, 12	100	117		121	122	115
19	6, 9	9					9
19	6, 9, 12				6		6
20	6, 9	43			52	42	46
20	6, 9, 12				121	83	102
20	6, 9, 12, 15	130	166		139	120	139
22	?, 6, 9, ?, ?, ?	20–50					20–50

* 1 U. = the bio-potency of 10 mgm. linoleic acid.

In all the experiments the rat-assay with restricted drinking-water was applied.

The nine fatty acids tested appear to have divergent potencies. Ordinary linolenic acid (18 : 3,6,9-term.) and the two C_{19}-acids (diene and triene) have very low potencies. Linoleic acid (18 : 6,9-term.), γ-linolenic acid (18 : 6,9,12-term.) and eicosatrienoic acid (20 : 6,9,12-term.) are about equally potent (about 100 U./gm.).

Arachidonic acid is synthesized *in vivo* from linoleic acid. The intermediary steps are not exactly known. It can be accepted that the intermediates must have the same or higher bio-potencies than linoleic acid (100 U./gm.). Therefore, 18 : 3,6,9-term., 19 : 6,9-term. and 20 : 6,9-term. cannot be intermediates. On the other hand the high potencies found for 18 : 6,9,12-term. and 20 : 6,9,12-term. are in agreement with the theory of Mead and Howton[4], who proposed the pathway:

linoleate (18 : 6,9-term.) → γ-linolenate (18 : 6, 9, 12-term.) → 8,11,14-eicosatrienoate (20 : 6,9,12-term.) → arachidonate (20 : 6,9,12,15-term.).

I thank my colleagues Dr. D. A. van Dorp, Mr. G. J. van Beers, Mr. G. J. N. Egmond and also Messrs. Hoffman la Roche, Basle, Switzerland, who supplied the fatty acids used in the bio-assays.

Release of Peroxidase from Eosinophil Granules *in vitro*

The eosinophil is a phagocytic cell[1], and following the ingestion by eosinophils of sensitized red cells many of the eosinophil granules disappear[2]. Histochemical studies recently have shown that eosinophil granules contain significant amounts of the enzyme peroxidase[3]. The conditions necessary for lysis of the granules and release of peroxidase were investigated in the present work, using preparations of eosinophils isolated from the peritoneal cavity of the rat.

Eosinophils together with other peritoneal cavity cells were collected by a method previously described[4]. Rats were used the peritoneal cavities of which had been repeatedly irrigated with physiological saline solution. This treatment is known to increase the yield of eosinophils and to decrease greatly the mast cells. Peritoneal cavity cells collected from 10 rats were added to 5 ml. heat-inactivated rat serum and the cells were homogenized at 0° C. in a 'Teflon'-tissue grinder. The homogenate was centrifuged at 250*g* in a refrigerated centrifuge held at 0° C. This centrifugal force was sufficient to deposit most of the cell debris, but the eosinophil granules remained suspended in solution. The supernatant solution containing the granules was centrifuged at 1,200*g* to deposit the eosinophil granules and the granules were washed once in a large volume of ice-cold physiological saline solution. The granules appeared intact when stained films of the deposit were examined with the light microscope. Only an occasional mast cell granule was present in these preparations.

In some experiments intact eosinophils were used. The eosinophils were separated from the other peritoneal cavity cells by centrifugation at 0° C. in a column of 42 per cent bovine albumin in physiological saline solution. Bovine albumin was obtained as a powder from the Commonwealth Serum Laboratories, Parkville, Victoria. The peritoneal cavity cells were mixed with 2·5 ml. of the albumin solution at 0° C. and layered above a 2·5 ml. column of 42 per cent albumin solution at 0° C. in a centrifuge tube. Eosinophils and mast cells have a higher specific gravity than other cells obtained from the peritoneal cavity, and following centrifugation at 1,200*g* the eosinophils and mast cells pass through the albumin solution and may be collected at the bottom of the tube. The other cells remain suspended in the albumin or pass to the top of the column. The deposited cells were collected and washed three times with physiological saline solution. Eosinophils constituted approximately 80 per cent of the cells present, the remainder being mononuclear cells together with occasional mast cells and red cells. When necessary contaminating red cells were removed by allowing the cells to sediment in physiological saline solution. The white cells were found to clump together and settle to the bottom of the tube, leaving the red cells suspended in the solution.

Peroxidase was measured quantitatively by the method of Jermyn and Thomas[5]. The optical density of the final solution containing the enzyme was measured at 400 mμ in a direct-reading Zeiss spectrophotometer. Crystalline horseradish peroxidase was obtained from Nutritional Biochemicals, New Jersey, and standard solutions were prepared in 0·1 *M* sodium acetate buffer at *p*H 5.

Peroxidase was released from intact eosinophils and isolated granules when these were placed in a sodium acetate buffer of ionic strength 0·02 *M* and *p*H less than 5·5. The enzyme was released more rapidly as the *p*H was reduced to 4. The amount of peroxidase released from one million rat eosinophils was found to be equivalent to 0·5 μgm. of crystalline horseradish peroxidase. Microscopic examination of stained films revealed that the eosinophil granules had disappeared in those preparations in which peroxidase was released. Peroxidase was not released and the granules remained intact when preparations of intact cells or isolated granules were added to distilled water at *p*H 6. Similarly peroxidase was not released from intact cells or granules exposed to 0·15 *N* saline when the *p*H was reduced to 4. The enzyme remained in solution at *p*H 5 and ionic strength 0·02 following centrifugation of the solution at 28,000*g* for 30 min. in a Spinco ultracentrifuge. Activity remained inside a dialysis bag following dialysis of the solution against distilled water for 24 hr. at room temperature. Peroxidase activity was destroyed by boiling or lowering the *p*H below 2. The enzyme was precipitated out of solution when the *p*H of the solution was increased to 8, but the precipitate redissolved in 0·02 *M* sodium acetate buffer at *p*H 5. The precipitate containing the enzyme was re-dissolved to a concentration equivalent to 10 μgm./ml. horseradish peroxidase and the solution was faintly yellow in colour. Following the addition of a few crystals of sodium dithionite the solution became faintly green and spectroscopic examination revealed the presence of an absorption band in the Soret region at approximately 440 mμ. The significance of the spectroscopic findings is being investigated separately.

Recent studies by Hirsch and Cohn[6] have shown that granules isolated from rabbit neutrophils undergo lysis and liberate their contained enzymes when exposed to an environment of low ionic strength and low *p*H. In the present work eosinophil granules underwent lysis with release of peroxidase under similar environmental conditions. Hirsch and Cohn have suggested that following phagocytosis by neutrophils there may be a fall in the *p*H of the cytoplasm sufficient to cause lysis of the granules. It is tempting to suggest a similar mechanism for the lysis of eosinophil granules following phagocytosis by eosinophils.

Inhibition of β-Glucuronidase by Endogenous Saccharate during Hydrolysis of Urinary Conjugates

THE use of β-glucuronidase as an agent for the liberation of a steroid from its urinary glucuronide conjugate has now become standard practice. The overall rate of the enzyme action is unpredictable, however, due to the presence in the urine of natural inhibitors and other substrates of varying affinity and ease of hydrolysis.

D-Glucosaccharic acid has been found to be a normal constituent of mammalian urine[1]; the excretion in adult human subjects is about 10 mgm. a day, and is doubled during pregnancy, returning to normal within a few days after parturition[2]. At the acid *p*H at which molluscan or mammalian β-glucuronidase preparations are normally used, there is partial conversion of saccharic acid to its 1:4-lactone, the potent and specific β-glucuronidase inhibitor[3]. This explains the progressive decrease in enzyme activity which occurs during incubation with urine[4].

Fig. 1 shows the inhibition by pregnancy urine of β-glucuronidase from rat liver, acting on phenolphthalein β-glucuronide. The urine was boiled for 15 min. after neutralizing, to destroy endogenous enzyme activity and to open existing lactone rings. It was then incubated for varying periods at 38°, after buffering with acetate to *p*H 4·5 or with phosphate to *p*H 6·1, and immediately tested as an inhibitor of β-glucuronidase in the usual 1-hr. assay. Whereas after incubation at *p*H 4·5 the urine became more inhibitory, there was no change at *p*H 6·1, where no

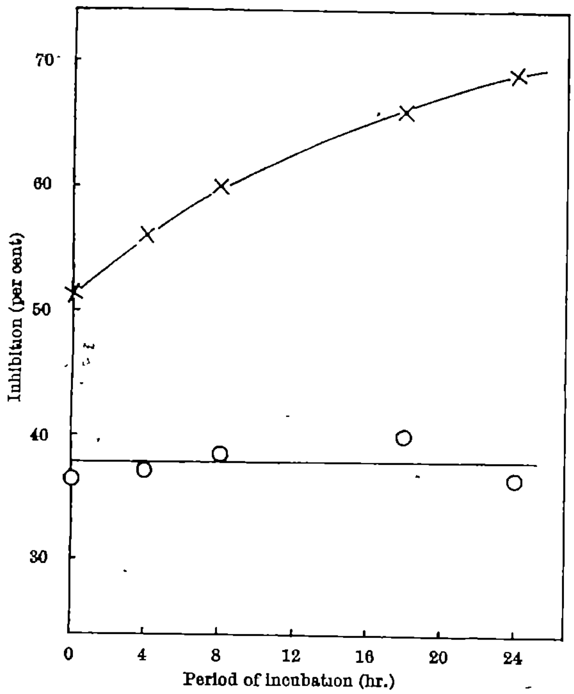

Fig. 1. Effect of incubating human pregnancy urine at pH 4·5 (×) or 6·1 (○) for varying periods, before testing at a concentration of 10 per cent as an inhibitor of rat-liver β-glucuronidase. The enzyme assay was carried out at the pH of the incubated urines with 0·63 mM phenolphthalein β-D-glucuronide as substrate

conversion occurs of saccharate to the inhibitory lactone[2].

It is therefore recommended that, if prolonged incubation with the molluscan or mammalian enzyme is necessary, acid urines should be neutralized before enzymatic digestion, to convert any existing saccharo-1 : 4-lactone into non-inhibitory saccharate, and the digestion should be carried out at as high a pH as is consistent with reasonable enzyme activity. The activity of mammalian or molluscan glucuronidase is unduly low (< 50 per cent optimal) at pH 6·1, however: bacterial β-glucuronidase preparations have optima at pH 5·5–7·0[4], but are inferior in potency to those from molluscan or mammalian sources, for example, limpet and female-rat preputial gland.

Oxytocic Lipids in Human Amniotic Fluid

It has been known for some years that human amniotic fluid contains lipids which have an oxytocic action. Hanon *et al.*[1] reviewed their work on these substances in 1953. They showed that the active principle, which they called eutocine, would cause isolated preparations of guinea pig uterus to contract, and was distinguishable from histamine, acetylcholine, choline, and pituitary oxytocin. Eutocine could be dissolved in lipid solvents and was particularly soluble in ether. Eliminating cholesterol and phospholipids from the extracts caused no loss of activity, which seemed to be concentrated in the fatty acids and glycerides.

In 1958 Ferraris[2] confirmed the observations that an ether extract of amniotic fluid had oxytocic activity, and showed that the active substance would stimulate isolated strips of non-pregnant human uterus.

In the present work I have used mainly specimens of amniotic fluid obtained from pregnant women at or near term, when the membranes were ruptured artificially to induce labour. In a few cases samples of fluid were obtained earlier, when a pregnancy was interrupted by therapeutic or spontaneous abortion.

Extracts of amniotic fluid were tested on isolated uterine cornua from immature guinea pigs (*K* strain, 3–4 weeks old), maintained in Krebs–Henseleit solution aerated with 95 per cent oxygen/5 per cent carbon dioxide at 37° C. Emulsions or solutions of the extracts in Krebs's solution were added to the bath fluid and contractions of the uterus recorded with a writing lever applied to a kymograph. Oxytocic activity was estimated by comparing the responses with contractions of the uterus produced by known doses of ricinoleic acid, which is active in concentrations of 1–10 μgm./ml. The potency of the extracts was expressed in units, one unit being the equivalent of the oxytocic activity of 1 μgm. of ricinoleic acid.

The great majority of the active substances obtainable from amniotic fluid with lipid solvents was removed by two extractions with equal volumes of ether. In general 95 per cent or more of the ether-extractable substances passed into the ether phase at the first partition. Subsequent extractions of the aqueous phase with petroleum ether (b.p. 60°–80° C.), dichloromethane or chloroform yielded considerable quantities of lipid but little or no oxytocic substances. Further amounts of lipids possessing slight activity were obtainable by acidifying the aqueous residue and repeatedly extracting with ether.

Subsequent work was confined to preparations made by evaporating ether extracts of neutral amniotic fluid to dryness under reduced pressure, taking up the residue in ether and filtering to obtain a clear solution free from pharmacologically inactive lipoproteins.

In early pregnancy (10–20 weeks) the amniotic fluid had a mean ether-extractable lipid content of 0·13 mgm./ml. (range 0·04–0·43, 11 cases). The lipid extracts had an average oxytocic activity of 14 units/mgm. (range 1–40). No difference was detected between specimens obtained by operation and the samples from spontaneous abortions. In late pregnancy, at or near term, the ether-extractable lipid content was higher (0·64 mgm./ml , range 0·04–2·76, 112 cases) but the average oxytocic activity of the extracts (3·6 units/mgm., range 1·2–10·0) was less.

The responses of the guinea pig uterus to the active substances were not antagonized by atropine sulphate (1 μgm./ml.) or by mepyramine acid maleate (1 μgm./ml.), indicating that the preparations were not contaminated by acetylcholine or histamine. Ether extracts of amniotic fluid had an oxytocic action on isolated strips of human uterus, obtained at operation in the first half of pregnancy.

The active substances appeared to resemble the oxytocic lipids which Pickles *et al.*[3–5] have found in endometrium and menstrual flow. Similar methods were used partly to purify the oxytocic lipids from amniotic fluid.

On partition of the ether extracts between 80 per cent methanol and heptane, the methanol fraction was several times as active as the heptane fraction, though most of the lipid passed into the latter. By concentrating the active constituents in this way, preparations with activities 15–150 units/mgm. were obtained. The methanol fractions were subjected to chromatography on silica gel, eluting with a graded mixture of petroleum ether containing an increasing proportion of diethyl ether, and finally methanol. This procedure demonstrated the presence of four active substances. One of these was eluted by 25–75 per cent diethyl ether in petroleum ether and could be further purified by passage from ether into 2·6 per cent aqueous sodium bicarbonate. It appeared to consist of free acid.

While it would be speculative to propose that these oxytocic lipids play a part in parturition, it is clearly of interest that they are present in human amniotic fluid, and are capable of stimulating human uterine muscle.

Tyrosine Metabolism in Melanoma

The urine in patients with generalized melanoma contains substances which cause its dark colour when exposed to air—urinary melanogens[1,2], of which there are two types[3]: (1) nitrogen melanogens, insoluble in ether or ethylacetate, giving a positive Thormählen test[4–6]—indole melanogens, as they are called, and (2) non-nitrogen melanogens, soluble in ether or ethylacetate, giving a negative Thormählen test—phenol melanogens.

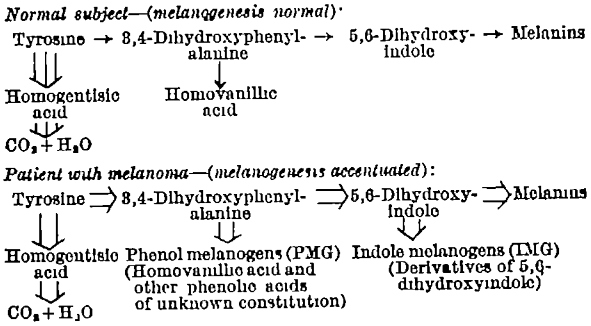
In our preliminary reports[7] we characterized phenol melanogens as a mixture of phenolic acids of an unknown constitution. We identified one of them as the homovanillic acid (HVA), the 3-methoxy-4-hydroxyphenylacetic acid[8].

A quantitative method for estimation of HVA was worked out[8] based on separation of HVA from ethylacetate extracts of urine, using paper chromatography[9]. The coloured spots obtained by detection of HVA with diazotized *p*-nitroaniline were cut out from the chromatograms, eluted and measured photocolorimetrically.

Using this method HVA excretion in the urine of patients with melanoma (metastases) was found to be 3–4 times greater than in normal people. After oral application of tyrosine, an increased urinary excretion of HVA occurred in these patients, whereas in normal health it was not changed[8].

Similar results were also obtained with indole melanogens. Concentration in the urine we estimated using a photocolorimetric modification of the Thormählen reaction according to Pechan[10]. It was found that after oral application of tyrosine an increased urinary excretion of indole melanogens occurred in melanoma patients[2,8].

Because HVA has recently been found to be a natural metabolite of endogenous 3,4-dihydroxyphenylalanine in normal people[11] and indole melanogens are derivatives of 5,6-dihydroxyindole[5,6], our findings appear to be in agreement with the well-known Raper–Mason scheme for melanogenesis:



Normal subject—(melanogenesis normal):
Tyrosine
3,4-Dihydroxyphenylalanine
5,6-Dihydroxyindole
Melanins
Homogentisic acid
Homovanillic acid
$CO_2 + H_2O$
Patient with melanoma—(melanogenesis accentuated):
Tyrosine
3,4-Dihydroxyphenylalanine
5,6-Dihydroxyindole
Melanins
Homogentisic acid
Phenol melanogens (PMG) (Homovanillic acid and other phenolic acids of unknown constitution)
Indole melanogens (IMG) (Derivatives of 5,6-dihydroxyindole)
$CO_2 + H_2O$

Interrelation between Tryptophan and Nicotinic Acid in Human Viral Hepatitis

Continuing the chromatographic work carried out on tryptophan–nicotinic acid metabolism on urine of mice affected with experimental *MHV*-3 virus[1], we have investigated the effect of viral hepatitis on the relationship between tryptophan and nicotinic acid in man.

Samples of urine were collected over a 24-hr period from normal subjects, from twenty-four subjects affected with viral hepatitis at various stages of the disease and from nine subjects who had recovered either recently or some time before. For chromatographic analysis of the urinary metabolites involved in the tryptophan–nicotinic acid system Dalgliesh's technique[2] was used. Identification of the compounds was carried out by examination of the fluorescence by ultra-violet light (3660 Å.) and by means of the characteristic colour reactions.

Of the 24 cases still suffering from the disease, in 22 we found kynurenine, in 17, 3-hydroxykynurenine, in 10, 3-hydroxyanthranilic acid, and in 3 cases anthranilic acid. Frequently, acetyl-kynurenine (15 cases), kynurenic and xanthurenic acids appeared. It must be realized that various chromatographic tests were carried out on different days for each patient, and these tests did not always give results which were perfectly identical. Usually the chromatographic pattern presented the greatest metabolic alterations at the time when the disease reached its maximum.

From the studies carried out on 9 patients who had recovered for a few months, the chromatographic picture was almost completely normalized. (Only in 3 cases in the urine did we find any 3-hydroxykynurenine and that in small quantity.)

In man, therefore, even though a blockage of the reaction catalysed by kynureninase prevails, it is however associated sometimes with other metabolic disturbances, thus in some cases causing an accumulation of 3-hydroxyanthranilic acid in the urine.

The dissimilarity of results obtained from investigations conducted on mice and those on human beings suffering from viral hepatitis (the presence in the urine of mice inoculated with virus *MHV*-3 of kynurenine and 3-hydroxykynurenine, the presence at times in the urine of human subjects affected with viral hepatitis of 3-hydroxyanthranilic acid also—never found in the urine of mice) may be explained as follows: in our experimental conditions, the infection in mice took a particularly dramatic and acute course, so extensive and severe that a wide blockage was caused in the enzymatic activities ahead of the reaction catalysed by 3-hydroxyanthranilic oxidase.

The human beings whom we investigated were suffering from a milder form of viral hepatitis; therefore it can be assumed that the activity of kynureninase was not always completely abolished, thus resulting in the possibility of revealing other metabolic disturbances beyond this enzymatic activity.

These studies on hepatitis patients have revealed an important point. In the course of this disease, which causes direct alterations of the liver parenchyma, we did not find such great, characteristic and durable changes as those which occur in cancer of the urinary bladder[3].

Thermodynamics of Biological Growth

According to some recent opinions, living organisms are nearer to open systems in the thermodynamic sense than to classical closed systems, although an organism plus its environment constitute a system which must be regarded as closed. While closed systems eventually reach equilibria characterized by minimum Gibbs free energy and maximum entropy, Prigogine[1] and de Groot[2] have predicted that open systems will approach steady states of minimum entropy production. On this basis, Prigogine and Wiame[3] have inferred that living organisms grow towards a state of minimum metabolism per unit mass, but this view and other discussions[4] on this theme are subject to two criticisms. On one hand, the theorem of minimum entropy production holds only for open systems very near to the steady state[5] and, on the other, it has never been tested experimentally for living organisms so that conclusions derived from it are weakened to some extent

A study of this problem has been initiated in this College to provide the experimental proof for the application of the entropy theorem to biological growth. Bacteria have been chosen as the representative organisms since these cells approximate closer to the theoretical models used in the derivation of the entropy theorem than are species containing more specialized organs within their structure. Bacterial cultures should tend towards a state of minimum entropy production per unit cell mass (σ) during their exponential phase of growth, provided the cells are well adapted to their growth medium and are growing at their maximum rate in a 'steady state'. As a first step in testing this hypothesis experimentally, the heat evolved by cultures of *Aerobacter aerogenes* growing in a synthetic glucose medium[6] has been measured in a simple microcalorimeter.

A microcalorimeter unit consisted essentially of a sterile culture tube, containing a known quantity (40 ml.) of medium, which fitted into a silvered Dewar flask with a silicone rubber bung assembly. The unit was immersed in a water bath maintained at 40·0 ± 0·01° C., with only the tops of an air-exit and thermometer pocket tubes above the water-level. Air saturated with water vapour was bubbled into the culture medium and served not only as an oxygen source, but also stirred the medium efficiently. Rises of temperature in the calorimeter were estimated from the resistance changes of a thermistor measured with a Pye Wheatstone bridge. The heat capacity of the calorimeter assembly and culture medium was determined by passing a known quantity of electrical energy through a Brightray heating coil immersed in the medium for about 2 hr. After switching off the current, a cooling curve was plotted for about 2–3 hr. from which the Newton cooling constant was calculated.

After the calorimeter had reached thermal equilibrium, an experimental run was started by inoculating the calorimeter with an arbitrarily fixed volume of suspension (*c*. 0·1 ml.). Exactly the same quantity of

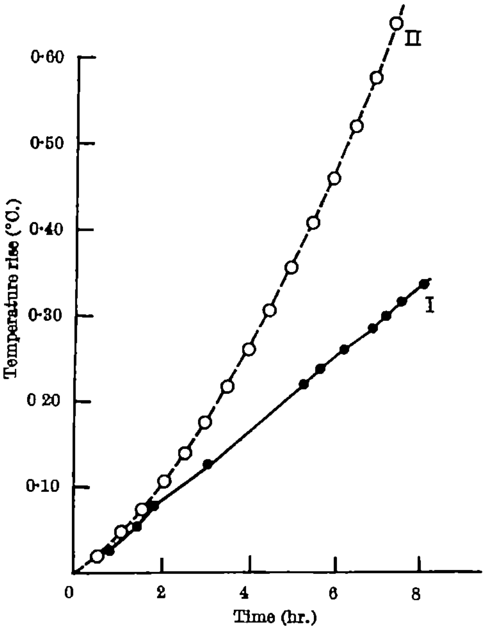

Fig. 1. Observed (I) and corrected (II) rises of temperature in the calorimeter during the aerobic growth of *Aerobacter aerogenes* in a synthetic glucose medium

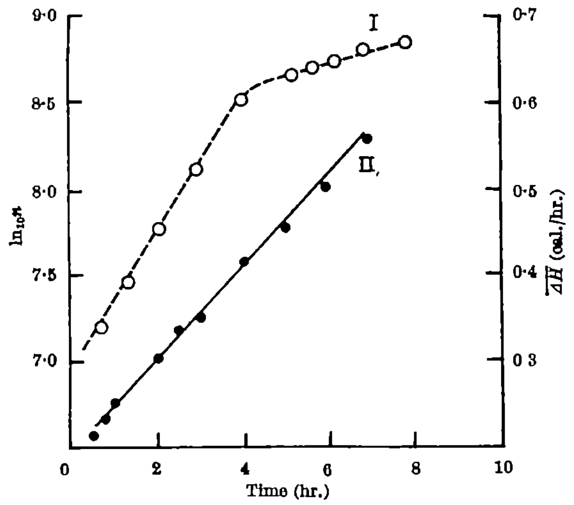

Fig. 2. Growth curve (I) and the rate of heat production, $\overline{\Delta H}$ (II). The cell population is n cells/ml.

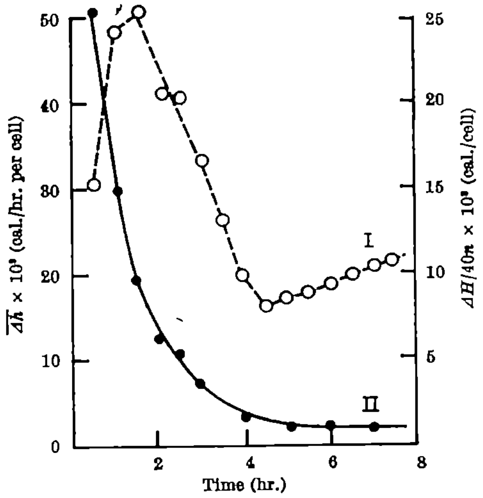

Fig. 3. The heat production per cell, $\Delta H/40n$ (I), and the rate of heat production per cell, $\overline{\Delta h}$ (II)

suspension was also inoculated into each of two ordinary culture tubes both containing the same volume of culture medium as the calorimeter: the growth of the culture in these two tubes was followed nephelometrically and their average cell count was taken to be that in the calorimeter chamber.

The total heat (ΔH) produced by the system and the rate of heat production ($\overline{\Delta H}$), after correction[7], showed no signs of tailing off after the culture had entered the stationary phase (Figs. 1 and 2). However, the variation of $\overline{\Delta H}$ per unit cell ($\overline{\Delta h}$) with time showed a different pattern (Fig. 3) : the curve quickly reached a maximum soon after the onset of the exponential phase, but then smoothly declined during growth and finally approached a minimum value asymptotically well into the stationary phase. This confirms Prigogine and Wiame's view[3] if Prigogine's suggestion[8], that the rate of Gibbs free energy change ($\overline{\Delta G}$) is zero in the steady state so that σ becomes simply related to $\overline{\Delta h}$, is conceded. On the other hand, the alternative hypothesis suggested earlier that σ approaches a minimum during the exponential phase cannot be rejected until some data for the $\overline{\Delta G}$, time relationship have been accumulated.

Further discussion of this problem and other relevant data will be published elsewhere together with the details of an improved adiabatic micro-calorimeter that by-passes the need for the large cooling corrections invoked by the conventional type described here.

I thank the Department of Scientific and Industrial Research for financial support for this project.

Influence of Temperature on the Syntheses of Contractile Proteins in *Triturus* Embryos

The influence of temperature on the syntheses of contractile proteins, actin and myosin, in early embryos of *Triturus pyrrhogaster* Boie, was examined.

Approximately, 1,000 embryos were divided into five equal groups which were raised separately at five different temperatures (10°, 15°, 18°, 20° and 25° C.). The determinations of the first detectable trace of actin and myosin formation in embryos were carried out by a serological technique that has been outlined before[1,2], in the period of 12 hr. following fertilization. Anti-sera against G-actin and myosin were prepared by injecting intravenously into rabbits a solution of G-actin and myosin, isolated from the skeletal muscle tissue of *Triturus pyrrhogaster* by Szent-Györgyi's method[3], and were raised to their serological specificity by resorption tests with saline extracts of liver, spleen and skin tissue of *Triturus*. Titres of both sera were adjusted to 1 : 512 before the precipitin reaction with a saline extract of embryos. Constant volumes of sera and progressively decreasing amounts of antigen were used in order to avoid an excess of antigen.

It was found that actin first became detectable 84, 120, 132, 144 and 156 hr. after fertilization in

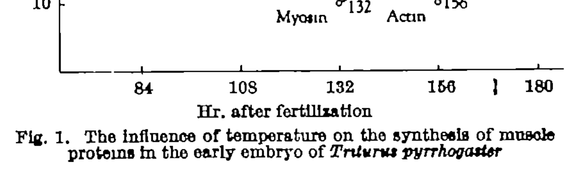

Fig. 1. The influence of temperature on the synthesis of muscle proteins in the early embryo of *Triturus pyrrhogaster*

embryos raised at 25°, 20°, 18°, 15° and 10° C. respectively. As to myosin formation, the first detectable trace was found 108 hr. after fertilization in embryos raised at 25° C., 168 hr. when raised at 20° C., 180 hr. at 18° C., then again 168 hr. at 15° C. and 132 hr. at 10° C., as shown in Fig. 1. Thus, actin formation in early embryos was markedly suppressed with dropping temperature under the above experimental conditions. On the contrary, myosin formation was most strikingly suppressed at 18° C. and from thereon was clearly promoted independently of falling or rising temperature.

This finding is unexpected, but the result is noteworthy, because the temperature of the natural breeding season of *Triturus* is about 18° C. We may imagine that many metabolic pass-ways are in competition for the materials that are required to keep a balance necessary for the growth of the embryo. For example, there may be a metabolite present which at the optimum temperature for growth appropriates the materials necessary for myosin formation.

The order of actin and myosin formation in embryos raised at 10° C. is opposite to that found in natural development. This result furnishes further evidence of the independence of actin and myosin formation one from the other[3,4].

This work was supported by a grant-in-aid for fundamental scientific research (No. 710267) of the Ministry of Education in Japan.

PHYSIOLOGY

Reconstitution of Cell Membrane Structure *in vitro* and Its Transformation into an Excitable System

THE formation of single, stable bimolecular lipid and proteolipid[1] membranes up to 10 mm.² in area has been accomplished routinely in 0·1 *M* saline solution by methods analogous to the formation of Hooke-Newton 'secondary black' in air soap films[2-4]. By forming such a membrane between two compartments filled with saline its transverse electrical properties can be measured, and controlled chemical investigations can be undertaken.

This experimental structure, invisible in transmitted light, appears as a faint grey sheen in reflected light at a large angle of incidence. It is grossly manipulable, resilient, self-sealing to puncture, liquid in the plane of the bilayer, stains with osmium tetroxide and is 60–90 Å. thick under the electron microscope. Electrical capacity is about 1μ F./cm.². Resistance is usually 10^7 but often greater than 10^8 ohm cm.² and is constant up to dieletric breakdown at 0·15–0·20 V. (2·5 × 10^5 V./cm.), whereupon the membrane shatters. It also breaks below *p*H 5·0 and above *p*H 9·0. In ionic gradients the unmodified membrane shows weak electrical polarization and poor ionic selectivity.

However, this inert structural barrier has been successfully modified by a variety of water-soluble macromolecules which spontaneously adsorb to it when added to the environmental solution. Some proteins adsorb but do not lower its resistance. Others adsorb and steadily lower the resistance to 10^3 ohm cm.² or less, probably by penetration and/or formation of channels.

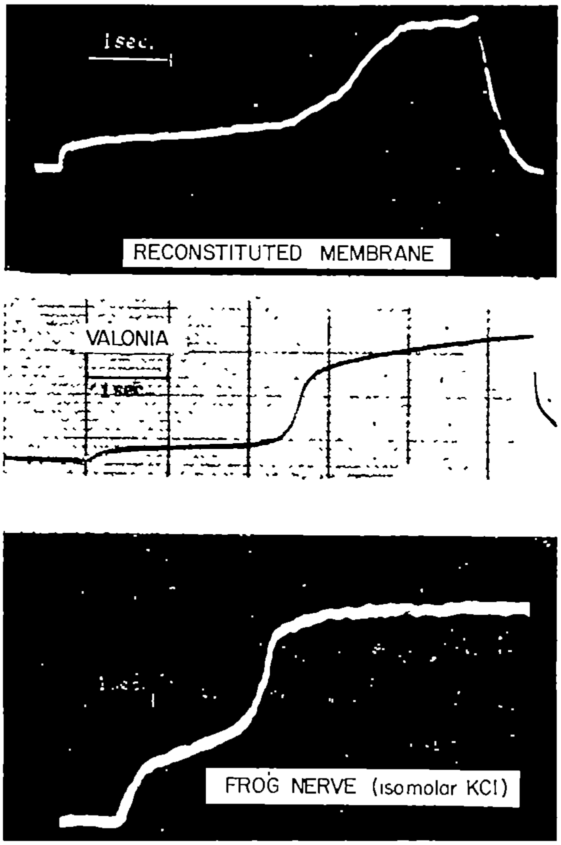

Fig. 1. Potential recordings of responses to applied rectangular currents. The membrane electromotance is very likely zero or close to zero in all three cases. Upper two are trans-membrane recordings, bottom record is proportional to trans-membrane potential of frog single node in 0·1 *N* potassium chloride (Middle figure reprinted by permission from Blinks, L. R., *J Gen. Physiol.*, **19**, 633; 1936)

One, as yet unidentified, heat-stable molecule obtained from bacterially de-sugared egg whites which can be precipitated by ammonium sulphate (50–100 per cent sat.), denatured by chloroform and has an estimated mol. wt. of 10^4–10^6 adsorbs, lowers the resistance and, in addition, regularly induces the following gating reaction to d.c. electrical stimulation. At a sharp and generally unidirectional threshold voltage, which can be varied by [Ca^{++}] between 15 and 50 mV., the resistance shifts 5-fold to a new steady value after a latency which changes inversely with applied potential (Fig. 1). Recovery is prompt, the phenomenon repeatable and indistinguishable in detail from the behaviour of the excitable alga, *Valonia*, in the 'variable resistance' state[5] and is similar to the resistance increase of the skin 'action potential'[6] and to the frog nerve 'action potential' in isotonic potassium chloride[7]. The above resistance-voltage kinetics, including the threshold, can be predicted quantitatively from the general theory of reaction-rates under the assumptions that the adsorbed molecules form a finite number of two state resistive channels (that is, gates) and that the number in each state is determined by the Δ F. between the two states and the applied potential.

Because these theoretical, mechanical, electron microscopic and electrical properties are like those attributed to the cell membrane and because this experimental membrane is made from solubilized lipids extracted from membrane structures of white matter, we suggest that it is reconstituted cell membrane structure. Evidently it can exist in stable form in the absence of all other cell components and, in addition, can show the cellular function of electrical excitability, and perhaps other cell functions as well, when the composition of the lipid phase and the nature of the adsorbed molecules are properly selected.

Some Extremely High Acuities of Taste for Phenylthiocarbamide

IN human population groups a primary dichotomy (so-called 'non-taster' and 'taster' classes with some overlap) in the distribution of thresholds of taste for phenylthiocarbamide (PTC) was established by the early work of Hartmann[1] and others. Falconer[2] noted the irregular nature of the distributions of 'non-taster' material; and Lugg and Whyte[3], from the results (corrected for the effects of age and sex) of their investigations of southern Chinese, European, southern Indian and Malay ethnic groups, considered these distributions to be potentially (if not always actually) bimodal, a view which was supported by subsequent work[4] on Negrito and Senoi subjects. They[3] also questioned the presumption that 'taster' material is always unimodally distributed; but it was realized[4] that the distribution irregularities might be due to sampling errors rather than to intrinsic causes. The question remained open, however, and it was hoped that clarification of the overall picture of threshold distributions might come with the accumulation of additional data from work on other ethnic groups.

Results of work recently done in Hokkaido on Japanese and Ainu ethnic groups and on persons of mixed origin support the view that 'taster' material is, potentially, not unimodally distributed. There is appreciable evidence that, apart from the earlier suggested category of 'high acuity tasters', a category of 'extremely high acuity tasters' exists in these, if not other, groups.

The PTC solutions used in these investigations comprise a series integrally numbered from zero, the concentration of solution numbered n being $2{\cdot}60 \times 2^{-n}$ gm. PTC/l. A subject demonstrates his ability to discriminate between solution n and solvent (distilled water) in a sorting trial, the chance of success by guesswork being 0·125, and his most likely threshold value[3] is $n + 0{\cdot}5$. The taste-quality he reports is not necessarily the characteristic quality, bitter, experienced with more concentrated solutions.

It was among the Kintak Bong Negritos of Malaya that the tasters of previously highest acuity were encountered[4], one subject succeeding with solution 18. His reaction in the trial was such as to suggest that he may have succeeded with at least solution 19 if it had been possible then to test him further. In the Hokkaido work it has been found necessary to extend the range to solution 24 in order to carry out the survey effectively. Of fifty 'pure' or almost 'pure' Ainu and of fifty Japanese subjects, seven in each sample succeeded with solution 18 or higher number; and of an extremely heterogeneous sample of fifty persons of mixed extraction containing many children in the 10–14-year age-range, a factor predisposing to more successes with solutions of higher number, twelve successes were recorded. In all, three subjects succeeded with solution 19, eight with 20, four with 21, three with 22 (one of them describing the taste as bitter and the other two as astringent), and one, a 14-year-old Ainu boy who described the taste as sweet, with 23.

Solutions 18 and 23 contain 9·9 and 0·31 μgm. PTC/l. and are $6{\cdot}6 \times 10^{-8}$ and $2{\cdot}1 \times 10^{-9}$ molar, respectively. The subject takes 2·5 ml. of solution (or solvent) into the mouth in each step of a sorting trial, representing $2{\cdot}5 \times 10^{-8}$ gm. or $1{\cdot}6 \times 10^{-10}$ mole or some 10^{14} molecules of PTC with solution 18, and 8×10^{-10} gm. or 5×10^{-12} mole or 3×10^{12} molecules with solution 23. If Moncrieff's[6] estimate is accepted, namely, that 0·05 ml. of solution, properly applied, is sufficient for taste-testing, the number of molecules of PTC involved would be 2×10^{12} with solution 18 (not 8×10^{9} stated earlier[5] as the result of a miscalculation) and 6×10^{10} with solution 23.

The Negrito subject's success with solution 18 ranked him as the most acute taster of any substance among human subjects examined up to that time[5]. Yet, of the 150 persons examined recently in Hokkaido some 17 per cent rank either in his company or (the 14-year-old Ainu boy *in excelsis*) considerably above him. Tasting acuities of this higher order lie far beyond any previously recorded and were utterly unexpected when the work was begun.

Proper acknowledgement of help received will be made elsewhere, when the full account of this work and discussion of its implications in anthropological studies are published. Mention can here be made only of the many forms of assistance rendered by Prof. S. Watanabe, but for whose prior interest the Hokkaido programme could not have been undertaken.

Hæmophilia and the Protease Inhibitor in Peanuts

Boudreaux and Frampton's report[1] on a hæmostatic factor in peanuts (*Arachis hypogaea*), orally active in hæmophilic patients, aroused great interest. Since these and other investigators have been unable to demonstrate restoration of blood coagulation in the treated patients, other mechanisms of action were suggested. Boudreaux and Frampton[1] considered vasoconstriction as a possible mechanism and they later found vasoconstrictive agents in ethanol extracts[2]. Verstraete *et al.*[3] extracted with ethanol from the skins of peanuts hæmostatically active anthocyanidines and flavones.

Peanuts contain a protease inhibitor[4], which might delay fibrinolysis. Retardation of fibrinolysis could then counteract the delayed formation of fibrin in hæmophilia, producing a hæmostatic effect[5]. This concept is supported by the findings that consumption of peanuts produced a decrease in spontaneous fibrinolytic activity in normal persons[5] and in patients with classical hæmophilia (Factor VIII deficiency)[6]. Increase in blood of an inhibitor against fibrinolysis has also been reported[7].

Thus patients deficient in Factor IX (*PTC*, Christmas factor) should also respond to treatment with peanuts. In our preliminary work[8] a group of 4 patients with Factor IX deficiency responded to flour prepared from raw peanuts similarly to a group of 6 patients with Factor VIII deficiency. Similar observations were made by Verstraete *et al.*[3]. Furthermore, Boudreaux, who first noticed the effect on himself, has since been found to be deficient in Factor IX and not in Factor VIII as originally reported (personal communication).

If the hæmostatic effect of peanuts is mediated through the fibrinolytic system little effect could be expected in patients with serious relapse in their hæmorrhagic condition, and only milder episodes could be improved. This is in agreement with observations made by several investigators, and could explain the variable and erratic clinical results. We have seen confirmation of this concept in our own work[8], and Moers and den Ottolander[9] reported especially on the ineffectiveness of peanuts in grave hæmorrhagic cases.

Large quantities of roasted peanuts are required. Boudreaux[1] recommended 180 gm. of the flour a day and the same amount was used by Verstraete[3]. The powder prepared by us from unheated peanuts with a cold extraction process had a high anti-protease activity and was used in a correspondingly smaller dose (8 gm. a day). Other authors using raw, unroasted peanuts[6,9] administered 20–50 gm. a day. For use in future studies we have made a concentrated preparation of the protease inhibitor as follows:

Cold prepared flour (200 gm.) from hexane extracted raw peanuts (supplied by Mecodumex Ltd., Copenhagen) was stirred for 1 hr. with 1 l. water and 2 gm. calcium hydroxide. After centrifugation calcium was removed with carbon dioxide and the final supernatant (800 ml.) was precipitated with 3 vol. acetone. The precipitate was isolated, resuspended in 200 ml. water, and made slightly acid (litmus paper) with citric acid (12 ml. of a 10 per cent solution was required). The suspension was precipitated with acetone followed by acetone and ether until dry. 5·7 gm. of a whitish powder was obtained, which contained nearly all the inhibitor activity of the original flour (assayed by the fibrin plate method against a plasminogen activator prepared from pig heart tissue).

This inhibitor preparation was tried (300 mgm. a day) in one of our patients (Factor VIII deficiency) with results similar to those obtained with the crude flour. The purified preparation was tested by Dr. Boudreaux for vasoconstrictor activity with negative results (personal communication). In samples of ethanol extract supplied by Dr. Boudreaux we found little or no protease inhibitor.

With the purified product available for trial on a large number of patients it should be possible to demonstrate first if a hæmostatic factor is present in the ethanol fraction or remains in the flour, and secondly whether our concept of a mediation of the effect through the fibrinolytic system, causing a change in the dynamic hæmostatic balance, is valid and can explain the limitations of this treatment.

This investigation was aided by the Josiah Macy, Jr. Foundation, New York, and the U.S. Public Health Service, National Heart Institute (*HE*-05020)

Acetylcholine Sensitivity of Rat Diaphragm maintained in Organ Culture

MUSCLE fibres in the diaphragm of adult rats are sensitive to externally applied acetylcholine only in the region of the nerve muscle junction and its immediate surroundings. If the motor-nerve is cut, the area of muscle membrane sensitive to acetylcholine increases until it involves the whole fibre surface[1].

Until now the development of generalized chemosensitivity has been examined only after the denervated muscle has remained *in situ* for the required time (about 1 week). Therefore, it was desirable to find out if a similar process of sensitization would occur in muscles kept *in vitro*, and for this purpose the organ culture technique described by Trowell[2] was used.

Strips of muscle, about 5 mm. wide, were cut from the diaphragm of rats. The muscle fibres and attached ribs were then cultured in the chemically defined medium *T*8 (ref. 2) at 36–37° C., with a gas phase of 5 per cent carbon dioxide in oxygen. After 5–6 days the muscles were taken out of the culture chamber and their response to acetylcholine was examined. Acetylcholine was applied to single muscle fibres by micro-ionophoresis through a fine pipette (less than 1μ at its tip), and it was found that the entire surface of many muscle fibres had become sensitive to acetylcholine. Potentials produced by acetylcholine applied to a muscle fibre at a region normally insensitive to the drug are shown in Fig. 1.

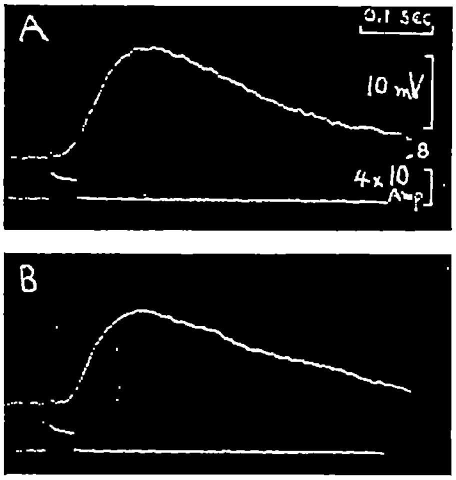

Fig. 1. Potential changes produced by micro-ionophoretic application of acetylcholine to a fibre, in a muscle cultured for 5 days at 37° C. Upper traces record intracellular potential while lower traces monitor the current which flows through the acetylcholine pipette and releases the drug. Acetylcholine was applied at a point about 1 mm. from the end of the muscle fibre in *A* and 1·5 mm. in *B*. Temperature, 14° C.

It was further observed that cholinesterase, which is normally concentrated at the site of the neuromuscular junction[3], is still active and localized in the same region of the muscle fibres after 5–6 days *in vitro*.

The main conclusions derived from these experiments are: (*a*) that adult skeletal muscle fibres can be kept alive in organ culture; (*b*) that the development of generalized chemo-sensitivity in muscle does not require the participation of other organs in the body. The muscle fibres themselves (and the synthetic medium) provide all that is required to produce the changes in the muscle fibre membrane which make it react to drugs.

HÆMATOLOGY

Significance of High γ-Globulin Content in Burmese Serum

THE γ-globulin content in serum of Indians[1,2], Africans[3] and Burmese[4] was found to be significantly higher than that reported for Europeans[5,6] and Americans[7].

An explanation for this finding remains largely a matter of speculation. It has been thought that people with high γ-globulin are those with greater immunity consequent on repeated exposure to infections[8]. However, total quantity of γ-globulin cannot be used as a criterion of immunity. The total quantity of circulating antibody to any particular antigen was so small that its presence cannot be detected electrophoretically, and even after repeated inoculations, which result in hyperimmunity, there was no correlative changes in the electrophoretic pattern[8].

An elevated serum γ-globulin is one of the most common abnormalities in liver diseases[9]. It has also been reported that there are non-contagious diseases peculiar to the tropics and sub-tropics the aetiology of which is unknown or uncertain and which are responsible for much ill-health and high mortality in the communities concerned. It was suggested that in these cases liver damage is involved resulting from a toxic factor derived from food or intestine helminths[10].

These observations led to the present work to elucidate if high γ-globulin value in Burmese serum involves liver diseases. A mixed sex group of 103 normal Burmese, ages ranging from 17 to 47 years, who gave no history of liver impairment were examined. Total serum protein was estimated by the biuret method, as described by Reinhold[11]. Freeze dried serum (batch number 9) of Glaxo Laboratories, Ltd., was used as the standard. Serum protein fractionation was done electrophoretically with barbitone buffer *p*H 8·6, 3 *MM* Whatman paper and set for 18 hr. Excess bromophenol blue dye was washed with 'Dioxan' and ether. After scanning, areas under graph were measured for relative serum protein contents. Daily amino-acid nitrogen excretion in urine was determined by the formol titration method[12]. Ammonia nitrogen was determined to get the true amino-acid nitrogen.

It was found that Burmese serum protein measured 6·7 ± 0·028 gm. per cent (mean ± *S.E.*) and urinary amino-acid nitrogen daily excretion was found to be 0·5 ± 0·033 gm. (mean ± *S.E.*). Electrophoretic analysis showed serum protein values as given in Table 1.

Table 1. RELATIVE PERCENTAGE OF PROTEIN VALUES (MEAN ± *S E*)

Albumin	43 59 ± 1·61
α-1-Globulin	6·46 ± 0·94
α-2-Globulin	12·73 ± 0 59
β-Globulin	12·28 ± 0 87
γ-Globulin	24·94 ± 0·86

Results show low albumin value. Values of α-1, α-2 and γ-globulin are high. It was found that one of the fairly constant effects of parenchymatous hepatic disease is reduction in the serum albumin[13]. High amino-acid nitrogen excretion was also found in

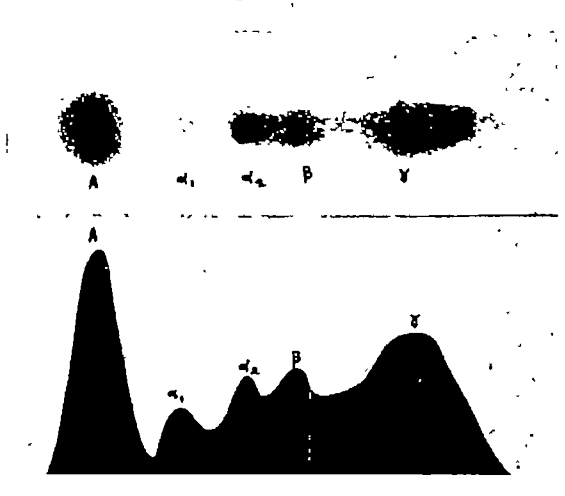

Fig. 1. Electrophoretic pattern in Burmese serum. *A*, Albumin; α_1, α-1-globulin; α_2, α-2-globulin; *β*, β-globulin; *γ*, γ-globulin

this series. Further work is in progress and details will be published elsewhere.

PHARMACOLOGY

Effect of Monoamine Oxidase Inhibitors on the Behaviour of Rats in Hall's Open Field

Although numerous methods are available for assessing the potency of monoamine oxidase inhibitors *in vivo*, these almost invariably rely either on the direct measurement of tissue levels of catecholamine, serotonin or some metabolite thereof[1], or on the ability of the inhibitor to potentiate or nullify the effects of some other drug such as 5-hydroxytryptophan, tryptamine or reserpine[2]. Direct behavioural effects of monoamine oxidase inhibitors at low doses are usually slight or detectable only by use of conditioned response techniques[3].

In a series of aralkylhydrazines we have noticed a correlation between the monoamide oxidase inhibitory powers of these compounds and their effectiveness in producing changes in the behaviour of normal untrained rats in Hall's open field[4]. Individual rats were placed for a period of 3 min. in an open drum 6 ft. in diam. with 2 ft. high walls. The floor of the drum was divided into foot squares. The number of times the rat preened, reared and defæcated were counted as well as the number of fæcal boluses passed and the number of squares traversed.

The results are shown in Table 1.

Inhibition by monoamine oxidase *in vitro* was measured by incubating various concentrations of the inhibitor with guinea pig liver mitochondria for 15 min. at pH 7·4 and 25°. Tyramine was then added and the residual monoamine oxidase was assayed by the dinitrophenylhydrazine method[5]. The concentration giving 50 per cent inhibition (I_{50}) was determined by interpolation. In the experiments in column (*a*) semi-carbazide, which is required in the assay, was present together with the enzyme and inhibitor; in those in column (*b*) semicarbazide was added with the tyramine. Although there are some quantitative differences in the results obtained by these two different procedures, the general order of activity was not greatly affected.

The doses of drug producing behavioural changes are of the same order as those required to counteract the sedative effects of reserpine. The effects observed with the aralkylhydrazines persisted at least 24 hr., consistent with the very slow recovery of the inhibited enzyme[6]. The effects with harmine were much shorter (< 3 hr.), harmine inhibition of monoamine oxidase being readily reversible[7].

The relationship of the behavioural changes to the anti-depressant action of monoamine oxidase inhibitors is not clear, particularly as different aspects of behaviour were affected at the minimal effective dose with different compounds. It is, however, interesting to compare these results with those obtained with tranquillizers such as chlorpromazine where all aspects of behaviour studied in the open field were depressed. This effect has also been reported by Ryall[8].

Variations in Inorganic Pyrophosphatase and Glutaminase in the Liver and Brain of Mice poisoned by Carbon Tetrachloride

J. Hagen[1] has shown that carbon tetrachloride poisoning in factory workers induces extensive biochemical and metabolic changes in the central nervous system, liver and kidneys. On investigating the action of carbon tetrachloride in mice, Frunder *et al.*[1-5] found significant changes in the metabolism of carbohydrates, proteins and lipids in the liver parenchyma.

We have examined the effect of carbon tetrachloride (oil solution) injected into mice[3] on liver glutaminase and pyrophosphatase, 2 hr. as well as 48 hr. after the injection, when the regenerating process is already in progress[4,5].

In Table 1 it is shown that 24 hr. after the injection, glutaminase is partially inactivated in the brain as well as in the liver. After 48 hr. there is a tendency towards recovery. The variations in pyrophosphatase are recorded in Table 2; it may be seen that, in the liver, the activity of this enzyme decreases 2 hr. following the injection, and continues to fall even after 48 hr. In the brain this enzyme decreases after 2 hr. but tends towards recovery after 48 hr. Glucose administration partially protects this enzyme.

Table 1. LIVER GLUTAMINASE WAS DETERMINED IN BUFFER SOLUTION AT pH 7·4 (REFS. 9 AND 10), BRAIN GLUTAMINASE WAS DETERMINED IN PHOSPHATE BUFFER SOLUTIONS AT pH 8·5 (REFS. 10 AND 11)

	M.mol. deaminated glutamin/gm. tissue	
	Liver	Brain
Normal controls	0·402	1·660
2 hr. after injection of carbon tetrachloride	0·280	0·860
48 hr. after injection of carbon tetrachloride	0·307	1·056

Table 2. VARIATIONS IN INORGANIC PYROPHOSPHATASE DUE TO ACTION OF CARBON TETRACHLORIDE

Enzymatic activity determined for pyrophosphatase in the liver (according to Rafter, ref. 7), and brain (according to Seal and Binkley, ref. 8), in total homogenates. Determinations were carried out by measuring the phosphorus using the Firske–Suborov method, using methol-methobisulphate as a reducer

	Liver		Brain	
	− Glucose	+ Glucose	− Glucose	+ Glucose
Normal controls	8·12	8·20	12·80	12·75
2 hr. after injection of carbon tetrachloride	5·40	6·81	8·90	10·20
48 hr. after injection of carbon tetrachloride	3·35	4·06	9 60	11·78

Our investigations confirm Frunder's concept[4,5] according to which carbon tetrachloride selectively attacks the cellular mitochondrial apparatus, both enzymes being sited in the mitochondria. It is believed that carbon tetrachloride alters especially —SH enzymes, both enzymes having also —SH groups. Reactivation by glucose apparently accounts for these effects as was shown by Rapoport and Schneider[6] for erythrocite pyrophosphatase.

Structure-action Relationships among Drugs acting on Connective Tissues (Anti-rheumatic Agents)

CONVENTIONAL assays for anti-inflammatory (anti-rheumatic) drugs frequently measure the inhibition by a drug of granuloma formation, induced by subcutaneously implanting foreign bodies (cotton pellets, plastic sponges, agar gels, etc.) in small laboratory animals. Other *in vivo* assays for anti-inflammatory activity, for example, inhibition of exudate formation by formalin-blisters, indicate the relationship between the activity of a compound in suppressing tissue inflammation and as an inhibitor of *de novo* connective tissue formation. This latter property is readily assayed *in vitro* by measuring the action of a drug on induced biogenesis of cartilage in tissue cultures[1] or on the biosynthesis of mucopolysaccharides in connective tissue slices[2]. In both these *in vitro* systems, anti-inflammatory corticosteroids and salicylate strongly inhibit the incorporation of inorganic sulphate-^{35}S ($^{35}S_i$) into mucopolysaccharides, thus reproducing the known effect of these drugs on $^{35}S_i$ incorporation into connective tissue polysaccharides *in vivo*. Using the techniques described[2], it has now been found that these particular drugs and other anti-inflammatory drugs such as phenylbutazone, chloroquine, their respective active congeners (oxyphenbutazone, sulphinpyrazone, hydroxychloroquine, etc.) and cinchophene, each inhibit the incorporation of glucose-U-^{14}C, acetate-1-^{14}C and $^{35}S_i$ into cartilage mucopolysaccharides and of $^{35}S_i$ into corneal mucopolysaccharides *in vitro* (Table 1). These drugs were active inhibitors at concentrations in the incubation medium which corresponded to the plasma levels required for therapeutic action (for example, salicylate, phenylbutazone). Sodium aurothiomalate had no significant effect, but thiomalic acid (10^{-3} *M*) and many other thiols (thiosalicylic acid, cysteamine) were potent inhibitors of polysaccharide sulphation.

Table 1. EFFECT OF SOME DRUGS ON THE BIOSYNTHESIS OF MUCOPOLYSACCHARIDES *in vitro*

Drug	Concentration $\times 10^{-3}$ *M*	Cartilage from glucose-^{14}C (per cent)	PS-^{14}C from acetate-^{14}C (per cent)	PS-^{35}S Cartilage (per cent)	PS-^{35}S Cornea (per cent)
None		100	100	100	100
Salicylate	4	45	65	40	20
Salicaldehyde	1	21	42	28	5
p-Hydroxybenzaldehyde	1	84	107	95	95
Phenylbutazone	0·5	38	25	28	20
Di-*p*-carboxyphenylbutazone	1·2	100	100	100	100
Chloroquine diphosphate	1	32	59	26	30
Cinchophene	1	33	57	33	28
Hydrocortisone	0 25	35	39	54	62

Mucopolysaccharides (PS) were isolated from slices of young cattle costal (or tracheal) cartilage and corneas, incubated with either glucose-4-^{14}C, acetate-1-^{14}C or $Na_2{}^{35}SO_4$: ^{14}C and ^{35}S content of PS in drug-incubated tissue slices is expressed as percentage of PS-^{14}C or PS-^{35}S in tissues incubated without drugs.

Many chemical analogues of these drugs were tested, usually at 10^{-3} *M*, using the inhibition of $^{35}S_i$ incorporation into cartilage and corneal polysaccharides, as an index of activity. The potency could be correlated with at least two physical properties: (1) ability to form complexes with metal ions; (2) lipophilic character, favouring partition into lipid rather than aqueous phases.

Among salicylate analogues, potency declined in the series; *O*-cresotate, salicylate, 2,3-dihydroxy-benzoate, 2,4-, 2,5- and other dihydroxybenzoates = 4-aminosalicylate (PAS) = 5-sulphosalicylate (all inactive) and in the parallel series: ortho-vanillin, salicaldehyde, 2,4- and 2,5-dihydroxybenzaldehydes, 2,4,6-trihydroxybenzaldehyde, 2,4- and 2,5-dihydroxybenzaldehydes, 2,4,6-trihydroxybenzaldehyde, pyridoxal, pyridoxal-5-phosphate. Potency increased in the series: salicylamide, salicylate, salicaldoxime, salicylanilide, 3,5-dihydroxy-naphth-2-oate, salicaldehyde, *o*-monohydroxynaphthoates, *o*-monohydroxynaphthaldehydes — the latter were strong inhibitors at 2×10^{-5} *M* and approximately 100 times as potent as salicylate. Saligenin, pyridoxine, *o*-methoxybenzoate, *o*-hydroxyacetophenone, methyl salicylate, *m*- and *p*-hydroxybenzaldehydes, 2,4-dimethoxybenzaldehyde, *m*- and *p*-hydroxybenzoates and other hydroxynaphthoates were almost devoid of *in vitro* activity and formed only weak, or no, complexes with ferric ions in ethanol.

Phenylbutazone (butazolidine) exists at physiological *p*H predominantly as the enol form (about 90 per cent, calculated from the optical density at 264 mμ) and will form complexes with metal ions in ethanol. The methyl enol-ether will not and is inactive as a drug *in vitro* and *in vivo*[3]. Among phenylbutazone (PB) analogues, potency decreased with increasing water solubility in the series: PB, 4-*n*-propyl analogue, oxy-PB, mono-*p*-carboxy(phenyl)-PB, di-*p*-carboxy(phenyl)-PB. This last compound is inactive *in vitro*, only feebly active *in vivo*[4]. Some pyrazol-5-ones exhibited activity *in vitro*, which diminished in the series: 1,3-diphenyl-pyrazol-5-one, picrolonic acid, 1-phenyl-3-methyl-pyrazol-5-one, 1-phenyl-2,3-dimethyl-pyrazol-5-one (antipyrine, and inactive). These pyrazolones formed highly coloured complexes with ferric chloride in ethanol. With the possible exception of antipyrine, they can exist as enols in aqueous solution.

Among analogues of cinchophene (2-phenyl-quinoline-4-carboxylic acid), activity decreased in the series: cinchophene, 2-hydroxyquinoline-4-carboxylic acid, isonicotinic acid (inactive). Hydroxychloroquine (plaquenil) was less active than chloroquine (resochin), in turn less potent than mepacrine (quinacrine, atebrin) and santoquin (3-methylchloroquine). These antimalarials only inhibited polysaccharide biosynthesis after a measurable time lag (1–2 hr.), reminiscent of their delayed therapeutic action *in vivo*[5]. Their drug action was not reversible. The action of all other drugs tested was reversed by washing the drug-incubated tissues and transferring them to a drug-free medium.

8-Hydroxyquinoline (oxine) was a potent inhibitor *in vitro* and has been shown to exhibit anti-inflammatory properties *in vivo*[6]. 2-hydroxyquinoline was inactive *in vitro*. Oxine, salicylic acid, salicaldehyde[7] and a number of anti-inflammatory corticosteroids[6] will chelate cuprous and ferrous ions in non-aqueous media. These collected observations and the inhibitory activity of lipophilic thiols able to form chelates (but not cysteine and glutathione) suggest that ability to interact with metal ions in (or across) a lipid phase may be the chief determinant in conferring anti-inflammatory properties on a compound, rather than ability to uncouple oxidative phosphorylation *per se*[8,9]. Extension of this hypothesis to the corticosteroids may explain the greater anti-inflammatory activity of methyl derivatives (dexamethasone, medrol, paramethasone)[10,11] and enol ethers[12] than the parent steroids, and the striking increase in anti-inflammatory activity of steroid 16α-, 17α-diols upon transformation to the corresponding acetonides[11,13].

OPHTHALMOLOGY

Anti-viral Activities of Several Iodinated Pyrimidine Deoxyribonucleosides

KAUFMAN[1] has reported that 5-iodo-2′-deoxyuridine (IUDR or IDU), the deoxyribonucleoside of 5-iodouracil, is effective in controlling herpes simplex keratitis in rabbit and human eyes. IUDR[2], 5-iodo-2′-deoxycytidine (ICDR), that is, the deoxyribonucleoside of 5-iodocytosine[3], as well as their 3′,5′-diacetyl derivatives, were synthesized with the view of examination of them as potential chemotherapeutic agents in cancer. Both IUDR and ICDR have been shown to inhibit the biosynthesis of deoxyribonucleic acid (DNA) and, in addition, to be incorporated as IUDR 5′-phosphate into DNA, in place of thymidine 5′-phosphate[4-6]. This communication confirms the efficacy of IUDR in the treatment of an infection of rabbit eyes with a DNA-virus, namely, herpes simplex, and describes a similar anti-viral activity for ICDR and 3′,5′-diacetyl-5-iodo-2′-deoxyuridine (Ac$_2$IUDR); in addition, a preliminary test of 3′,5′-diacetyl-5-iodo-2′-deoxycytidine (Ac$_2$ICDR) has indicated that this derivative is also active.

Both eyes of 14 and 17 rabbits in the first and second experiment, respectively (Table 1), were infected with the *MP* strain of herpes simplex after scratching the cornea; in all cases, marked lesions developed within 3 days. In the first experiment, the left eyes were treated with the test compounds dissolved in Hanks's balanced salt solution supplemented with penicillin (500 u./ml.) and streptomycin (100 μgm./ml.), while the right eyes were treated with only the antibiotic agents in the saline solution. Two drops of the solution were placed into each conjunctival sac at hourly intervals for 10 hr. and at intervals of 2 hr. for 14 hr.; this regimen of dosage was repeated during a second 24-hr. period. The animals were divided into 2 groups (Table 1).

After treatment for 48 hr., all the right eyes, to which antibiotic agents only were administered, showed severe corneal lesions, while the left eyes showed marked regression of the lesions from the pre-

Table 1. Comparison of Various Iodinated Pyrimidine Nucleosides in the Treatment of Herpes Simplex Keratitis

Exp. No.	Compound administered	No. of eyes treated	Concentration of compound mgm./ml.	Relative molar concentrations	Clinical effectiveness
1	IUDR	7	1·24	1·0	+ + + +
	Ac_2IUDR	7	1·7	1·1	+ + + +
	None	14	—	—	0
2	IUDR	6	1·0	1·0	+ + + +
	IUDR	6	4·0	4·0	+ + + +
	ICDR	6	1·0	1·0	+ + + +

	IUR	5	4·0	4·0	0
	None	6	—	—	0

treatment condition. The right eyes had large areas of epithelial ulceration with circumcorneal congestion and in many cases an anterior uveal reaction. Ulceration was minimal or absent in the left eyes and none of these eyes showed anterior uveal reaction. In the concentrations used, IUDR and its diacetyl derivative were both effective in controlling infection.

In the second experiment, a comparison was made of IUDR and ICDR, each at two equivalent concentrations (Table 1). In addition, it was shown that 5-iodo-uridine (IUR), the ribonucleoside of 5-iodouracil, a compound which undergoes metabolic degradation in a manner similar to that of IUDR, but exerts no inhibitory effect on the biosynthesis of DNA, is without anti-viral activity. The compounds were dissolved in the manner described above and 2 drops of the appropriate solution were placed into each conjunctival sac at intervals of 1 min. for 5 min. and thereafter at intervals of 0·5 hr., but for only 8 hr.; this regimen was repeated during the subsequent 2 days. All the control eyes, as well as those treated with IUR, developed severe corneal lesions, whereas in those eyes which received IUDR or ICDR in each of the concentrations used, the lesions regressed strikingly, in a manner similar to that observed in the first experiment.

This more intensive but abbreviated regimen of treatment appears to be as effective as that used in the first experiment and no evidence of corneal irritation was observed. In the concentrations administered, IUDR and ICDR appeared to be equally efficacious.

In a preliminary experiment, in which the anti-viral activity of ICDR at 5·1 mgm./ml. was shown, its diacetyl derivative also was active. Further experiments with these four compounds will be required in order to determine whether there are significant qualitative or quantitative differences between these iodinated pyrimidine deoxyribonucleosides. It is clear, however, that each compound has marked activity in prevention of spread and in causing the regression of the severe corneal lesions caused by this pathogenic DNA-virus.

The mechanism of action of IUDR as an inhibitor of the biosynthesis of DNA has been discussed in several papers[4,5,7–9] and has been attributed to the intracellular formation of phosphorylated derivatives of IUDR. The concept of obtaining a metabolically more stable compound than is the case with 5-bromo- and 5-iodo-2′-deoxyuridine, through the formation of the corresponding derivatives of 2′-deoxycytidine, has been discussed in some detail elsewhere[9]. Suffice it to say here that ICDR, which is also much more thermostable and soluble than IUDR, acts as a reservoir-form of IUDR and of its 5′-phosphorylated derivatives, and that these compounds inhibit the utilization of thymidine and its 5′-phosphorylated derivatives, normal precursors of DNA; in addition, as has been shown elsewhere[5,6], 5-iodo-2′-deoxyuridine 5′-phosphate, formed metabolically from either IUDR or ICDR, can enter DNA in place of thymidine 5′-phosphate. It is proposed that, in this manner, the replication of the DNA-virus either is inhibited or a 'fraudulent' viral DNA is formed that fails to replicate, or both. The corneal epithelium appears to offer an unusual opportunity for selective chemotherapeutic inhibition of the replication of a pathogenic DNA-virus, in circumstances that avoid the toxicity of these agents for reproducing mammalian cells.

The 3′,5′-diacetyl derivatives of IUDR and ICDR were designed to achieve greater lipid-solubility than is exhibited by the parent compounds, with the view of two possible applications: one, oral administration in systemic chemotherapy[9], and two, the local treatment of viral lesions of the mucous membranes and skin. The results of the experiments described herein show that the diacetyl derivatives are converted, presumably by the corneal epithelial cells, to the active metabolites. Although the relative activities of these and the parent compounds have not yet been determined, the clinical importance of the application of these agents in the chemotherapy of herpes simplex lesions of the cornea justifies this report of the confirmation and extension of the findings of Kaufman[1].

Effect of Fluorinated Pyrimidines on Herpes Simplex Virus

Several reports have appeared recently regarding the effects of 5-fluoropyrimidines on nucleic acid metabolism[1–10]. One of these compounds, 5-fluorouracil, has been shown to exert a profound effect on the quantity of thymine component of nucleic acids, perhaps by interfering with the methylation of thymine[1,2,8]. Other investigators have shown that this fluoropyrimidine can be incorporated into RNA of tobacco mosaic virus, *E. coli*, mouse tumours and rat liver[3-7,9,10]. Horowitz *et al.* have also examined the effect of several other fluoro-derivatives as well as 5-fluorouracil on the synthesis of bacterial proteins and nucleic acids[11]. These investigators found that the 5-fluoropyrimidines invariably inhibited the synthesis of DNA in several strains of *E. coli*.

These observations suggested the possibility that one or more of the 5-fluoropyrimidines might have a similar effect on nucleic acid metabolism in the herpes simplex virus.

The virus was grown on the chorioallantoic membrane of the chick embryo. In view of the repeated passages of virus required for this experiment, the virulence and viability of the virus were checked at alternate passages by inoculation into mouse brain and by adding anti-herpetic horse serum to one or two allantoic membranes. The effect of 5-fluorodeoxyuridine (5-FDU) and 5-fluorouracil (5-FU) (both kindly supplied by Dr. W. E. Scott of Hoffmann-La Roche, Inc.) on the growth of herpes simplex virus and on nucleic acid synthesis was investigated by adding 5 μgm. of 5-FDU or 5-FU in 0·1 ml. sterile water to each membrane at two different time-periods. These analogues were either added at the time the allantoic membrane was inoculated with a virus suspension or 24 hr. after the initial virus inoculation (at which time pock-forming units are already visible). In the control experiments, saline was substituted for the fluoropyrimidines. All the membranes were removed after 48 hr., the number of pock-forming units were counted and the virus collected from the membranes according to Serry's method[12]. Nucleic acids were extracted according to the method of Brown and Martin[13] and measured by spectral assay. A modification of Ceriotti's method[14] was used for measuring DNA and the orcinol method[15] was used for RNA.

In those experiments in which 5-FU was used there was no apparent effect on virus growth (as measured by the number of pock-forming units per membrane) nor on the total amount of nucleic acid extracted (expressed as μgm. per pock-forming units). In both the control and 5-FU experiments the number of pock-forming units (48 hr. after inoculation with virus) averaged 250–300 per membrane.

When 5-FDU was used, there was a very marked decrease in the number of pock-forming units per membrane. Depending on the dilution of virus used at the time of inoculation, virus growth was inhibited by 70–100 per cent after 48 hr. Fig. 1 shows a control membrane containing 280 pock-forming units while Fig. 2 shows a representative membrane to which 5 μgm. of 5-FDU was added 24 hr. after inoculation with the virus. There are only 8 pock-forming units present in this membrane, representing more than 97 per cent inhibition of growth. When 5-FDU was added at the time of viral inoculation, no growth was observed in these membranes.

The results of these experiments indicate that 5-FDU is a potent inhibitor of herpes simplex virus. Since this virus attacks the corneal epithelium initially it should be particularly sensitive to the action of 5-FDU and preliminary clinical investigations indicate that this drug may prove to be effective in the therapy of herpes simplex keratitis. (It is interesting to note that a closely related compound, 5-iodo-2 deoxyuridine, has recently been used with apparent clinical success in the therapy of herpes keratitis[16].) Preliminary evidence also indicates that 5-FDU used in 0·1–0·5 per cent concentration does not affect the epithelium of the rabbit cornea nor does it inhibit the rate of re-epithelialization of abraded corneas. However, from observations on these membranes in which there was less than 90 per cent inhibition of herpes virus, there is the possibility that injudicious use of this compound may be followed by a rebound phenomenon which would indicate that all patients should be watched carefully for 2–3 weeks after therapy has ceased for evidence of a recurrence.

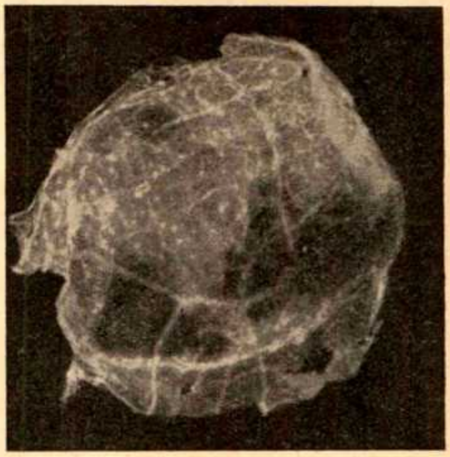

Fig. 1. Chorioallantoic membrane containing 280 pock-forming units (herpes simplex virus)

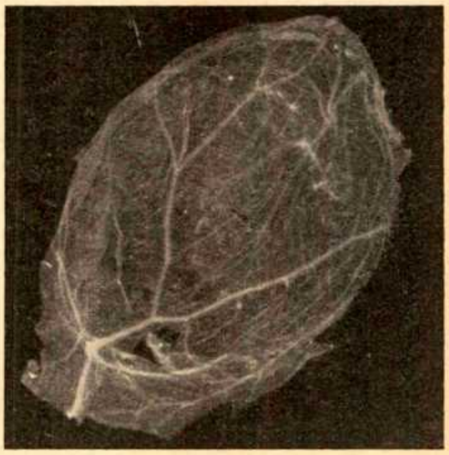

Fig. 2. Marked inhibition of herpes simplex virus growth (eight pock-forming units) on chorioallantoic membrane to which 5 μgm. of 5-FDU were added

The results with the other fluoropyrimidine used in this experiment are interesting since there was no apparent effect on viral replication nor on nucleic acid synthesis. Present evidence indicates that in certain bacteria 5-FU interferes with the synthesis of the thymine component of nucleic acids by inhibiting the enzyme responsible for the introduction of the methyl group[11]. These experiments indicate that 5-FDU inhibits the synthesis of DNA thymine in herpes simplex virus while 5-FU has no effect on DNA thymine synthesis in this virus. However, preliminary studies in our laboratory indicate that herpes simplex virus may contain some RNA and there is the possibility that 5-FU is being incorporated into the nucleic acids. This possibility is now being investigated.

BIOLOGY

Production of Fæcal Pellets in the Wild Rabbit

Professional rabbit-catchers in Pembrokeshire, when asked what was the average number of fæcal pellets dropped by the wild rabbit (*Oryctolagus cuniculus* L.) in 24 hr., estimated the 'output' to be between 20 and 50 pellets. They based their estimates of numbers of rabbits present in a warren on these figures for pellets visible on the ground; which figures had, of course, to be multiplied by the number of days during which, they believed, a fæcal pellet survived above ground—about one week in wet, and several weeks in dry or frosty, weather—before it disintegrated or disappeared.

During the course of a four-year investigation[1] (grant-aided by the Nature Conservancy) of the wild rabbit in enclosures at Orielton, near Pembroke, this disappearance or 'decay rate' of rabbit pellets was found to vary as widely as the rabbit-catchers had estimated—between a few days to several weeks, depending on temperature, humidity and the activity of the dung-eating ground fauna. But the average production of fæcal pellets proved to be much higher than 20–50 in 24 hr.

An adult male wild rabbit at Orielton was taken from one of the large (one-acre) enclosed study warrens and placed in a contiguous enclosure sufficiently large—250 sq. yd.—to provide it with ample grazing. For cover, an artificial burrow was provided with a concrete-lined sleeping chamber to which this buck retired to rest during the day. His behaviour could be watched through a plate-glass window protected by an observation hut; and over several weeks he became accustomed to artificial light when this was switched on during periods of observation. Most of his time underground he slept, occasionally preening and re-ingesting fæcal pellets collected at irregular intervals from the anus.

Neither during re-ingestion nor during any other time spent underground was this male or any other rabbit, male or female (observed at intervals over three years in this artificial burrow and sleeping chamber), seen to drop any pellets or urinate below ground. The entry–exit passages and the sleeping chambers were thus kept dry and sanitary. All fæcal pellets that were not re-ingested were dropped outside on the grazing area.

Several weeks after this male had settled down in isolation, but within close proximity to other rabbits on the other side of the wire-netting fence, and when he appeared to be behaving naturally, all pellets were cleared from his enclosure on January 15, 1958. Each morning afterwards, until February 10, the pellets in the enclosure were collected, counted and removed. After an interval of seven weeks, on April 1, 3,254 pellets were collected—all surviving over this interval—and for 13 days following collections were made daily.

In result there was a very wide variation (see Table 1), from the lowest of 116 pellets after the first 24 hr. of the experiment to a top yield of 522 on April 14.

Table 1. Number of Fæcal Pellets produced by an Adult Male Rabbit

3	387		14	522	

The daily production in January and early February was probably affected by cold weather (with snow on January 21–22). Over the first 26 days the average daily yield was 276 pellets. In thirteen days of April the average was 446 pellets a day. When an adult doe was introduced on April 14, production over four days averaged 448 pellets a day per rabbit (Table 2).

Table 2. Production of One Pair of Adults

April 15	822
16	927
17	1,067
18	770

Although figures for captive animals are open to objection, it is interesting to compare them with figures for free-ranging animals. In captivity at Orielton a 9-month-old tame rabbit in a hutch, supplied with abundant green food, produced 302 pellets in 24 hr. In captivity, the cottontail, *Sylvilagus floridanus mearnsii*, averaged 320 pellets a day at 3–4 weeks old[2]. Trippense[3] records that two adults of the same species averaged 265·6 pellets per 24 hr. Dalke and Sime[4] found about 500 pellets were produced by the cottontails, *S. f. mallurus* and *S. transitionalis*, per day over 44 days on a meagre diet of bark, twigs, and buds.

The daily variability and the wide difference between the winter and spring counts at Orielton are theoretically explicable as variations due to weather conditions affecting movement and appetite. In winter, rabbits (which are usually in fat condition in late autumn) appear to graze less and defæcate less. It is possible, but not proved, that in bad weather and snow, while remaining underground, they re-ingest more fæcal pellets than in summer. This would be a compensatory habit in idleness and shelter when grazing conditions are difficult.

Ultrastructure of the Sterilizing 'Knobbed-Sperm' Defect in the Bull

IT seems to be generally accepted that the galea capitis of the mammalian sperm plays an important part in the fertilization process although the details of this process are still unknown.

In a previous investigation of the ultrastructure of the sperm head in the bull a characteristic structure, that is, the apical body, situated at the front edge of the galea capitis, has been described[1].

In order to obtain a better understanding of the functional mechanism of this apical body it seems relevant to compare the ultrastructure of sperm heads from normal fertile bulls with that of sperm heads from non-fertile bulls, which are known to show a defect in the front part of the galea capitis. This type of sterility does exist. The defect is known as the well-characterized, so-called 'knobbed-sperm' defect or 'acrosomal-defect' described by various workers[2–6]. The defect has been demonstrated mainly in the Friesian breed and is genetically determined. The semen of such bulls shows a normal sperm concentration with practically normal motility. The only abnormality found is a somewhat rounded and slightly eccentric thickening in the front part of the sperm head easily seen in indian ink smears.

In May 1961, thanks to the generous co-operation of three British colleagues, we obtained two ejaculates from such a 2-year-old sterile Friesian bull. While investigating the breeding problem in the herd, semen from this bull was found to show the typical 'knobbed-sperm' defect in the heads of the majority of sperms.

The samples were sent by air to Copenhagen in a thermos flask. On arrival a motility of about 60 per cent was found and counts on indian ink smears revealed the defect in 87·4 and 87·2 per cent of the sperm heads. Other primary sperm abnormalities amounted to 2·4 and 2·0 per cent.

About 48 hr. after ejaculation, specimens were prepared for thin sectioning and electron microscopy as previously described[7]. However, in addition to 'Araldite' embedding[8] an embedding in 'Vestopal-*W*' (ref. 9) was used.

From the examination of a rather great number of electron micrographs of sections of sperm heads from this bull we find it justifiable to conclude that only the galea capitis of the sperm, and in particular the apical body, shows any morphological abnormalities. A great many transverse, longitudinal and median sagittal sections were studied, but no other region of the sperm head showed any defects and especially the nuclear part of the head presented a normal ultrastructure.

A survey field of sperm from the sterile bull is shown in Fig. 1. A sperm head cut through the median sagittal plane is seen in the centre of the field. The apical body at the tip of this sperm head is cut in the same manner as that of the normal sperm shown in our previous publication[1].

The abnormal apical body is shown at higher magnification in Fig. 2 *A*. In addition, the appearance of a sperm head from a normal fertile bull of the Red Danish Milk-breed is given at the same magnification, in Fig. 2 *B*. The apical body is here shown in the closed form, that is, closely applied to the tip of the nucleus and still enclosed within the practically intact cell membrane.

Figs. 1 and 2 *A* show the abnormal apical body as a greatly swollen and rather deformed organelle. It is approximately 6–8 times bigger than in the normal sperm head. Most of the swollen part consists of a cyst-like structure, about 1μ in diameter, outlined by a well-defined wall or membrane. In the case shown the cyst contains two membrane-bounded circular or ellipsoidal bodies, in the interior of which vacuoles, vesicles, and fragments of membranes are found. In addition to the cyst-like swollen structure of the abnormal apical body, the basal part of this organelle seems to be lined with a rim of electron-dense

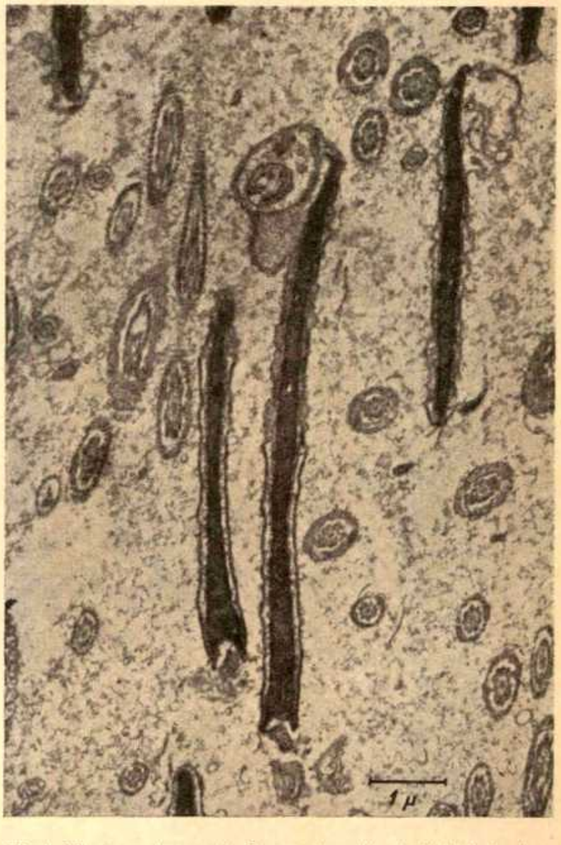

Fig. 1. Electron micrograph of sperm from the sterile bull showing the 'knobbed-sperm' defect. In the centre of the field a median sagittal sectioned sperm head with the abnormal swollen apical body. 'Vestopal-*W*' embedding; uranylacetate counterstained (× 10,000)

material of the same type as that which constitutes the galea capitis proper.

The observations presented in this preliminary report show that only the front part of the galea capitis, the apical body, is involved in the formation of the abnormality.

In our opinion this adds supplementary knowledge to observations made earlier on bull sperm showing the 'knobbed-sperm' defect. It is obvious that the swollen structure in the front part of the sperm head given by Hancock[6] represents the abnormal apical body described in this communication.

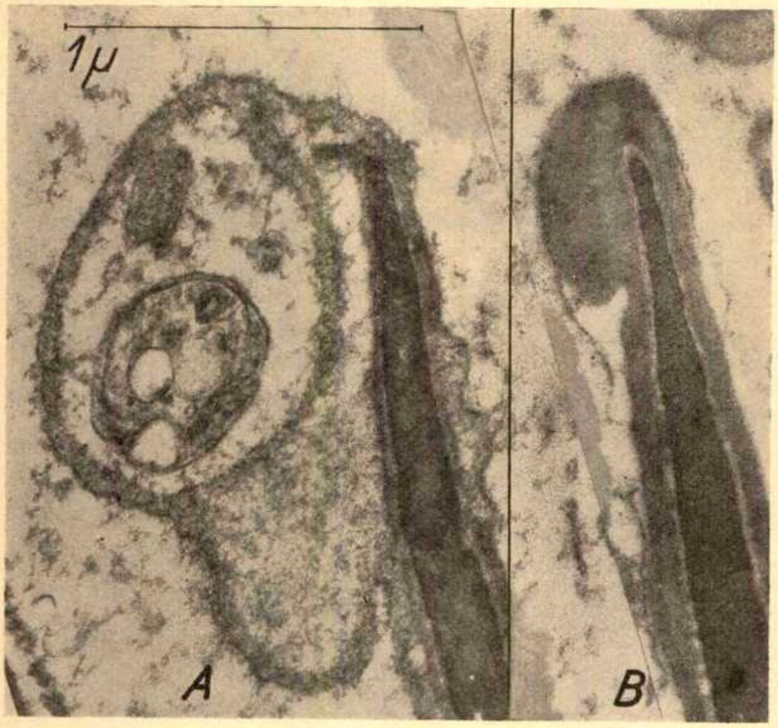

Fig. 2. *A*, Higher magnification of the same abnormal apical body, as shown in Fig. 1. Note the cyst-like swelling of the apical body and the two inclusions described in text. *B*, This electron micrograph shows for comparison the ultrastructure of the apical body of a sperm head from a normal fertile bull. Here the apical body is present in the typical closed form still enveloped by the intact cell membrane. 'Araldite' embedding. Uranyl-acetate counterstained (× 47,000)

We thank Mr. G. F. Smith, chief veterinary officer, Thames Ditton, Mr. T. H. Jones, veterinary officer, Longford, and Mr. J. A. O'Neil, veterinary officer, Wadhurst, all of the Milk Marketing Board, for their assistance in tracing the sterile bull and supplying us with the semen samples.

Influence of Uterine Position on the Response of the Mouse Embryo to Anoxia

THE exposure of the pregnant female mouse to the effects of a severe degree of anoxia results in the reduction of litter size and the birth of deformed young[1]. The object of the present investigation was to determine whether the chances of an embryo surviving the effects of anoxia were in any way affected by the position which it occupied in the uterine horn relative to its siblings.

Female mice of the Strong *A* line were used in these experiments and brother–sister mating was used throughout. The onset of pregnancy was determined by the presence of a vaginal plug, the day on which the plug was detected being taken as day 1 of the pregnancy. On day 10 of pregnancy each dam was placed in a low-pressure chamber and exposed to an atmospheric pressure reduced to 22 mm. mercury for a period of 5 hr., 15 min. being spent both in decompression and in recompression. On day 18 of pregnancy, the dam was killed and the uterine horns examined for the presence of live, dead and resorbed fœtuses.

The findings are shown in Table 1. It can be seen from this that the effects of anoxia fall most heavily on fœtuses which have implanted at the medial or vaginal end of the uterine horn, while those at the lateral or ovarian end of the horn tend to develop normally.

It has been suggested by McLaren and Michie[2] that a major factor limiting fœtal growth in the mouse may be the blood supply of the uterus, and they have pointed out that embryos at the ovarian end of the uterine horn may be particularly vulnerable in this regard. The sensitivity of the fœtus to the teratogenic activity of hypervitaminosis-A has been shown to be greater if the fœtus occupies the medial end of the uterine horn[3]. It would be possible to reconcile these two statements by postulating that the poorer blood supply at the ovarian end of the horn prevented the fœtus from being exposed to the effects of the vitamin to the same degree as at the vaginal end. One would have expected, however, that anoxia would affect most severely embryos at the ovarian end, if the blood

supply at that end is less adequate. It may be that the embryo at the ovarian end, normally in receipt of less oxygen, is therefore better able to withstand sudden lack of oxygen than his sibling at the vaginal end of the horn. On the other hand, since it is probable that implantation occurs at different times at the two ends, it may be that the dissimilar response to anoxia is determined by the fact that the embryos in one uterine horn are not all necessarily at exactly the same stage of development. Further experiments are in progress.

We thank Prof. T. H. Ingalls for advice on the construction of the low-pressure chamber. The work was supported by a grant from the Medical Research Council.

Double Circulation in the Amphibian *Amphiuma tridactylum*

The nature of a double circulation (the separation of the pulmonary and systemic circuits) in amphibians is a highly debated subject. Some maintain[1,2] in accordance with the classical theory of Brücke[3] that blood is selectively distributed between the carotid, arches, the aortic and the pulmocutaneous arteries. Others reject this hypothesis[4,5] and advocate an entirely random distribution with no selective preference. Still others[6,7] offer support for a compromise and feel that a separate distribution may prevail under certain conditions. Most investigators arrive at their conclusions from various kinds of injection experiments most of which suffer from a lack of quantitation necessary for an exact evaluation of the mixing conditions. The delicate pressure relations within the heart cavities and larger vessels are also prone to be disturbed when applying such procedures. The material used in earlier experiments was very selective. Species of *Rana* were the case in point while experiments on Urodeles are very scarce.

One accepted method for a quantitative evaluation of the mixing problem would be careful analysis of the blood oxygen content in the incoming vessels to the heart compared with the proper conduits leaving the heart. No such analysis has ever been reported for any species of Amphibia in spite of the fact that such procedures have put an end to the discussion on mixing conditions in the reptilian heart[8,9].

In our laboratory the large urodele amphibian *Amphiuma tridactylum* (500–800 gm.) was selected for analysis of blood oxygen as outlined here. The large size of this animal renders it very suitable for withdrawal of blood samples with no resulting effect of loss of blood or disturbance of the normal dynamics of the heart. The animals were lightly anæsthetized in *MS* 222. The tip of one lung was cannulated 10 cm. cranial to the cloacal opening, ensuring access in order to inflate the lungs with selected gas mixtures. A small incision in the region of the heart allowed for exposure of one aortic arch and one pulmonary artery (pulmocutaneous arch). A small incision in the posterior half of the pericardium gave access to the sinus venosus and pulmonary vein. Simultaneous samples were collected from the pulmonary artery and aortic arch followed by immediate sampling from the sinus venosus and pulmonary vein. The sampling was done by inserting a 30-gauge cannula through the proper vessel. The cannula was connected by a small plastic adapter directly on to a micro-pipette used in analysis of the blood gas. The volume withdrawn was very slight, 25 mm.^{3}, and was anaerobically transferred to the blood gas analyser for analysis by the method of Scholander *et al.*[10].

In most experiments the lung was inflated with pure oxygen some time prior to an experiment. The skin was kept moist to maintain normal cutaneous respiration. The results from 8 animals are given in Table 1. These offer unquestionable evidence of a selective distribution of the blood going through the heart of *Amphiuma*. The selection is, however, easily disturbed and abolished. A factor of prime importance is the general level of pressure in the heart, bulbus arteriosus and various arterial arches. At low pressures a perfect mixing seemed to ensue. Of interest is the small arterio-venous differences in oxygen content even following lung respiration with pure oxygen. This serves to emphasize the importance of cutaneous respiration in aquatic Amphibia. If skin respiration was restricted by drying the skin the measured arterio-venous differences in oxygen content increased markedly. Blood returning from the skin is drained in the sinus venosus and contributes only to a general elevation of the blood oxygen. From Table 1 it is apparent that the selective distribution consists of a slight or no shunting at all of blood from the

venous side to the aortic arches, while the shunting of oxygen rich blood towards the pulmonary circuit could be larger. However, under conditions of unrestricted cutaneous respiration the difference in oxygen content between blood from the sinus venosus and the pulmocutaneous arches was small. It is concluded that a selective distribution of blood traversing the amphibian heart is possible and actually present in spite of the lack of a correlative anatomical separation.

Heart Mechanism in a Conchostracan, *Limnadia lenticularis* (L.)

THE present evidence suggests that the crustaceans can be divided in two groups according to the mechanism of their heart beat: branchiopods which have a myogenic heart; the other crustaceans with their neurogenic hearts, thus resembling the heart of other arthropods[1-4]. The branchiopods so far investigated include cladocerans (*Daphnia*[3,5-9], *Simocephalus*[3]) and anostracans (*Artemia*[3-4], *Eubranchipus*[4]). So far, nothing was known about the physiology of the heart in Conchostraca and Notostraca[3].

One of the few European species among Conchostraca, *Limnadia lenticularis*, originally described by Linnæus in 1758 on the basis of Finnish material, is occasionally found in Finland, always as a temporary inhabitant of rock pools with acid, humified fresh water on the rocky islands in the south-west archipelago. Females living in some pools in the vicinity of the Lohm Marine Biological Station were collected for experiments. The occurrence of *Limnadia* in this locality in June, 1960, was pointed out by Mr. Aatos Petäjä.

The heart of *Limnadia* is tubular, extending through 4 entire segments, open at both ends and equipped with 4 pairs of slit-like lateral ostia. The blood is drawn through the posterior opening and the ostiæ and forced by simultaneous contraction of the entire heart to move forwards and out through the opening at the anterior end of the heart. The anterior part with the first pair of ostia is situated on the place of attachment of the animal to its shell. This part of the heart is larger and apparently more effective than its other parts.

Ether (1/2–1/4 saturated aqueous solution), acetylcholine (10^{-2}, 10^{-3}, 10^{-4}) and adrenaline (10^{-3}, 10^{-4}, 10^{-5}) were externally applied at temperatures of 11–13° C. and 18–20° C. and the heart-rate recorded *in situ*. The heart-rates recorded previously after the application of the drugs and those of animals kept continuously during the experiment in the solvent served as controls. The control heart-rates ranged from 26 to 53 min.^{-1} at 11°–12° C. and from 86 to 125 min.^{-1} at 19° C. for females with a shell length of 10–11 mm.

When immersed in the ether solution, the movements of the telson, the legs, antennæ and the gut ceased in about 20 min., while the heart continued to beat at unchanged frequency. Acetylcholine was without any effect, observable for 1 hr. Adrenaline in concentrations of 10^{-4} and 10^{-5} in 15–20 min. caused an increase of about 50 per cent in the heart-rate. Adrenaline 10^{-3} caused a transient increase of the heart-rate and afterwards a decrease which in 40 min. from the beginning of the experiment resulted in a complete arrest of the heart, this arrest being reversible.

These observations suggest that the heart-beat is myogenic in Conchostraca, as in the other branchiopods studied. As the cessation of active leg movement and the closure of shell caused by mechanical stimulation were found to be accompanied by a rapid decrease in the heart-rate, the heart probably is under nervous control in Conchostraca. Anostraca seem to lack cardioregulatory nerves[4]. Further knowledge on the physiology of Conchostraca[10] would be interesting from the comparative point of view.

Rate of Replacement of the Molluscan Radula

DURING investigations of the mechanism of secretion and replacement of the molluscan radula an attempt was made to determine the rate of replacement. Carriker[1] collected the fæces of *Lymnaea stagnalis* and counted the number of broken radula teeth present—over 23 days he collected 613 teeth. As there are approximately 100 teeth in a transverse row it can be calculated from Carriker's figures that approximately 0·266 row of teeth is formed a day. This is obviously a minimum figure. It was decided to use an operative technique—*Lymnaea stagnalis* 2·5–3·5 cm. long were anæsthetized using 'Nembutal' and *M.S.* 222 (Sandoz)[2], an incision was made behind and below the left tentacle and the tip of the radula gland was cauterized over a small area. The survival-rate was very low; out of 93 animals only 11 survived for a sufficient length of time. The animals were killed over a period of 10 weeks and the radula isolated. Only the undamaged part of the radula gland continued secreting after the operation. The number of new rows were counted where possible, but in the case of two animals no new growth occurred while the old radula was shed at the normal rate. In these cases the number of remaining transverse teeth rows were subtracted from the average number of transverse rows (110) found in normal individuals.

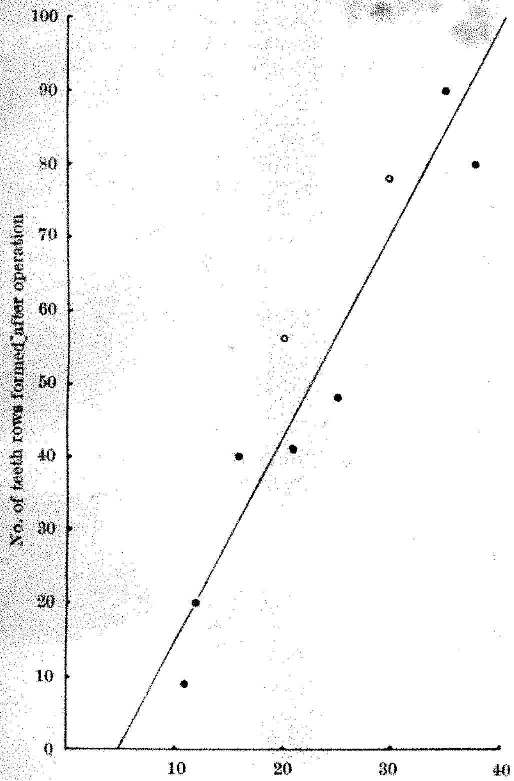

Fig. 1. Rate of radula replacement. ●, Number of new rows; ○, 110—number of remaining old rows

From Fig. 1 it can be seen that the animals took approximately 5 days to recover from the operation and that the rate of replacement of the radula was very approximately 2·8 rows a day, that is, an average radula (110 rows) would be completely replaced in about 40 days. In animals killed at 68 and 69 days none of the old radula remained. This very rapid replacement-rate accounts for the fact that, while there is a very great difference in size between the radula teeth of young and old individuals, in any one animal the teeth at the old and the new ends of the radula are approximately the same size.

Fate of the 'Tail' during the Larval Development of *Raillietina cesticillus* in the Confused Flour Beetle, *Tribolium confusum*

Unparasitized confused flour beetles were fed cast proglottids of *R. cesticillus*, and were then maintained on whole wheat flour, without being re-infected.

During the early development of the cestode, the tail arises as a posterior lobe which gradually constricts at the base to form a slender stalk. Usually, some of the six larval hooks are included in the tail while others remain in the stalk or body. The tail is pinched off as a small, perfect sphere, the stalk remaining attached to the body. The tail is shed at the end of the procercoid-like phase of development, designated as stage 5 by Wisseman[1], and is therefore lost at the same stage as in the primitive pseudophyllidean life-cycle.

The cast tail does not disintegrate, but survives and proliferates while the body continues its normal development to the cysticercoid stage. The tail becomes indented and lobed, its shape becoming increasingly irregular as it enlarges. It usually begins to lose its spherical shape when development of the body has reached stage 10 of Wisseman, which precedes the withdrawal of the scolex into the posterior portion. One abnormal animal was observed in which the tail had not been cast, and was enlarged and misshapen while still attached to the body; the scolex was well developed.

The growth of the tail is unaccompanied by differentiation, and is unregulated and unlimited, often resulting in bizarre shapes. Eventually a very large, lobular mass of proliferating material is produced. The lobes are drawn out at the base into fine stalks and are constricted off as rounded bodies. The stalks remain projecting from the main cellular mass. The spherical bodies, which are usually without hooks, appear in turn to increase in size.

The proliferation of the cast tail is of no advantage to the species, and probably requires nutrients from the hæmolymph of the host which could be utilized by the developing cysticercoids. The process is not one of asexual reproduction; the cellular masses do not differentiate, and are not protected against digestion in the gut of the definitive host.

Preservation of Tissue Culture Cells with Liquid Nitrogen

For prolonged storage of biological materials it is generally considered that temperatures of −100° C. or lower are necessary[1], and as thermodynamic changes have been demonstrated in mixtures of glycerol and Earle's solution in this temperature region[2] and in ice at −130° C.[3] it is preferable to use a lower storage temperature such as is provided by liquid nitrogen.

Storage in a small liquid nitrogen flask such as the Linde *LNR*-25-*B* (supplied by Union Carbide, Ltd., 8 Grafton Street, London, W.1) is now practical for small laboratories and it provides a temperature of −195° C. in the liquid and −185° C. in the gas.

In order to freeze tissue culture cells for low-temperature storage it is recommended that the average rate of cooling should be not more than 1° C. per minute down to −25° C.[1,4], and to do this several devices have been made[4–6]. With the liquid nitrogen flask it was felt that the normal continuous loss of cold nitrogen gas could be conveniently used as the coolant and the following simple procedure was devised.

It consists of a plug of expanded polystyrene ('Polyzote', supplied by Expanded Plastics, Ltd.,

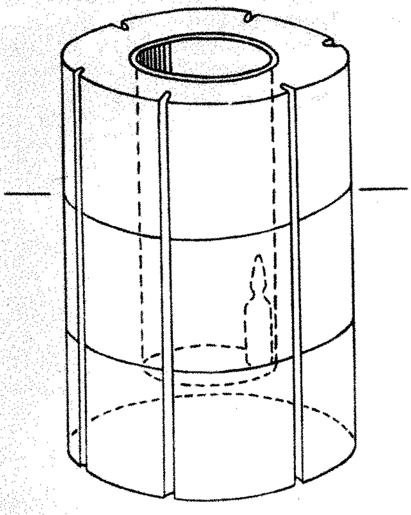

Fig. 1. Diagram of polystyrene plug freezer. Horizontal lines indicate level of rim of flask

Mitcham Road, Croydon, Surrey) of the same diameter, 3¼ in., and with 6 vertical grooves, each ⅛ in. wide and ¼ in. deep, as in the normal Linde-25-*B* plug (Fig. 1). It is made from 3 rings cut from a 3-in. thick slab of polystyrene, glued together with 'Bostik *C*' (made by B. B. Chemical Co., Ltd., Ulverscroft Road, Leicester), with a cardboard tube of 1½-in. internal diameter which lines a central hole that extends to 2 in. above the bottom of the plug. The hole inside the plug is therefore surrounded by about ¾ in. of insulation at the sides and 2 in. at the bottom. A group of 8 upright 1-ml. thin-walled glass ampoules can be lowered to the bottom of this well, and the temperature of the air around them read from a thermometer with its bulb among them.

Insertion of the loaded plug 6 in. into the neck of the flask gives the required rate of cooling when the ampoules contain dimethyl sulphoxide freezing solution. When less than 8 ampoules require freezing the number is made up with blanks containing medium only. After 3½–4 hr. a nearly constant temperature of about −100° C. is obtained, and the ampoules can be transferred to the body of the flask.

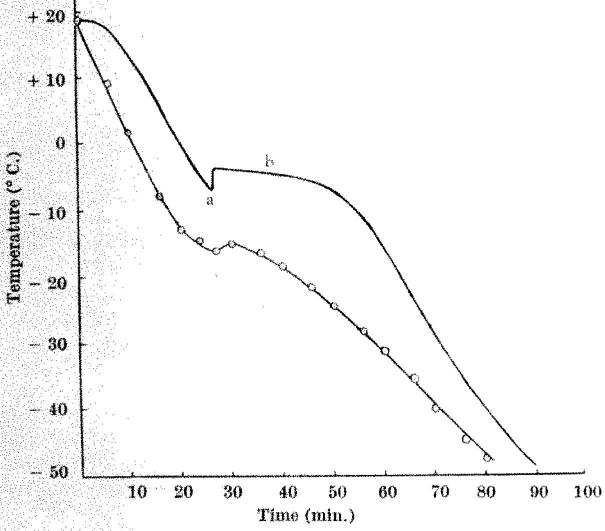

Fig. 2. Freezing curve. Continuous line is a tracing from a thermocouple inside an ampoule. Lower curve is plotted from thermometer readings at 2-min. intervals. The dip (*a*) in the upper record is produced by supercooling and the plateau (*b*) is produced during freezing of the dimethyl sulphoxide solution

The ambient temperatures, read either by thermocouple or thermometer, are generally about 10° C. lower than the temperatures recorded by a thermocouple in the contents of an ampoule. The temperature of the contents of an ampoule shows that an initial fall and supercooling precede a slow fall during freezing, which takes about 25 min.; thereafter rapid cooling is resumed (Fig. 2).

Although this is probably not the optimum curve for all tissue culture cells it has provided excellent results with a representative selection.

The superiority of dimethyl sulphoxide over glycerol[6–8] as an additive is confirmed under these conditions and we have used 10 per cent dimethyl sulphoxide with 15 per cent calf serum in Gey's salt solution in preference to other mixtures since R. M. Dougherty kindly made his experimental results available to us before publication[6].

For reconstitution, ampoules are thawed by being plunged into water at 37° C. and their contents diluted to 10 ml. or more with the appropriate growth medium modified only by reduction of the sodium bicarbonate to 0·035 per cent[9] and distributed at the rate of 150–200,000 cells per ml.

Consistently high recovery-rates have been obtained with this method, that is, 80–100 per cent of cells remained viable. Continuous cell lines frozen include several HeLa strains, and *MK*2. Primary cultures include human amnion, human embryo kidney and lung, and monkey kidney.

Primary cultures may be frozen immediately after trypsinization of the original tissue, and on reconstitution follow the pattern to be expected if not frozen. For example, amnion cells remain rounded for 1–2 days before growth begins and only reach confluence in 4–5 days; human embryo kidney cells show little change for 2 days and then grow rapidly to reach confluence in about 5 days.

However, if after trypsinization amnion and kidney cells are grown out for 4–5 days and then stripped off the glass with 'Versene' and frozen down they will, on reconstitution, start to grow where they left off and a confluent sheet can be obtained in 1–2 days, depending on the size of the inoculum.

This method of storage enables a wide variety of cells to be kept in the form of a tissue culture 'cell bank' which can be available for use within a day or two—an invaluable asset in the case of those cells which are difficult to obtain such as human embryonic cells and others which are only required at infrequent intervals.

MICROBIOLOGY

Muller's Phenomenon

MULLER's phenomenon, which may be defined as the appearance of small circular areas or plaques of clearing around the growth of a *Staphylococcus pyogenes* on a serum-containing chromo-protein agar substrate, has been recently reviewed by Elek[1], who suggests that this proteolytic effect is due either to a non-pathogenic virus or to a hitherto unrecognized enzyme precursor present in sera and activated by a staphylococcal factor.

Five per cent human serum–milk–agar is suitable for the demonstration of this phenomenon (Fig. 1*a*), and on this medium 197 of 202 strains of coagulase-positive *Staphylococci* of human origin produced the plaques of clearing characteristic of this effect, while none of 41 coagulase-negative strains or of 130 strains of other common micro-organisms did so. The 197 strains of coagulase-positive, 'Muller-positive' *Staphylococci* were also fibrinolytic on a heated plasma agar medium, but the 5 strains of coagulase-positive *Staphylococci* which failed to produce Muller's phenomenon were non-fibrinolytic[2]. This finding supports the assumption of Christie, Graydon and Woods[3] that staphylococcal fibrinolysin is the agent responsible for Muller's phenomenon.

If the concentration of serum in a serum–milk–agar medium is increased to 50 per cent, as in that recommended by Fisk and Mordvin[4], plaques of clearing do not develop but a zone of proteolysis appears spreading outwards from the staphylococcal growth. With concentrations of serum less than 50 per cent plaques may afterwards develop in an irregular ring beyond the zone of lysis, or plaques, which have previously appeared around the staphylococcal growth, may be engulfed by the extension of this zone.

The staphylococcal factor which is essential for the development of this proteolytic effect has been prepared free from living staphylococcal cells. A Seitz-filtered or a centrifuged and heat-killed broth culture of a suitable strain of a *Staphylococcus*, that is, coagulase-positive, 'Muller-positive' and fibrinolytic, will produce plaques of clearing when incorporated in serum–milk–agar, incubated at 37° C. These plaques may take 2–20 hr. to appear, depending on the amount and activity of the staphylococcal factor and on the concentration of serum. The plaques may persist as separate and distinct areas of proteolysis so long as the plate is retained or they may coalesce, resulting in complete destruction of the milk in the medium, the outcome being dependent on the concentration of the staphylococcal factor and serum.

Proteolysis by *Staphylococci* can be achieved either by the direct action of staphylococcal protease or by the activation of serum plasminogen to plasmin by staphylokinase[5-7]. Protease activity is independent of the presence of serum and is unaffected by soya bean trypsin inhibitor. Proteolysis brought about by staphylokinase-activated plasminogen, however, is inhibited by soya bean trypsin inhibitor. Muller's phenomenon does not develop in a milk–agar medium without serum, the only evidence of proteolytic activity in such a substrate being a slight clearing of the milk around colonies of *Staphylococci* which produce protease.

Inhibition of Muller's phenomenon and of proteolysis can be demonstrated on serum–milk–agar in which soya bean trypsin inhibitor has been incorporated. Soya bean trypsin inhibitor will also prevent the development of plaques and proteolysis in serum–milk–agar containing the staphylococcal factor (Fig. 1*b*). It would appear, therefore, that staphylokinase is the staphylococcal factor necessary for the demonstration of Muller's phenomenon.

The conditions necessary for the manifestation of plaques have been investigated, and of importance are the concentrations of serum and staphylococcal factor, the nature and strength of the gel and the amount of sodium chloride in the medium. The nature of the test protein is also of great importance in that, on certain proteins such as milk and heated hæmoglobin, plaque production is more easily observed than on others. If living cultures of *Staphylococci* are used to demonstrate the effect, the nature and amount of nutriment incorporated in the serum–milk–agar medium are worthy of note in that they influence the number and size of the plaques.

Muller's phenomenon, it would appear, is a manifestation of proteolysis brought about by staphylokinase-activated plasminogen, plaque formation being determined by the physical conditions in the gel.

Synthesis of Optically Active γ- and δ-Lactones by Microbiological Reduction

MICROBIOLOGICAL reductions of α-keto-groups have been reported by Neuberg *et al.*[1]. Lemieux and Giquere[2] carried out reductions of β-keto-caproic and β-keto-caprylic acids. Microbiological reductions of γ- and δ-keto-acids to yield optically active lactones have so far not been described in the literature.

We used a simple method to test the ability of micro-organisms to reduce γ- and δ-keto-acids. About 300 mgm. cell material of the micro-organism to be tested was incubated in water agar at 30° C. for 48 hr., with and without added keto-acid (2 mgm.) and glucose (20 mgm.). The appearance of the characteristic odour of lactone is indicative for a positive effect.

A number of yeasts (*Candida* and *Saccharomyces* group), some moulds (*Penicillium notatum*, *Cladosporium butyri*, and *Cl. suaveolens*), and some bacteria (*Sarcina lutea*) produced an odour of lactone.

To be able to isolate the lactone formed and investigate its properties, these micro-organisms were cultivated on a somewhat larger scale on nutrient agar. About 12 gm. moist cell material and 10 gm. glucose were used for the reduction of 500 mgm. δ-keto-capric acid.

The hydroxy-acids were extracted from the filtrate and lactonized at 130–140° C. *in vacuo* for 1 hr. The crude lactone was purified. The rotation was measured in methanolic solution. The results obtained, starting with 500 mgm. δ-keto-capric acid, are given in Table 1.

Table 1

Micro-organism	δ-deca-lactone obtained (mgm.)	$[\alpha]_D$
Cladosporium butyri	71	−15°
Saccharomyces cerevisiae	355	+48·2°
Saccharomyces fragilis	229	+48·5°
Candida pseudotropicalis	252	+48·2°
Candida globiformis	233	+55·8°
Sarcina lutea	302	−29·2°
	1,400*	−36·8°

* From 2,400 mgm. keto-acid.

The odour of dextrorotatory and lævorotatory δ-deca-lactones was identical.

With *Saccharomyces cerevisiae* (baker's yeast) we carried out reductions of various keto-acids, each time using 10 per cent yeast slurry, 0·05–0·1 per cent keto-acid, 5–10 per cent glucose (incubation at 30° C. for 48 hr.). The results are given in Table 2.

Table 2

Keto-acid	(gm.)	Yeast (gm.)	Glucose (gm.)	Volume (ml.)	Lactone yield (per cent)	$[\alpha]_D$
γ–C9	10	1,800	450	18,000	77	+50·4°
γ–C10	10	680	680	10,200	85	+46·1°
γ–C11	10	1,800	450	18,000	72	+44·1°
γ–C12	10	1,330	1,330	20,000	60	+40·4°
δ–C8	10	1,000	300	6,000	13	+58·4°
δ–C9	8·8	1,800	1,800	18,000	55	+58·2°
δ–C10	200	12,000	12,000	102,000	47	+55·6°
δ–C11	3	600	600	6,000	63	+47·9°
δ–C12	7	600	300	6,000	46	+48·8°

Thus, it proved to be possible to prepare optically active γ- and δ-lactones by microbiological reduction. There is no exact proof of the optical purity of the lactones measured. Further details will be published elsewhere. Patents have been applied for[3]. We wish to thank Dr. J. Boldingh for his advice.

VETERINARY SCIENCE

Infection of the Fowl by the Parenteral Inoculation of Oocysts of *Eimeria*

Under natural conditions infection with coccidia occurs as a result of the ingestion of viable sporulated oocysts, and this method of infection, that is, the inoculation of oocysts *per os*, is used experimentally to establish coccidia in laboratory animals.

Occasionally, however, other methods of infection, using different stages of the developmental cycle of the coccidia, are effective. For example, to obtain oocysts of *Eimeria necatrix* free from contamination with other species of *Eimeria* of the fowl, second-generation merozoites of the parasite can be inoculated *per os* or *per rectum* into susceptible chicks. Oocysts of *E. necatrix* are produced after a period of approximately two days, that is, the normal interval between schizogony and oocyst production. Similarly, the inoculation of first or second generation merozoites of *E. tenella* results in the production of oocysts after an appropriate interval. Such techniques, which involve the inoculation of a number of different developmental stages directly into the alimentary canal, are sufficiently reliable to be used routinely in this laboratory in maintaining pure infections of *E. tenella* and *E. necatrix* and in chemotherapeutic and immunological experiments.

Recently, Landers[1], in a series of observations on the factors necessary for the excystation of oocysts of *E. nieschulzi*, noted that oocysts excysted successfully following their inoculation into the thigh musculature of the rat, into the femoral and jugular veins and into the peritoneal cavity.

At Weybridge, similar experiments with oocysts of four species of *Eimeria* of the fowl have demonstrated that oocysts excyst successfully following parenteral inoculation into chicks (Table 1). Furthermore, schizogony has occurred in the sites normally invaded by the coccidia and oocysts have been produced after the normal interval of time. In some birds the prepatent period has been slightly prolonged.

Table 1. Parenteral Inoculation of Oocysts of *Eimeria* of the Fowl

Species	Route of inoculation	Number of oocysts	First appearance of oocysts days after inoculation
E. acervulina	Intravenous	650,000	6
	Intramuscular	650,000	Negative
	Intraperitoneal	650,000	6
E. maxima	i/v	100,000	7
	i/m	100,000	Negative
	i/p	100,000	Negative
E. necatrix	i/v	100,000	8
	i/m	100,000	Negative
	i/p	100,000	7
	i/p	150,000	8
E. tenella	i/v	50,000	7
	i/v	200,000	Negative
	i/m	200,000	7
	i/p	200,000	7
	Subcutaneous	200,000	6

In a majority of experiments the infections have been less severe than those which would be expected if similar numbers of oocysts had been inoculated *per os* and sometimes infection has not been established. The reason for the failures is not known. On several occasions, however, severe lesions of coccidiosis have been noted in the intestine, or in the cæca, and deaths have occurred.

Preliminary experiments with second generation merozoites of *E. tenella* have indicated that gametogony and oocyst production follow the intraperitoneal injection of merozoites but not their injection by the intramuscular or subcutaneous routes.

It appears, therefore, that one or more stages in the life-cycle of *Eimeria* possess considerable powers of migration. Limited migration of the first-generation merozoites of *E. tenella* and *E. necatrix* within parasitized epithelial cells was described by Tyzzer[2,3] and more recently local migration in sub-epithelial tissues of the sporozoites of *E. tenella* and *E. necatrix* has been described by Van Doorninck and Becker[4] and Pattillo[5].

Our results suggest that migration of the developmental stages of species of *Eimeria* may be a more important characteristic of the life-history than has previously been believed.

GENETICS

Competition Experiments with Isoalleles

Isoalleles, that is, alleles with minor differences in activity which are indistinguishable except by means of special tests, are of considerable importance in evolution. For example, the evolution of dominance for the wild-type characters must have been a selection process among isoalleles with different activity, favouring the most active one. Hochman[1,2] has been able to perform competition experiments with wild-type isoalleles at the *ci* locus in chromosome IV of *Drosophila melanogaster*, using their different degree of dominance for discrimination. His results support the view that alleles with complete dominance have a higher adaptive value and supersede the hypomorphic ones.

The molecular basis of variations in degree of dominance is not known, but such phenomena are best explained by the assumption of varying capacity of enzyme formation. A case where an isoallele is biochemically defined has been examined by one of us (B. R.)[3,4], namely, a slightly hypomorphic wild-type allele at the *w* locus of *Drosophila melanogaster*. In females, heterozygous for *w*, this allele produces a little less red eye pigments than w^+. The difference is too small to be observed visually, but was revealed by spectrophotometric analysis. However, this allele is also characterized by a very low amount of isoxanthopterin in the testis of the males, and it was indeed first discovered because of this characteristic. It was then called *is* (isoxanthopterinless); but as it was later located to the *w* locus, its proper designation is w^{is}. It is of special interest to follow the competition between w^{is} and w^+ in population experiments, because this is a case where something is known about not only the biochemical activity of the isoalleles, but also differences in their chromosomal structure, extensive genetical tests[4] having shown w^{is} to be a small intra-genic duplication within the *w* locus.

Five such population experiments have been undertaken. Phenotypically all the competing animals were wild-type, but the gene frequencies of w^{is} and w^+ could be determined by taking out samples of males and subjecting them to chromatographic analysis. The isoxanthopterin (IX) compound belongs to the fluorescent pteridines, and its presence can be observed in ultra-violet light after chromatographic separation of the pteridines. This test can be performed on single males, the genotype of which can thus be determined as being w^{is} if the amount of IX is low, and w^+ if it is high.

The populations were kept in units containing six bottles with standard food, one of which was discarded and substituted by a fresh one each week. The bottles were connected by short rubber tubes to a narrow oblong chamber made of transparent plastic and with wire-netting at the ends. For determinations of gene frequencies a small sample of food was taken out of the one-week-old bottle. The sample contained numerous young larvæ, and was transferred to a fresh bottle, where the flies could develop under more favourable conditions than the population unit could provide. This was to assure an optimal development of the males to be analysed. Small size and undernourishment might otherwise influence the amount of pteridines. The newly hatched males were collected and aged for about a week before being analysed. The chromatographic separation was performed on the abdomen of single males. These were crushed on Whatman 1 paper, 10 on each sheet, and developed in darkness for 18 hr., using a solvent of butanol/5 *N* acetic acid in proportions 2 : 1. When observed in ultra-violet light the deep blue spots of IX could easily be recognized and the number of males with low and with high content could be determined. There was some variation in the normal amount of IX, and in the two first experiments this caused difficulties for the discrimination of the genotypes. When this could not be made quite reliable, the experiments were abandoned.

The w^+ allele was derived from two different sources, the wild-type stocks 602 and Canton-*S*. No attempts were made to render the stocks isogeneous before the start of the experiments. It was believed that the genotypic background would soon be equalized in relation to the competing alleles, except for the immediate vicinity of the *w* locus, and this could not be controlled even in extensive isogenization attempts

Table 1

Exp. No.	w^+ allele from	Date of onset	Environment	Duration in months	Gene frequency determinations No.	Gene frequency determinations No. of males in each
1	602	Sept. 1959	25°, constant	2·5	4	80
2	602	Sept. 1959	greenhouse	2·5	4	80
3	602	May 1960	25°, constant	17	4	40
4	Canton-*S*	Aug. 1960	25°, constant	13	10	20–60
5	Canton-*S*	Aug. 1960	greenhouse	9	8	20–40
			25°, constant	4	2	40–50

The data for the experiments are shown in Table 1. Each experiment was started with 20 heterozygous *is*/+ females and equal numbers of *is* and + males. The initial gene frequencies were thus always 0·5. When Exps. Nos. 1 and 2 were discarded because of discrimination difficulties, the number of flies in each unit was recorded and was found to be between 2,000 and 2,500. It is supposed that all the populations were numerous enough to make the influence of genetic drift insignificant.

The results of the gene frequency determinations are shown in Figs. 1 and 2. The length of one generation is taken as 14 days in Exps. Nos. 1, 3 and 4, which were kept in a constant temperature of 25° C. In the other experiments the length of one generation depends on the season. These populations were placed in a greenhouse, where the temperature never fell below 12° C., but in daytime rose up to 30° C. and was higher during spring and summer than during the dark months. On the basis of performed tests, the generation-length was estimated to 21 days during March–October and to 25 days from October to March.

Fig. 1 shows the situation during the first few generations in Exps. Nos. 1 and 2, 4 and 5. It is probable that the fluctuations during this initial

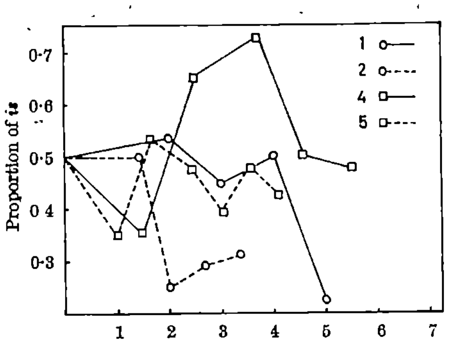

Fig. 1. Gene frequency changes during the initial stage of Exps. Nos. 1 and 2, 4 and 5

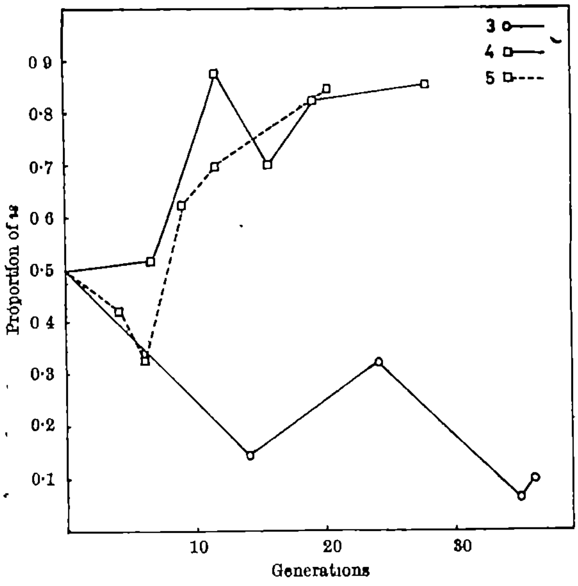

Fig. 2. Long-term gene frequency changes in Exps. Nos. 3, 4 and 5

period are due to an unequal distribution of the background genotype in relation to the alleles studied, and has little bearing on the adaptive values of these. The only definite trend to be seen is a decrease in the frequency of *is* in Exps. Nos. 1 and 2. This decrease is found again in Exp. No. 3, which was not studied during the earlier generations, but was kept going for more than 30 generations. It is shown in Fig. 2, together with the long-term progress of Exps. Nos. 4 and 5. A profound difference is found between the situation in Exp. No. 3, where *is* had to compete with the + allele of stock 602, and that in Exps. Nos. 4 and 5, where the + allele originated from Canton-*S*. In the first case the frequency of *is* has decreased to less than 10 per cent and presumably *is* will eventually disappear from this population, whereas in the latter *is* is superseding the + allele and is well on the way of being fixed. This holds for both experiments with Canton-*S* and the difference in environment does not seem to have had any other effect than to delay the progress in the greenhouse experiment.

The conclusions to be drawn from this investigation are that this special isoallele of w^+ is well enough adapted to compete successfully with normal w^+ alleles, but the outcome depends on the type of w^+ stock used. This suggests also that the w^+ alleles, which cannot at present be distinguished from each other, have different adaptive values. Finally, in one of two cases the w^{is} duplication has shown a selective advantage over the normal chromosome. This case represents an authentic instance where an increase of genetic material has taken place by means of the incorporation of a small duplication in the genome, which is postulated to have occurred repeatedly during evolution as a means to increased genetic organization.

STATISTICS

A Fundamental Complementary Principle for Inductive Logic

The class $\{L_i\}$, of all finitely axiomatizable systems, is well known to be formalizable in a particularly simple way, for example, as Post[1] normal systems on the axioms and rules (A, R) of each L. Now already within this class there is a potential complementarity of the following kind; for given L if one fixes R then A may vary over the equivalence class of all true sentences in L, and likewise fixing A one can show, via Turing machines, that there is an equivalence class for R.

However, and this is the vital point, such complementarity is not realizable without a postulate as to how $\{L_i\}$ is to be related by some observer, O, to the external world U. The appropriate one is that A is to be taken as an interrogation (or selective punctuation[2]) of U the response S of which is a string leading from A to a true sentence $\bar{S}$ in some L. Now O's problem, having decided on an optimality criterio $L(S, \bar{S})$ for the relation between S and $\bar{S}$, is to fin the probability distribution of R.

One can set up a formalism on this basis analogou to many particle quantum mechanics in whic $L(S, \bar{S})$ plays the part of a Lagrangian function. Th analogy is to the many-particle theory becaus $L(S, \bar{S})$ must always contain the results of indefinitel many other punctuations. This in itself is of considerable interest because existing second quantu theory is in serious difficulties, due principally to th fact it is not known what makes the restriction to 4 co-ordinate dimensions. The above formalism doe not have this restriction so one can consider wha logical conditions on $L(S, \bar{S})$ would give it. Elsewhere[3] I show that there is a rather surprising answe to this question.

The principal interest of this formalism, however is that it is appropriate to investigating the relatio between an evolutionary system such as O and it environment U.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Tuesday, June 12

Royal Society of Medicine, Experimental Medicine and Therapeutics Section (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Prof. C. H. Best: "Insulin and some of Its Scientific Offspring" (Dixon Memorial Lecture).

Wednesday, June 13

Institute of Fuel (at the Institution of Civil Engineers, Great George Street, London, S.W.1), at 9.30 a.m. and 2.30 p.m.—Second Symposium on "Flames and Industry".

Royal Institution (at 21 Albemarle Street, London, W.1). at 5.15 p.m.—Prof. P. P. Ewald, F.R.S. (Polytechnic Institute of Brooklyn): "William Henry Bragg and the New Crystallography" (First Bragg Lecture).*

Thursday, June 14

Royal Society (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Prof. J. D. Bernal, F.R.S.: "The Structure of Liquids" (The Bakerian Lecture).

Friday, June 15

Institution of Navigation (at the Royal Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1), at 5.30 p.m.—Capt. T. St. B. Freer and Capt. R. McDougall: "Safe Altitude Information for Pilots".

University of London (in the Anatomy Lecture Theatre, University College, Gower Street, London, W.C.1), at 5.30 p.m.—Prof. Harcourt Brown (Brown University, U.S.A.): "Scientists and Men of Letters—Maupertuis and Voltaire"*. (Further lecture on June 18).

Monday, June 18

Royal Geographical Society (at 1 Kensington Gore, London, S.W.7), at 3 p.m.—Annual General Meeting.

British Society for the Philosophy of Science—(in the Joint Staff Common Room, University College, Gower Street, London' W.C.1), at 5.30 p.m.—Prof. H. Fain. "Some Problems of Causation".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer (with special interests in plant breeding) in Botany—The Registrar, The University, Hull (June 15).

Demonstrator in the Botany Department—The Registrar, University College of Wales, Aberystwyth (June 15).

Demonstrator (with, or about to obtain, a good honours degree) in Physics—The Registrar, The University, Keele, Staffs (June 15).

Lecturer/Assistant Lecturer (preferably with experience in the field of magnetic resonance or microwave techniques) in the Department of Physics—The Registrar, The University, Keele, Staffs (June 15).

Research Assistant (preferably with an honours degree in geography, geology or botany with chemistry advanced level), for work under Dr. M. M. Cole on the vegetation and soils of the southern Pennines—The Registrar, The University, Keele, Staffs (June 15).

Sub-Librarian (graduate with appropriate library qualifications and experience) in the Library of the University of York—The Registrar, University of York, King's Manor, York (June 15).

Lecturer in Mathematics and Director of the Computing Laboratory—The Secretary, The University, Exeter (June 16).

Manchester Royal Botanical Society Lecturer in Horticulture—The Registrar, The University, Manchester (June 16).

Junior Lecturer in Philosophy—The Registrar, Trinity College, Dublin, Republic of Ireland (June 19).

Assistant Chief Officer (with a degree in botany, agricultural botany or agriculture or an equivalent qualification, and preferably experience of seed improvement and staff administration) at the Official Seed Testing Station—The Secretary, National Institute of Agricultural Botany, Huntingdon Road, Cambridge (June 20).

Assistant Librarians (2) (with a good honours degree, and preferably with experience and professional diplomas)—The Librarian, University of Sussex, Stanmer House, Stanmer, Brighton, Sussex (June 20).

Chair of Psychology; and a Chair of Sociology—The Secretary, The University, Exeter (June 22).

Lecturer and Assistant Lecturer in Physics (Theoretical and Experimental); and a Lecturer and Assistant Lecturer in Mathematics—The Registrar, University of Sussex, Stanmer House, Stanmer, Brighton (June 23).

Lecturer or Assistant Lecturer (with good qualifications and teaching experience in physics and chemistry, and preferably a higher degree in education) in Education—The Registrar, The University, Keele, Staffs (June 23).

Senior Lecturers or Lecturers in Pure Mathematics and in Applied Mathematics at Monash University, Melbourne, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, June 25).

Assistant Librarian (graduate or suitably qualified non-graduate) in the Science Library—The Registrar, The University, Nottingham (June 30).

Demonstrator (with a degree in biochemistry, agricultural chemistry, chemistry or physics, and an interest in applying this knowledge to problems in food handling and processing) in Food Science—The Registrar, The University, Nottingham (June 30).

Lecturer in Fuel Technology and Chemical Engineering—The Registrar, The University, Sheffield (June 30).

Lecturer in Geography at the University of Adelaide—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia, June 30).

Research Demonstrator (with good honours qualifications in organic chemistry) in the Department of Chemistry—The Registrar, University College, Singleton Park, Swansea (June 30).

Assistant Experimental Officer (with a pass degree or H.N.C. in physics or engineering) in the Physics Department, to work on irrigation and associated problems of micro-meteorology and soil water—The Secretary, Rothamsted Experimental Station, Harpenden, Herts (July 2).

Lecturer in Biochemistry at the University College, Ibadan, Nigeria—The Secretary, Senate Committee on Colleges Overseas in Special Relation, Senate House, University of London, London, W.C.1 (July 2).

Chair of Statistics in the University of Otago—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1; or the Registrar, University of Otago, Dunedin, New Zealand (New Zealand and London, July 31).

Senior Research Assistant in the Meteorological Physics Section, to work in the field of infra-red spectroscopy, using interferometric techniques—The Secretary, Department of Physics, Cavendish Laboratory, Free School Lane, Cambridge (July 31).

Head (with qualifications, teaching and research experience necessary for recognition as a teacher of the University of London) of the Department of Chemistry—The Secretary, Sir John Cass College, Jewry Street, London, E.C.3.

Lecturer in Experimental Aspects of Animal Growth in the Department of Growth and Development—The Secretary, Institute of Child Health (University of London), Great Ormond Street, London, W.C.1.

Mathematics Master—The Headmaster, Queen Elizabeth's Grammar School, Blackburn.

Reader (with a high academic qualification in either physics, physiology, biology or psychology, and experience in research) in Ophthalmic Optics—The Secretary, Northampton College of Advanced Technology, St. John Street, Clerkenwell, London, E.C.1.

Research Posts in High Energy Experimental Nuclear Physics, involving the use of high energy machines at C.E.R.N., Geneva and the Rutherford Laboratory, Harwell—The Secretary to Council, Westfield College (University of London), Kidderpore Avenue, Hampstead, London, N.W.3.

Spectrochemist (under 45, with several years experience in a spectrochemical laboratory, preferably in one where research is also undertaken) with the East African Agricultural and Forestry Research Organization, to take charge of the Spectrochemical Section of the General Analytical Division, including the analysis of soil and plant materials, and initiating analytical research projects—The Director of Recruitment, Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. R.C.264/348/06/T.

Tutor (graduate with good teaching experience) in Mathematics and/or Physics—The Bursar, College of Air Training, Hamble, Southampton.

REPORTS and other PUBLICATIONS

SECURITY IN BRITISH GOVERNMENT SERVICES

ALMOST exactly six years after the statement on the findings, but not the report itself, of the Conference of Privy Councillors on Security was published in March 1956 the Government has published the recommendations of the Radcliffe Committee, appointed in May 1961, to review security procedures and practices in the public service*. Although once again the Government decided that it would not be in the public interest to publish the report in full, the Committee's recommendations are supported with the text of the report to the maximum extent compatible with the public interest and the requirements of security. The Leader of the Opposition indicated his concurrence with the decision of the Government as to the parts withheld from publication, and Lord Radcliffe has agreed that the text, despite these omissions, preserves as nearly as possible in the Committee's own words the substance of the Committee's argument relating to security procedures and practices in the public service generally.

The White Paper in which the recommendations and arguments of the Committee are published indicates that the Government has already accepted the recommendations. Although the Radcliffe Committee formed the opinion that, while in certain respects improvements in the security services are still possible, the quality of the security organization and procedures and the general standard of security discipline are good. This confirms the earlier opinion of the Conference of Privy Councillors that there is nothing organically wrong or unsound about the British security arrangements. All in all, the White Paper is a far more useful document than the earlier statement, and merits attention by the scientist, for its findings in some matters are closely in line with the conclusions of responsible scientists on secrecy in relation to security and scientific advance, both in Britain and in the United States. Scientists will have only themselves to blame if they fail to ensure that due and continued attention is given to the Committee's recommendations for preventing abuse or excessive use of security measures as regards secrecy.

The report, in fact, corrects an impression that was derived from the statement of the Conference of Privy Councillors in 1956 who suggested that one of the chief problems of security was to identify the members of the British Communist Party, to be informed of its activities and to identify that wider body of those who are both sympathetic to Communism or susceptible to Communist pressure and present a danger to security. Thereafter, steps should be taken to see that secret information is not handled by anyone who, for ideological or other motives, might betray it. The Radcliffe Committee, however, while satisfied that much the most serious source of danger to-day lies in the intelligence services of the Soviet *bloc*, which are believed to be co-ordinated as between the various countries participating, does not regard the activities of the Communist Party of Great Britain as of the same order as a threat to security and consequently did not accept this assessment of the Privy Councillors. It believes that the central threat lies farther back, and that nothing is more important to effective security than the basic measures of physical security, if well planned and consistently executed. Safeguarding premises, documents and ciphers and eliminating carelessness are of the first importance.

No system of personnel security, however much elaborated, can be effective enough to modify the primary value of such physical measures, and the Radcliffe Committee further points out that counter-espionage against enemy agents is an indispensable part of the defensive system. None of the various defensive measures can safely be neglected in reliance on another, and the balance and sanity of this report offer some assurance against the eruption of any ill-judged measures of 'McCarthyism'. The Committee frankly recognizes that the social and political system of Britain is inimical to effective security, particularly the general public tradition that any individual is entitled to a fair hearing in respect of any accusation made against him and to fair treatment irrespective of political or public convenience. It further observes that security weaknesses of this kind are part of the price that must be paid for a social and political system that men want to defend.

It is indeed because of this that the Radcliffe Committee rightly stresses the need to persuade Government employees that security is the concern of everyone in the Government service. It is understandable that it should find patchiness in the security arrangements of the dozen departments it examined fairly closely rather than a uniform level of active concern for security, and that the subject was frequently treated as in practice of low importance. The practical danger seems to be this apathy rather than friction between the Security Service and the departments, of which it found no evidence. The Committee suggests that if any conflict of view should arise between the Director-General of the Security Service and the head of a department it should become the recognized procedure for the Director-General to seek an interview with the departmental head and state frankly his reasons for disquiet on security grounds. Much importance is attached to its being brought home to the Civil Service as a whole that security is a subject of active concern to those at its highest levels, and the Committee recommends that the structure of the interdepartmental committee in this field should be supported by measures designed to associate the supervising committee more directly with the work of the junior committees.

---

* Security Procedures in the Public Service. Pp. vi+42. (Cmnd. 1681.) (London: H.M.S.O., 1962.) 3*s*. net.

On security organization in departments, the Committee makes a sharp distinction between the issue of security instructions and education in security. The former are, and should be, orders, and every member of the departmental staff who is handling classified information must be instructed in his or her personal responsibility for security and in the various security rules and procedure in force. The latter should be clear, firm and precise and the Committee adds that the preparation of instructions calls for the exercise of judgment and imagination and should be regarded as one of the most important tasks that fall to a departmental security officer. Generally, the Committee suggests that security in all its aspects should be included in the responsibilities of the principal establishment officer, and in support of this it cites the views expressed by the Plowden Committee. What is needed, it reiterates, is that the standards of the best departments should become general.

The Committee is on more controversial ground in its comments on the Civil Service Staff Associations and Trade Unions. It was disturbed at the number of Communist and Communist sympathizers who hold positions in these bodies either as permanent full-time paid officials, or as unpaid officers or members of executive committees. This massing of Communist effort in the Civil Service unions appears to be the outcome of apathy or neglect on the part of the general body of members rather than to any exceptional effort on the part of Communists themselves, but nevertheless the situation is regarded as most dangerous to security, and the Committee suggests that any department should have the right in respect of establishments or staff employed on secret work to deny access to or to refuse to negotiate with a named trade union official when it had reason to believe him to be a Communist under the definition used in the purge procedure. It is envisaged that the department would be required to challenge the union official formally and that he would have a right of appeal to the Three Advisers.

The Committee recognizes that this suggestion has drawbacks, if not risks of its own, and opposition to it will not be minimized in the absence of any evidence that Communist union officers have been detected in any act of espionage. Nevertheless, it is right to hold that it is essential that Civil servants should understand that trade union and staff association officials are not entitled, merely by virtue of their office, to be given secret information. The difficulty, however, is one that could well be resolved by a wise and far-reaching campaign of education, as the Committee itself seems to be aware when it observes that the dangers of the present situation are aggravated by the fact that very few people are conscious that the dangers exist. Of itself, the process of education in secrecy should foster loyalty if widely conducted, and specifically the Radcliffe Committee believes that Civil servants who participate in staff negotiations should be warned in general terms that the Communist representation among Civil Service union officials is disproportionately high and that they should be as careful to avoid disclosing secret information to union officials as to anyone else outside the Government service.

To the scientist perhaps the most welcome feature of the report is its discussion of security classification, even if no new constructive proposals emerge. Witnesses before the Committee were unanimous that the security system is at present trying to protect too much. Many documents are being given a security classification higher than is really necessary or in circumstances where no classification is really needed at all, and classifications originally necessary are retained after the need for them has disappeared. This view is so widespread that the Committee does not think it can be ignored, and it regards the situation as representing a serious defect in the security system. Security arrangements are probably more effective the more limited the field to which they are applied, and accordingly the Committee suggests that the time is ripe for a high-level re-appraisal as to what relative priorities of security ought to be given to which types of information. In the sphere of defence, for example, radical changes in strategic thought do not appear to have been accompanied by a parallel reassessment of security priorities, although a start has been made towards reassessing the relative priorities appropriate to the security of defence, economic and political information.

This reappraisal should be pressed forward, but the Committee recommends that it should be supported by amplification in each department of the standard definitions with examples drawn from its own field of activity. It recommends also that some limitation of authority to apply the higher security classifications should be seriously considered; alternatively, such classifications should be regarded as provisional until confirmed by an officer above a certain rank. Further, the Committee suggests extending to other fields the technique of the body which determines and regularly reviews the security gradings to be applied to classified information of a technical nature, while, with full awareness of the difficulties, it recommends that departments should make a determined effort to check the further accumulation of papers with obsolete classifications.

No one of these measures alone would probably have much effect in reducing the volume of classified information, but in the aggregate the effect of applying such measures firmly and intelligently might be really considerable and the security system would be strengthened at the same time. Constructive thought, however, is required continuously and some of this must come from the scientific and technical side if downgrading of information is to be achieved and the mass of restricted papers kept to a minimum.

Here, and again in the question of personnel security and what is known as the Positive Vetting Process, it is very largely a matter of common sense and of education in security of a type designed to encourage co-operation and understanding. Moreover, as the report also emphasizes, this is not a matter for the Civil Service alone: it involves industry also, at least to the extent of Government contractors.

The Radcliffe report is marked throughout by this refreshing air of common sense. It offers no support for the indiscriminate application or extension of security measures or procedures, and its respect for individual rights is as unmistakable as its recognition of the vital importance of an intelligent and adequate security system, even if no feasible system can offer complete assurance that every member of the public service who has access to secret information will prove trustworthy at all times and in all circumstances. Maintenance of a high standard of physical and documentary security will always remain of the first importance and the regular and proper observance of standards or procedures depends largely on the provision of adequate training and education.

Once again the Committee puts first a deliberate attempt to apply the principle that classified information should be kept to a minimum and disseminated no wider than is required for the efficient discharge of the business in hand. Those Civil servants or Service officers who are appointed to deal specifically with security questions should be given some formal training in security work; this training should be the responsibility of the Security Service and carried out by that Service. Even more vital is the much wider task of persuading the general body of public servants who are handling, or are liable to handle, classified information that security is a matter of practical importance and for this a sustained and skilfully directed educational effort to overcome the attitude of mind which questions the existence of any substantial threat to security is required. The Radcliffe Committee recommends that a programme on these lines should be drawn up. However, the effectiveness of any such programme will be greatly strengthened if scientists and technologists, who rightly emphasize the handicap to scientific and technical advance which any measure of secrecy in regard to scientific information represents, and also the futility of attempting to maintain secrecy in such matters for more than a limited period, associate themselves constructively with practical security arrangements. The difficult task of declassification could sometimes be assisted, for example, if scientists or technologists were prompt in directing attention to independent publication of such information as a result of work elsewhere. The report considers in some detail the problem of Press co-operation, but scarcely refers to the co-operation of the scientist and technologist. Such co-operation, however, is no less essential: in a free society, understanding, intelligence and goodwill are indispensable elements in any worth-while security system, and without them it is unlikely to function effectively. The ultimate safeguard of the individual as of the State rests on vision, sense and untiring vigilance.

MAMMARY ACTIVITY

Milk

The Mammary Gland and Its Secretion. Edited by S. K. Kon and A. T. Cowie. Vol. 1: Pp. viii + 515. 14 dollars; 100*s*. Vol. 2: Pp. ix + 423. 12 dollars. 86*s*. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1961.)

BEGINNING in a small way nearly thirty years ago, research on the physiology and biochemistry of lactation (including research on the morphogenesis, histology and cytology of the mammary gland) has been providing, at a steadily accelerating rate, new knowledge on every aspect of mammary activity. The reasons for this rising output of significant new information are not far to seek. In the first place, in most western countries, as also in New Zealand, Australia, India and the U.S.S.R., milk production and processing together form a major industry, increasingly concerned with science and technology. As a consequence, funds for research, either from State or industrial sources, have become available both for the investigation of *ad hoc* problems and for more basic research in lactation. In the second place the important part played by milk and milk products in human nutrition, particularly in the nutrition of the young (a part emphasized by war-time experience), has been increasingly recognized, with renewed interest in the detailed reasons for their nutritional importance. In the third place, the astonishingly active processes taking place in the mammary gland, which were almost completely neglected for many years, have grown in interest and provided a fascinating field of research for an increasing number of research workers. In addition, a substantial inducement to many of these workers has been that many of the findings have had not only academic importance, but also applications in the dairy industry or in human or veterinary medicine.

The two volumes under review meet a need which has been felt for some years by students and teachers of mammary physiology and biochemistry for the bringing together in an authoritative text of the research findings that have emerged during the past decade or more on various aspects of mammary function. These recently published volumes provide such a text in the form of a connected series of short monographs, each written by a person or a small group that has made original contributions to knowledge of lactation. It is especially appropriate that the volumes have been organized and edited by members of the staff of the National Institute for Research in Dairying, Reading, since the stimulus and early impetus to much of the work recorded came from the pioneer investigations begun in that Institute in the early 1930's. This is particularly the case as regards the endocrinological control of lactation, the synthesis of milk constituents, the relation in the ruminant between diet, rumenal fermentation and milk quality and volume, and the composition and nutritional value of milk.

In all, there are twenty chapters—virtually short reviews, each with a comprehensive bibliography—in the two volumes. The chapters are conveniently associated into six groups as follow: (1) the mammary gland, morphogenesis, structure and growth; (2) functional physiology of the mammary gland; (3) lactation in man and farm animals; (4) biochemical activities of the mammary gland; (5) nutrition of the lactating animals; (6) nutritional value of milk (including a chapter on immunological aspects of colostrum). Though one or two of the individual chapters are a little discursive, all are a pleasure to read and of engrossing interest to any advanced student of mammalian (including human) physiology or biochemistry. Excellent author- and subject-indexes are provided.

The volumes, if a little expensive for British pockets, are very well produced and adequately illustrated; no library concerned with physiology or biochemistry, with human or veterinary medicine or with dairy science can spend 186*s*. to better advantage than by their purchase. H. D. KAY

QUEST FOR NATURAL LAWS IN PLANT ECOLOGY

Introduction to Plant Ecology

By Dr. Maurice Ashby. Pp. vii+249. (London: Macmillan and Co., Ltd.; New York: St. Martin's Press, Inc., 1961.) 25*s*. net.

The Plant Community

By Prof. Herbert C. Hanson and Ethan D. Churchill. Pp. xii+218. (New York: Reinhold Publishing Corporation; London: Chapman and Hall, Ltd., 1961.) 40*s*. net.

THE science of plant ecology is growing slowly out of its early descriptive phases and is becoming analytical and tentatively synthetic. It is no overstatement to say that the contribution of the present and next generation of ecologists may well be the establishment of principles analogous to those governing Newtonian physics or genetics.

Dr. Ashby's book, confessedly not new, is aimed to give pupils in school sixth forms and first-year university undergraduates a synopsis of these current aspects of plant ecology. He stresses the actual natural situations and the reactions of plants to them, making autecology the basis of his approach, using nine out of eleven chapters to develop a review of soils (thoroughly), root systems in relation to soil, effects of light, temperature and water on shoots, and biotic factors. He follows on with a study of "aggression", analysing factors concerned in spread and dispersal of species. One chapter is devoted to the nature of plant communities, succession and climaxes. A useful chapter and an appendix cover aims and methods of studying vegetation. A bibliography is provided.

The book is fairly well produced, having regard to its price, and contains lucid figures and some photographs. Even when price and costs are borne in mind, English text-books are not generally as attractive as American ones: an important point is arousing interest in schools. One has but to see how sixth-form pupils become absorbed in American books to appreciate the advances needed in book production elsewhere.

Dr. Ashby has trodden in the footsteps of the Pasteur of British ecology—the late Sir Arthur Tansley—and has woven into his work some of the modern developments of the topics Tansley the pioneer delineated. Thus we find chemistry, statistics and factorial interactions rightly stressed.

It is no fault of Dr. Ashby's or the American authors that plant ecology has become tainted with a most unfortunate form of anthropomorphism in the use of words like 'tolerance', 'sociability', 'fidelity', 'aggression', 'peaceful relations' and 'competition'. Perhaps the trend began with Darwin's use of the phrase 'struggle for existence'. Do we really have evidence of a plant psychology? Do we really have evidence that seedlings can act 'aggressively' (that is, launch an unprovoked attack)? Or are we as scientists so poor in vocabulary that we are unable to choose (or adapt classical) suitable words to express the interaction of physico-chemical systems concerned in given situations, for example, climate, soil and organism? Perhaps it is too late for ecologists to change their terminology; but the International Botanical Congress at Edinburgh in 1963 may find it possible to examine this unfortunate nomenclature.

Prof. Hanson and Mr. Churchill set out from a different starting point from Dr. Ashby's. They aim to supplement an elementary course by approaching the study of plant communities analytically and synthetically: a synecological study. Thus more than half their beautifully produced American book is concerned with the factorial interactions which influence groupings of species. It is not derogatory to suggest that in this liberally illustrated work, with many good photographs and tabulated information, some diagrams could have been more lucid than they are.

It is in the fourth part of the book that one glimpses the new synthetic approach to the classification of plant communities ('synsystematics'). Here are set out the inklings of the new principles, such as the predictive value of the presence of a given species, acting not merely as an indicator, say, of soil-type, but also as an index to the other species that will occur in the community. This book might well find a place on the shelves of school and university libraries to give reading matter to follow up an elementary course.

At a time of grave responsibility for agriculturists in the feeding of the world, the more an understaning of ecological principles and their application there is, the better for us all. Both books contribute to this end in different ways. L. M. J. KRAMER

MORPHOGENESIS

Advances in Morphogenesis

Vol. 1. Edited by M. Abercrombie and Jean Brachet. Pp. xiii+445. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1961.) 89*s*. 6*d*.

INVESTIGATIONS over the past thirty years or so have, for all practical purposes, converted the embryologist into a morphogeneticist. Embryology, *sensuo stricto*, has grown enormously; some allied kinds of investigations, such as in regeneration, now form a respectable part of it. The subject has also spread into interesting and valuable contact with other biological endeavours; one recalls the influence on the subject by studies in, for example, many aspects of cell biology, such as in genetics, in protein synthesis, on micro-organisms, in immunology, etc. The erstwhile embryologist now not only has his finger in a pretty big pie of his own, but also has a hungry eye focused on the pies of many others. Such gluttony is exciting, but it brings problems in its trail; more and more does it become difficult to see the main themes of the meal or even indeed to partake of it all.

In *Advances in Morphogenesis* the editors are making an encouraging and timely attempt to meet this situation. Their conception of morphogenesis is rightly a wide one—"any study of the new formation or of the remodelling of living material". In this and subsequent volumes they hope to "encourage the synthesis of some much-needed general ideas about mechanisms of development" and to "discourage the proliferation of clones of scientific thought". They hope to do this by publishing various kinds of review articles, giving authors, to judge from this first volume, space enough adequately to develop these general ideas.

There is always a danger in reviews of a lack of detail, and that those most interested know all about it anyway. The papers in this volume are generally successful in riding these dangers. It would be surprising if at least some of the essays did not provide food for thought for most morphogeneticists. The articles will also commend themselves to advanced students in the subject, for whom there has been insufficient reading matter of this kind.

The contributions to this volume range from a consideration of the structural and dynamic aspects of development of the teleost egg (Ch. Devillers), the embryology of ascidians (G. Reverberi), and the problem of the organizer from the chemical point of view (T. Tamada); through the morphogenesis of the eye (G. V. Lopashov and O. G. Stroeva) and limb (Edgar Zwilling), and regeneration of appendages (R. J. Goss) in vertebrates; to a rather less embryological approach in the differentiation of vertebrate pigment cells (C. E. Wilde), the action of morphostatic substances and the role of proteases in regenerating tissues and tumour cells (F. G. Lehmann), and determining factors in cell growth in relation to morphogenesis in plants (F. C. Steward and H. Y. Mohan Ram). It is not possible to comment individually on these contributions in a short review such as this; they are generally lively and stimulating, although not all the articles are entirely original. Of particular interest, perhaps, is the inclusion of material on plant morphogenesis; a greater *rapport* between botanists and zoologists will be of considerable benefit to both. The standard of production of the book is high and it contains but few errors. In addition to the usual reference lists associated with each article, the volume contains comprehensive author- and subject-indexes.

L. J. Hale

ASPECTS OF SOCIOLOGY

Hobhouse Memorial Lectures, 1951–1960

Pp. vi + 284. (London : The Athlone Press, University of London, 1962. Distributed by Constable and Co., Ltd.) 25*s*. net.

TEN annual lectures delivered under the auspices of the Hobhouse Memorial Trust are brought together in this volume. Although at first sight there seems to be little relation between subjects ranging from the philosophy of history, through psychology and archæology to the Welfare State, a certain coherence is given to the volume as one reads on and notes from the tributes paid by the various contributors to the memory of the late Prof. L. T. Hobhouse that each reflects some facet of Hobhouse's wide interpretation of sociology. Hobhouse was one of the great pioneers in a subject which has had a hard struggle for recognition in Britain, though elsewhere, notably in the United States, it is much studied and exerts great influence.

The lectures included in this volume were delivered between 1951 and 1960. Dr. Charles Singer opens with an exceptionally well-written and stimulating account of "Technology and History", and is followed by Sir Cyril Burt on "Contributions of Psychology to Social Problems" in what is by far the longest, but probably the most outstanding, of the ten lectures, illuminating the border country where the spheres of psychology and sociology overlap. Other lectures reprinted which are concerned with problems of social change and development are those of Prof. D. M. Mackinnon "On the Notion of a Philosophy of History", Sir Aubrey Lewis on "Agents of Cultural Advance" and Sir Mortimer Wheeler on "Aspects of the Ascent of a Civilisation".

A second group of lectures deal with social policy. Prof. W. A. Robson in his lecture on the "Welfare State" argues that the aim should be to bring about conditions which, while ensuring a relatively high general level of welfare, will be such as to evoke the exceptional efforts of men and women of outstanding ability. Gunnar Myrdal, who combined the roles of professor and international civil servant, examines "Realities and Illusions in Regard to Inter-governmental Organizations", while Prof. A. Macbeath poses the question "Can Social Policies be Rationally Tested?".

The remaining two lectures do not fall readily into any classification. One is a valuable, balanced and most interesting account of "The Curious Strength of Positivism in English Political Thought" by Mr. Noel Annan, provost of King's College, Cambridge, and the other, by Mr. T. H. Marshall, discusses "International Comprehension in and through Social Science". Mr. Marshall believes that the chief need in sociology is for the deeper study of the differences which distinguish one culture from another, and would like to see comparative studies, for example, of Europe and Asia in which European and Asian sociologists collaborate, each studying both cultures.

Taken together, though their quality is somewhat uneven, the ten lectures give an excellent idea of the contributions which sociology can make to our present problems and to our knowledge of society.

K. G. Fenelon

LARGE STRUCTURES OF HYDRAULIC ENGINEERING

Irrigation and Hydraulic Design

By Prof. Serge Leliavsky. Vol. 3: Hydraulic Structures for Irrigation and other Purposes. Pp. xvii + 765 (825 figures). (London: Chapman and Hall, Ltd., 1960.) 273*s*. net.

THIS, the third volume of the author's monumental work on irrigation and hydraulic design, is mainly concerned with the larger structures of hydraulic engineering. The first volume dealt with the hydraulic effects following the introduction of a structure into a river including seepage under structures, and the second with the planning and design of irrigation schemes and associated minor structures such as regulators, barrages and siphons. The present volume, comprising Chapters 9–13 of the whole work, discusses structures which are not necessarily connected with irrigation, but may be intended for navigation or hydraulic power production. It may therefore be of interest to a slightly different section of engineers than the second volume, and it is fortunate for such specialist readers that each chapter is largely self-contained.

The scope of the book is sufficiently well described by the chapter headings, namely: "Diversion Headworks in Alluvial Rivers" (9), "Locks" (10), "Arches" (11), "Dams" (12), "Electrification of Irrigation Works" (13), and it is written in the lucid style which we have come to expect of this author. The text is extremely well illustrated, as will be evident from the number of figures, and includes a number of dimensioned drawings of existing structures, the most detailed of these being a set of working drawings showing the arrangement of the steel bars in a reinforced concrete skeleton of a completed power house.

As one might expect from an author with wide experience in Egypt, many of the works chosen for detailed examination were built on the Nile and much space is devoted to the formidable difficulties associated with structures founded on alluvium. For example, much of the first chapter is concerned with the types of cut-off utilized in this situation, the construction of temporary sudds, de-watering and methods used in building the floor of such structures. In the second chapter also, particular attention is given to the design of locks with continuous concrete foundations, which are necessary where the soil is particularly treacherous. This leads to a certain lack of balance of the treatment, which is particularly evident in the chapter on dams. This chapter takes up more than a third of the book and deals with the structural design of gravity, arch, buttress and hollow dams. The gravity dam is treated in great detail and includes an analysis of the thermal movements and stresses in dams and the effects of uplift. In contrast, the treatment of the others is somewhat superficial, although a number of references is given to supplement the text. This is perhaps natural, for gravity dams have been in existence for centuries and a well-organized body of theory and experience is available for their design, while arch dams are a relatively recent innovation and their structural design is not yet standardized.

Throughout the book, as in previous volumes, the approach is historical and discursive and the author has been at pains to show the gradual evolution of design methods and modifications in the light of experience. Such a treatment is invaluable to the student and research worker, and it may also commend itself to those designers who are not only interested in the more accepted design methods but also in the fringe areas of their subject where progress is still being made but advances are not yet consolidated.

G. H. Lean

MINING RESEARCH

Proceedings of an International Symposium on Mining Research

Held at the University of Missouri, February 1961. Edited by George B. Clark. Vol. 1: Pp. xii+1–472. Vol. 2: Pp. vi+473–859. (London and New York: Pergamon Press, 1962.) 200*s*. net per set.

The proceedings of the symposium held at the University of Missouri in February 1961 have been reproduced in two volumes, containing a total of 50 papers. Volume 1 contains 31 papers, 19 of which are concerned with explosives and blasting. Three out of the 19 papers deal with the composition of ammonium nitrate—fuel-oil explosives, and four are concerned with their application. There are twelve papers on various aspects of blasting, one basic research into detonating pressure, and the remainder on applied research including the evaluation of explosive performance, techniques of blasting, efficiency of blasting, pneumatic cartridge loaders, pre-splitting, nuclear and chemical explosive cratering, blasting in cherty metallic iron formation, bench blasting with ammonium nitrate explosives and millisecond delay-firing.

The remaining contributions in Volume 1 consist of fundamental studies of liquid–solid systems in pipelines and steel wave behaviour in percussive drill-steels. Applied papers included the gyro-theodolite, mine environmental studies (a review), the life of drill steel equipment, the Castaing microanalyser, exploratory boring, applied statistics to determine mine working, methane drainage, ore analysis by X-ray and by γ-ray spectroscopy, and statistical analysis to plan sampling programmes.

Volume 2 contains 19 papers. There are several basic studies in rock mechanics, including direct measurement of strains by photoelasticity, behaviour and strength of rocks, correlation of rock properties, sonic techniques in exploring roof strata and roof bolting. Contributions to applied research in rock mechanics include block caving, subsidence, changes in stress accompanying wall closure in steeply dipping stopes, determinations of stress around an underground mine opening and the determination of dynamic elastic constants of rocks.

In addition to rock mechanics, Volume 2 contains papers on the use of jet-piercing for blast-hole production in taconite, disturbances resulting from shot-firing and also basic researches comprising studies of shock-waves in solids from explosives, effects of transient stress-waves in rocks, distribution of stress beneath a statically loaded drill-bit, stress-pulses in percussive drilling and the basic mechanics of coal ploughing.

The papers presented on explosives and blasting and on rock mechanics alone represent a substantial addition to the literature in these fields of study. The remaining papers, a little less than half the total, cover several aspects of mining research and include some interesting and very useful individual contributions. Half the papers presented come from the United States and the remainder from Great Britain, Sweden, France, Japan, West Germany, the U.S.S.R., Canada, Czechoslovakia, Austria and India.

The standard of the papers is high, and they represent a nice balance between fundamental studies, applied research and field trials. The work will be invaluable for reference purposes as well as providing much new information of immediate practical value. Its appeal will be not only to the mining engineer, but also to the civil engineer, engineering geologist, minerals engineer, etc. Most of the papers have a list of references or a bibliography attached, and there is a useful index at the end of Volume 2.

A word of praise is due to the editor for the presentation of the collected papers, which are conveniently arranged and suitably concise The large number of graphs, line diagrams and photographs provide neat, adequate illustrations, and the two volumes are well produced with large clear print and attractive binding.

The work constitutes an important and welcome addition to the literature on mining research, and is a good example of the high standard of research presentation which can result from an international symposium.

W. G. Thomas

Short-range Guided Weapons

By J. Clemow. (Temple Press Monographs on Rockets and Missiles.) Pp. vii + 79. (London : Temple Press, Ltd., 1961.) 15*s*. net.

THIS is the first monograph of a series, the later numbers of which will cover missile control, missile guidance, missile aerodynamics and propulsion—both solid-fuel rockets and ram-jets. This monograph is meant to serve as an introduction to the series. After considering the advantages of guided weapons and outlining the main parts of a guided missile it considers the same areas as will be covered by subsequent monographs. The last chapter deals with the hypothetical design problem of a particular ship to air missile and indicates some of the overall system problems involved in guided missile design. A selected bibliography is included.

This monograph provides a very adequate introduction to the subject, particularly bearing in mind the limitations which are inevitably imposed by security and the problem of covering a very wide range of techniques. It will be particularly interesting to those who have some scientific and technical background and as a useful introduction to the remainder of the series for any young professional missile engineer beginning his career.

In the hypothetical design problem some of the introductory general remarks are rather dogmatic and perhaps stem from the author's particular experience. Some of the remarks would certainly be qualified by other experts in the field. This chapter does give an indication of the complexity of the system problems involved, but with the limitations set by security and the allowable details it inevitably presents a somewhat oversimplified picture.

J. D. CLARE

Rhythmic Activity in Animal Physiology and Behaviour

By Prof. J. L. Cloudsley-Thompson. (Theoretical and Experimental Biology: an International Series of Monographs, Vol. 1.) Pp. vii + 236. (New York: Academic Press, Inc.; London: Academic Press, Inc. (London), Ltd., 1961.) 54*s*. 6*d*.

THE rhythms with which this book is concerned are mainly the diurnal, lunar, tidal and seasonal ones, expressing themselves in an animal's behaviour or in those aspects of its physiology which border on behaviour. Prof. Cloudsley-Thompson's approach is broad and his erudition considerable. His treatment of his material is highly individual. His style is breezy rather than rigorous and some of his writing shows signs of haste (for example, "They claim these rhythms appear to be statistical rather than overt, for they become apparent only when the data of several days is averaged", p. 109). The result is a stimulating, unorthodox and somewhat slapdash review, most valuable perhaps to the outsider or newcomer to the field. Such a reader can scarcely fail to be interested by Prof. Cloudsley-Thompson's exposition and will be duly introduced not only to all the main problems on which attention is focused at present but also to the names and attitudes of the leading investigators. The ecological aspect is emphasized. On the Brown–Pittendrigh controversy, the author concludes: "Until further evidence is available it will be wise to keep a fairly open mind". The rhythms the periods of which do not happen to coincide with those of environmental cycles receive attention when relevant to the main theme. There is a useful bibliography.

G. P. WELLS

Bird Study

By Prof. Andrew J. Berger. Pp. xi + 389. (New York and London: John Wiley and Sons, Inc., 1961.) 72*s*.

BIRD STUDY is well named, for it is a book about the study of birds from all angles, including observation in the field and anatomical details. Though written primarily for the student it will be helpful even to the most advanced ornithologists, who will find much in it to interest them and give them material for thought.

The author, Prof. Andrew J. Berger, is an American, and the background of his work is the vast bird population of the North American continent. He writes, "the emphasis of this book is on the living bird and primarily of North American birds", and he never forgets the student to whom, as already said, this volume is chiefly addressed.

It is no doubt in consequence of this that he is not very much concerned with other readers, including natives of Britain, who may occasionally find the use of American popular names a trifle confusing; for example. the many references to "the robin", which remarks do not concern the pert little red-breasted bird so familiar in England, but a handsome member of the Turdidae of similar coloration, this latter being named after the European robin by the early settlers.

However, this is of small importance where there is so much of general excellence, including a large number of photographic illustrations and many diagrams and line drawings. These are illustrations in the full sense of the word and assist the text of the eleven chapters that cover so much ground, beginning with an introduction to the bird. moving on to "Field Identification", and continuing to the last chapters on "Conservation" and "Systematics".

FRANCES PITT

Approaches to Thermonuclear Power

By Dr. R. F. Saxe. (Nuclear Engineering Monographs, No. 10.) Pp. x + 65. (London: Temple Press, Ltd., 1960.) 12*s*. 6*d*. net.

THE book begins by discussing the conditions necessary to the operation of a fusion reactor, not considering problems outside the core such as losses of energy in the field coils or the regeneration of tritium in a deuterium–tritium reactor. A theoretical outline of plasma behaviour at high temperatures is then given, adequate for the purposes of the book. However, it would be better to say that instabilities grow at rates dependent on the Alfvèn speed rather than on the sound speed in the plasma. Next the linear pinch is treated, the early experimental results being quite well described. The fourth chapter reviews toroidal machines and curious explanations appear. To give two examples, a typical characteristic for a symmetrical double Langmuir probe is shown, and the text describes this in detail as the behaviour of a single probe. Again, it is stated that deuterium cannot be used for spectroscopic measurements of temperature because of its large Stark effect, though deuterium is stripped completely in hot plasmas and does not radiate at all. In the last chapter, mirror machines are better handled. There is a final résumé in which ion energies seem to be regarded as equivalent to ion temperatures, a most dangerous confusion. This monograph would considerably enlighten the inquiring engineer for whom it is written; but the physics is sometimes misleading and the description of achievements optimistic.

P. F. LITTLE

UNCONSCIOUS MENTAL IMAGERY IN ART AND SCIENCE*

By ANTON EHRENZWEIG

THE psychoanalytic concept of the unconscious is often refuted as unscientific because it is impossible to prove unconscious processes empirically. This is a narrow view. The unconscious is not a physical fact, but merely an explanatory concept which allows us to understand phenomena that could not be accounted for otherwise. Neither for that matter can an electron be observed directly. A few flickerings on a screen may be seen; all the rest is deductive reasoning producing explanatory concepts that are not open to immediate demonstration. In the case of the unconscious it follows from its definition that it cannot be observed directly.

I myself had to expand the use of the term 'unconscious' to a new field. I needed the concept of an unconscious mental imagery underlying creative thought, in order to break the deadlock which has held up the progress of psychoanalytical æsthetics for half a century. The beginnings of psychoanalytical æsthetics were highly promising. Freud had analysed the typical structure of dreams in which he recognized the working of the so-called primary process characteristic of the unconscious. In order to interpret the dream he had to assume that the primary process distorts meaning in a very specific way, for example, by condensations, displacements, representations by the opposite and the like. By undoing these distortions Freud was able to show a new meaning behind our dreaming activity which until then was usually dismissed as meaningless and the result of mental dysfunction. It showed the value of the new interpretation technique that Freud was able to transfer the whole inventory of dream symbolism to other fields, pre-eminently clinical, and also to a new understanding of æsthetics. It could be generally assumed that wherever typical primary-process forms of condensations, displacements, etc., occurred the primary process of the unconscious had been at work.

One of the first applications in the æsthetic field was surprisingly the joke, a border subject of æsthetics. Classical æsthetics had recognized that the specific structure of the joke had something to do with its laughter-raising quality. The joke liked to express too much by too little. Polonius in "Hamlet" speaks of brevity as "the soul of wit". The search for the joke's structure was akin to similar searches for æsthetic form. Men like Hogarth would link æsthetic feelings of sublimity with large awe-inspiring structures or gracefulness with slender small-scale shapes. But gradually the æstheticians lost heart in establishing empirically valid links between subjective feelings and objective structures outside. There was too much disagreement about what was beautiful. What seemed ugly at first sight gained beauty as it became more familiar. Æstheticians lost prestige by invoking allegedly universal laws of beauty in order to discredit the modern art of their time. Hanslick's polemics against Wagner are the best-known example. Such laws did not need refutation. It was only necessary for the modern art of the time to become universally accepted to prove the futility of the æsthetic laws. This frequent failure contributed to a gradual change of aim in nineteenth-century æsthetics. Instead of searching the objective structures in the physical outside world, æsthetics turned to analysing the subjective experience. Fechner and Lipps helped in this re-orientation of æsthetics towards psychology.

It seems paradoxical though gratifying that Freud, himself a psychologist and as an æsthetician influenced by Fechner and Lipps, should have solved the æsthetic border problem of the joke's structure in a truly classical manner. In his unjustly neglected book *The Joke and its Relation to the Unconscious* he applied the structural analysis of dreams to a similar analysis of the joke. He was led into æsthetics by the disconcerting reaction of some patients when he interpreted primary-process material. They laughed, as though he had told them a joke. Unabashed Freud went on to examine ordinary jokes and discovered that they expressed a half-hidden obscene or aggressive idea in the distorted and distorting way characteristic of the primary process. 'Seeing through' these distortions arouses laughter.

Freud started his review of jokes with a well-known joke by Heine cast in the form of a condensation. Heine condenses two words, 'familiar' and 'millionaire'. In the joke a poor man boasts about the intimate way in which he was entertained by a very rich relative. But instead of speaking about the rich man's gratifying familiarity, he distorts the intended word and speaks of the 'famillionaire' treatment he had met. His relative had not really been friendly, but instead displayed the superficial politeness that emphasized the social gulf between him and the poor man. Telescoped words like 'famillionaire' also occur in dreams. As words are rare in dreams, we find more often condensed images. Surrealist artists tried to imitate dream images deliberately by producing such condensations. Salvadore Dali would paint a chest-of-drawers sprouting human limbs. The joke and the dream share other primary-process structures. Displacement is one of them. The unconscious generally tends to express its symbolism in inconspicuous details which escape detection. The interpretation of dreams must often shift the displaced emphasis to those unobtrusive details. Such unexpected displacements of emphasis are also witty. Freud quotes one of the many jokes about the so said uncleanliness of Jews. One Jew meets another in the vicinity of a public bath and asks him: "Have you taken a bath?" and gets the surprised answer: "Why, is one missing?" The answer displaces the emphasis of the question to the inconspicuous word 'taken', giving it the stronger meaning of 'taken away', 'stolen'. Another important primary-process form in dreams and jokes are representations by the opposite which in a joke acquire a sarcastic meaning. In terms of normal rational thought primary-process distortions are nonsensical. We have to interpret or —in the case of the joke—have to guess their hidden meaning. I maintain that the unconscious mind understands the concealed meaning because on an unconscious level words and images lose their precise definition and become undifferentiated, until a limit is approached where all distinctions are submerged in a single oceanic image.

---

* Substance of a lecture given before the British Society of Aesthetics on April 4.

But let me first continue my account of Freud's success as an æsthetician. I stated that Freud by identifying the joke's structure as a typical primary-process structure solved a border problem of æsthetics in a classical manner; subjective feeling was firmly related to objective structure. But Freud did more. If the joke was cast into the forms of the primary process this proved that it was shaped spontaneously by the unconscious mind. This spontaneity can be demonstrated by a purely behaviouristic observation. If we catch a witty person in the act of inventing a really new joke, we shall notice how he will suddenly stop in his tracks. An absent-minded expression will creep into his face and then, as from nowhere, the new joke occurs to him. He will communicate it as soon as possible as though he was not quite sure of the full implications of his witticism. There is a good deal more to be said about the spontaneity and truly unconscious quality of a new joke. What matters to the æsthetician is Freud's discovery that any spontaneously created structures can be expected to show the imprint of the primary-process forms which he first discovered in the dream.

One could have expected, therefore, that Freud would continue his incursion into æsthetics and solve the problem of art form at least so far as it is created spontaneously and unconsciously without conscious deliberation and planning. Art was dear to Freud's heart, who was a master of the German language. Freud was pleased when he found that he could transfer the whole inventory of dream symbolism for a better understanding of myths, fairy tales and literary works of art. But if he could thus reach the unconscious content of art, he failed to explain its unconscious structure. I stated that it was legitimate to expect that the spontaneous forms of art should carry the impression of the primary process, perhaps even more so than the relatively shallow joke which expresses only lightly concealed obscene and aggressive ideas and not—like the dream and art—deeply repressed unconscious phantasy. Otto Rank was one of the first psychoanalysts to explore the structure of art in this way and searched art for primary-process forms such as condensations. He pointed out that the German word for poet, *Dichter*, meant the condenser. Myth, folklore and also art abound in dream-like phantasmagorias, composite monsters like sphinxes, chimæras, winged angels condensed from animal and human forms. But these occasional intrusions of primary-process structures did not add up to an exhaustive catalogue of all spontaneous forms in art. Apart from the impossibility of emulating Freud's achievement in the complete survey of all possible joke forms—nobody has succeeded in cataloguing all possible art forms—it proves impossible to relate a catalogue of art forms, however incomplete, to primary-process structures. Art form generally in its often stringent and logical coherence seems a far cry from the nonsensical twists of the primary process in the dream and the joke. Half a century has gone by since Freud's book on the joke and its relation to the unconscious was published, and psychoanalysis has not made substantial progress towards solving the central problem of æsthetics—the character and origin of the forms of art. I think we have to accept the failure as definite.

Acceptance of failure does not exclude progress because it allows examination of the possible reasons for the failure. The most celebrated example for a fertile interpretation of failure is the invention of non-Euclidean geometry. It came after centuries of vain attempts at proving all Euclidean postulates. The acceptance of that failure led to a new conception of space which contradicts commonsense visualization, but nevertheless helps to explain phenomena that otherwise would remain unexplained.

The difficulty in accepting the failure was certainly connected with the difficulty, if not impossibility, in visualizing non-Euclidean space. It keeps shifting and destroys stable focusing points. A similar difficulty in visualization may be involved in tracing the unconscious roots of art. One can interpret our failure to discover those roots in two ways. One can either deny that art has an unconscious sub-structure (this is what the classical theory of psychoanalysis, as expounded by E. Kris, ultimately did) or else one can assume that the unconscious sub-structure exists, but for certain reasons resists conscious visualization. This will be my approach.

I could never accept the current theory which confines the structuring process of art exclusively to the conscious and preconscious mind. This view is inconsistent with Freud's treatment of the joke, which according to Freud is spontaneously created by the primary process of the unconscious. The spontaneity of artistic creation can be far more profound. Though a large part of the artistic composition is usually produced by deliberate planning excluding spontaneity, important components of the composition may emerge without any premeditation and even run against the artist's explicit intentions. Yet the artist, if he is inspired, will accept them as integral parts of the artistic structure. Such form elements must be conceded roots in the unconscious mind that are even deeper than the relatively superficial spontaneity of the joke. Certain spontaneous form elements of art even share with the joke an initial impression of unorganized chaos. The nonsensical condensations, displacements, representations by the opposite that go into the making of a joke impress us as nonsensical chaos and distortions of normal rational thought so long as we have not guessed the joke's half-concealed meaning. But once we have laughed at the joke—which is the signal of sudden enlightenment—the formulation of the joke loses its chaotic quality and will appear as a cogent and neatly turned formulation of a witty idea. Freud in his detailed survey of jocular structures behaves very much like a *connoisseur* who does not tire of pointing out the relative æsthetic merits of various jokes. The same transformation applies to the spontaneous form elements of art, such as the chaotic-looking scribblings and textures of artistic 'handwriting' or the endless undulations of primitive song with its inarticulate *portamenti* and *vibratos*. We cannot adduce a conscious law for the application of such inarticulate form elements and must leave their execution entirely to intuition and spontaneity, but they still obey some æsthetic discipline which is no less cogent for not being open to conscious visualization and formulation.

When I first wrote on psychoanalytic æsthetics about fifteen years ago, I commented on the crudity of our conscious powers of visualization. which cannot possibly do justice to the complexity of the artistic structure. The chief limitation of conscious visualization is borne out by the extensive experiments of *gestalt* psychology. In normal vision we are forced to select from the available sum of stimuli only a limited number which can be drawn together into an easily focusable *gestalt* pattern. The rest recedes into an indistinct background. The visual field is thus always bisected into a selected figure standing out from a ground the details of which are lost. Now bisecting the visual field into relevant figure and irrelevant background forms is precisely what the artist cannot afford to do. I have just written of the hidden discipline ruling the seemingly accidental and spontaneous scribblings of artistic handwriting. Only a bad artist will treat such textures as accidental and less-significant background forms and concentrate on the prominent large-scale composition (the selected 'figure' of *gestalt* psychology). Every single detail however paltry-looking has to be firmly related to the overall structure. This need constitutes the extreme complexity of any work of art. It defeats our normal powers of vision, which as we have seen cannot scan the entire visual field in a single act of attention. I concluded at the time that the artist must have powers of vision transcending our normal conscious faculties of visualization. There must be an unconscious undifferentiated type of visualization which is free from the compulsion of bisecting the visual field into figure and ground and can scan it in its entirety with impartial equality.

Much to my delight recent experiments in subliminal perception confirmed this hypothesis. It was found that our subliminal perception can, in a fraction of a second, register far more stimuli than can our normal conscious powers of visualization and is able to register details belonging to the background with equal acuity as the elements of the figure.

'Subliminal' is only another term for unconscious. We cannot demonstrate subliminal perception directly, but have to infer it (as a purely explanatory concept) from conscious phenomena which could not otherwise be satisfactorily explained. Nevertheless, we can make statements about unconscious techniques of perception owing to the gradual transition between conscious and unconscious (subliminal) processes reflected in a successive waning of our powers of visualization. If we cut down with the help of a tachistoscope the duration for which a picture is projected on a screen, the weakening of the physiological stimulus tends to produce a kind of vision that is strangely akin to our dream vision. The flicking picture becomes increasingly vague and incomplete and is easily distorted in the manner of the primary process. When the subliminal threshold is reached even the faintest and vaguest flicker disappears and the screen remains empty so far as conscious experience is concerned. Vision has turned subliminal and unconscious. Subliminal vision proves its kinship with dreaming by the ease with which traces of the subliminal picture reappear in later dreams. Recently a New York psychoanalyst, Charles Fisher, took the same short cut which Freud took to the unconscious when he discarded hypnosis as a method of treatment. Fisher, after exposing subliminal images, asked his observers to make drawings by uncontrolled 'free' association. Traces of the subliminal images duly emerged. For the sake of experimental rigour Fisher intermixed truly blank slides among his exposures and significant differences resulted.

The same series beginning with vagueness and distortion, followed by the gradual dissolution of precise spatial relations and ending in total blankness, is found also in dreams and in creative work. Recent psychoanalytic research into dreams penetrated below the nonsensical but still distinct primary-process structures. At first precise space relationships become uncertain. The dreamer may feel opposite an immense wall (an example of the so-called 'dream-screen') and at the same time feel also inside that wall. The psychoanalyst–anthropologist, Roheim, treats this conflict between an undifferentiated inner dream space (dream 'womb') and a more articulate outer dream space as part of a basic dream conflict. Roheim often uses strangely undifferentiated language. The dreamer, he says, may have the experience of entering his own dream womb. The vague space experience may disintegrate ultimately into a completely blank dream-filled intense emotion pointing to the existence of unconscious-subliminal phantasy.

This 'full' blankness, like the hidden discipline of 'chaos', would be the result of failure in our conscious powers of visualization. Our conscious vision has learned to differentiate sharply not only between figure and ground, but also between articulate patterns as such in order to construct a precise space. *Gestalt* psychology once assumed that this ability or rather compulsion to select and differentiate patterns was an inborn faculty. But the survey by von Senden of case-histories of people born blind who acquired vision by an operation in adult life show the incredible difficulties encountered by them as they were faced by the undifferentiated colour patches filling the visual field. Many of them, sometimes due to lacking guidance on the part of the physicians, faltered in their purpose and could not muster the effort for learning to project patterns into the chaos. Some of them felt profound relief when blindness overcame them once again.

The facts of subliminal vision suggest that we retain on an unconscious level the infantile type of vision that does not yet differentiate the visual field. But what is primitive weakness in the child becomes creative strength in the artist who, according to my hypothesis, resorts to an undifferentiated low-level vision so as to control the overall structure of the work of art. Let me put on record that it was the need for this æsthetic control which first suggested to me the hypothesis of an unconscious undifferentiated vision and so anticipated the confirmation by experiments in subliminal perception. No such confirmation is as yet forthcoming for other facets of the hypothetical undifferentiated vision in the unconscious. But æsthetic facts suggest to me an unconscious-subliminal vision that is altogether free from normal spatial differentiation. I spoke of certain dreams which suspend the normal differentiation between inside and outside space. But in art the suspension of differentiated space seems to go farther. For example, it would be difficult to explain the well-known effect of the golden section in any other way. Try to divide a line according to the rules of the golden section and you will see how difficult it is. The section rests on a simple enough mathematical formula: $a : b = b : (a + b)$, that is to say, the smaller section relates to the bigger section as the bigger section does to the undivided whole. But comparing the two proportions in order to make them identical is difficult if not impossible because of their confusing spatial distribution. a is juxtaposed to b, but b is contained within the whole $(a + b)$ into which it is 'telescoped'. The eye movements taking the two proportions are quite different in each case and do not allow proper comparison. Yet the golden section has undoubted æsthetic merits; to have this merit it must be perceived without much ado, if not consciously then unconsciously by a vision that is not bound by the normal distribution in space. Again, the hypothesis of an unconscious vision cannot be demonstrated directly, but serves only to explain the otherwise unexplainable.

It could be said that the golden section is mathematically simple, but obscure as a visual fact, a contrast that may have given it its mystic panache. Once we assume that it can be perceived by a spatially undifferentiated unconscious vision, its mystique disappears. Mathematical simplicity and perceptual obscurity are also found in the serialization of musical elements. Mathematically it could not be simpler, that is, a permutation of a finite number of elements such as the twelve tones of the chromatic scale. But the permutation of the tones destroys all vestiges of repetition and recognizable pattern and so produces chaos in our commonsense experience. It is easy, therefore, to dismiss serialization as an intellectual artifice unrelated to direct musical appreciation. Æstheticians were not slow in invoking the *gestalt* laws of perception in order to reject serialization as perceptually meaningless. But the æsthetician better beware of imposing rules on the artist and is better advised to accept the facts of art even if they do not fit in with current laws of psychology. As serialization wins the day, as it inevitably must, we are driven to the conclusion that its regularity must be perceived, if not consciously, then by an unconscious undifferentiated mode of hearing that is not bound by the normal sequence in time. It would be capable of recognizing a theme in any possible permutation of its constituent tones, whether they are played back to front, mirrorwise or in any other sequence.

If we assume this unconscious lack of differentiation, of time as well as of spatial distribution, then the initial impression of chaos turns into a hidden order. The double aspect of undifferentiation, conscious chaos against unconscious order belongs to the core of psychoanalytical æsthetics. Psychoanalysis has accepted all along that the primary process of the unconscious was undifferentiated and did not distinguish between different categories of things or even between opposites. Freud compared the undifferentiated meaning of unconscious symbols to archaic languages which, like Latin, do not differentiate between opposite meanings. The Latin word *altus* means both high and deep. The words hostility and hospitality go back to the same Latin root *host*. I said at the time that the reason why the unconscious mind can see through condensations like 'famillionaire' (which fuses friendliness and hostility) is found in its failure to differentiate between opposites and expressing them by the same symbol. Psychoanalytic writing, as a rule, does not realize that there may exist an unconscious type of vision for which these undifferentiated concepts become actual percepts so that different things can be actually seen as the same thing or high and low give the same space experience. A recently published psychoanalytical book dealing with man's view of the world casually mentions a patient's dream in which a man talked to a chair. The author marvels at a vision that does not distinguish between a man and a chair and treats it as a rare intrusion of psychopathological imagery into a dream. This interpretation is a far cry from my own, which assumes that all unconscious-subliminal imagery fails to make the ordinary distinctions of space and time.

Creative thinkers, however, have known that such a vision underlies creative work. The French philosopher, Henri Bergson, describes the structure of creative imagination (intuition) in just this way, namely, as a kind of vision where the normal differentiation of space and time ceases to operate and where incompatible things can extend into each other. Bergson advises the reader to evoke in himself a state of intuition by trying to visualize incompatible things (as a man and a chair would be) occupying the same spot in space. The main point which I wish to make is that unconscious undifferentiation may be a primitive infantile mode of vision, but in creative work becomes a sophisticated achievement. If the painter undoes the division between figure and ground and holds the entire visual field in a single glance he certainly regresses to an infantile mode of vision which has not yet learned to differentiate the visual field. That the child has undifferentiated concepts is a familiar fact. For him all males are still 'dada' while he has already learned to treat his mother as a distinct individual. But as I have maintained 'dada' would be more than a primitive concept. It is probably also a percept. The baby sees all males as having the same appearance as we adults fail to perceive fundamental individual differences if the biological incentive is lacking. The flies buzzing around the lamp-shade really look the same to us, as do all Chinese before we have established bonds of love and hate with single individuals.

The artist and scientist suspends the normal differentiation between concrete things in order to refine his power of abstraction. Prof. E. Gombrich, the well-known art historian, once poked his gentle but fierce fun at the pretensions of modern abstract art by pointing out—in my view correctly—that the modern artist's much-vaunted power of abstraction differs little from the child's still weak capacity for properly differentiating his environment. When Picasso gradually pares down the naturalistic shape of a bull into an abstract cipher he reverts to the vision of the child playing with his hobby horse who treats a mere stick like a living animal. Nor is it increased power of abstraction that prompts the drunkard to lift his hat to the nearest lamp-post. But Gombrich does not really debunk creative abstract art because, as I was so anxious to show, creative imagination turns primitive weakness into a sophisticated achievement, a dynamic transformation that belongs to the essence of the sublimation process as psychoanalysis conceives it. It is perhaps wrong or an oversimplification to say that the creative mind passively 'regresses' to the child's primitive vision. He actively undoes the basic differentiations of time and space itself into new types of visualization such as may have never been actually experienced in childhood.

The abstract concepts of science resemble abstraction in art; they are based on undoing commonsense differentiations between concrete things. A scientific abstraction extracts from different, often incompatible, things a common property and turns it into a new abstract concept. What is not sufficiently appreciated is that this 'seeing together' involves a capacity for undifferentiated vision. A new abstract concept at first sight seems empty of all mental imagery. But it is empty only in the way in which a blank dream or a subliminal image appear empty though they are filled with unconscious imagery. I am of course speaking only of truly creative abstraction in science. It differs from a sterile empty generalization as truly creative abstract art differs from a flat and empty ornament. Creative abstraction in art as well as in science is supported on a subliminal level by the multitude of incompatible visions that gave birth to it in the first place and which cancelled each other out on the way up to conscious visualization.

The need for seeing incompatible images 'together' is more clearly discerned in periods of transition when science is still groping for new concepts or models that would resolve existing contradictions. I owe a hypothetical example to a physicist friend of mine who once discussed the two complementary models of light which represent two conflicting images. Light is visualized in one context as a wave, in another as a stream of solid bodies. My friend suggested that a future scientist possessing powers of abstraction superior to our own may have no difficulty in visualizing light in terms of a more abstract concept that is neither a wave nor a solid body, but both at the same time. Such a potent abstract concept could only be formed by suspending temporarily the commonsense differentiation between incompatible things. So long as we have not achieved this high degree of undifferentiation it seems as incomprehensible to us as is the undifferentiated world of the child.

Psychoanalysis knows as yet little about the lower levels of perception that become activated during creative work. So far it has been more concerned with the content of the unconscious and its fantastic symbolism. The study of creative work requires more. The complexity of scientific and artistic work is such that it presses us to look for explanations in a subliminal sub-structure of conscious imagery. Its misleading impression of unstructured chaos has held up depth-psychological investigation even longer than has the irrational content of unconscious phantasy. We have only caught a passing glimpse of its hidden order and efficiency. Our descent into the depth of mental imagery has just begun.

PSYCHOTIC ILLNESS AND ARTISTIC PRODUCTION

SUBSTANCE OF A FRIDAY EVENING DISCOURSE BEFORE THE ROYAL INSTITUTION

By Prof. G. M. CARSTAIRS
University of Edinburgh

MENTAL illness is no respecter of persons. It afflicts rich and poor, intelligent and stupid, the gifted and the untalented alike. From the patient's point of view, its visitation is usually unwelcome, bringing suffering and handicap; in this it has some resemblance to the mixed blessing of unusual artistic sensibility. Like the artist, the psychotic sees the world differently from ordinary men; for him it often assumes a personal, or a threatening, implication—but above all it is full of the unexpected.

In our everyday life we tend to surround ourselves with familiar things, familiar sights, sounds, routines, gestures; and familiarity dulls perception. We notice this when we first arrive in a strange country —the sights and sounds of that first day are more vividly registered than they will be in a few days' time. The artist and the schizophrenic in their different ways seem to preserve that acuteness of perception which Sir Herbert Read has described as "the innocent eye"; but the schizophrenic's awareness is not just the freshness of a child's outlook on the world. It is a heightened awareness indeed, but one heightened by dread. He is aware of an element of threat in his surroundings. This is especially true during the active stage of the illness, which will sometimes recur with renewed intensity after a period of relative calm.

The depressed patient lives in a world drained of life, colour and hope. He is painfully aware that he himself has changed, and he is filled not with self-pity (although his state arouses compassion in others), but with self-loathing which may lead to self-destruction. Fortunately, severe depression is a disorder of limited duration: the sufferer can emerge from the depths and return to active life again. This was the experience of one of the earliest painters whose mental illness has been fully documented.

Hugo van der Goes (1440–82), an early Flemish master, twice experienced depressive illnesses of psychotic intensity. He achieved celebrity while still a young man and his work was in demand in places as far apart as Vienna and Edinburgh. His *Trinity Altar* from Holyroodhouse includes portraits of James III of Scotland and of Queen Margaret of Denmark among the attendant figures. Van der Goes was a man of restless energy, but he was not a happy man. He was subject to bouts of depression, and, like many depressives, he began to drink to excess in an attempt to relieve his feelings. At the age of thirty-five he temporarily renounced his vocation and retired to a monastery. It was not until five years later, however, that he became frankly deranged, crying out in despair that he was doomed. The monks, mindful no doubt of David's playing to Saul in similar circumstances, tried to exorcise his fit by playing music before him; but it was only gradually that he returned to something like his former state. In 1481 he was able to paint again; his *Death of the Virgin* (Bruges) was completed in that year, but it was probably his last work: in the following year his madness returned and he died soon afterwards. He himself protested that it was his own fame and success which caused his mind to become unhinged: but this sounds like the typical self-depreciation of the melancholic. Critics, wise after the event, have discerned qualities of tension and seriousness in his work; but it is surely remarkable for the technical mastery which survived rather than for any revelation of his serious illness.

It was a different matter in the case of Piranesi (1720–78). He too was a man noted for precocious gifts and exceptional energy. Born in Venice, the son of a stonemason, he was already drawing the buildings around where he lived at the age of eight. and his work was the talk of the town by the time he was fifteen. He was apprenticed to an uncle who was an architect, but his early years were punctuated by violent disputes both in Venice and in Rome, where he studied for a time under Tiepolo. He quarrelled with his uncle, with his father and with Vasi, who taught him engraving.

At the age of twenty-one he made a characteristically impetuous marriage, after a courtship lasting five days, and set up the engraver's workshop which was to establish his lasting fame. From this date until his death at the age of fifty-eight he produced nearly 1,200 etchings, many of great complexity. For several generations his visions of the antiquities of Rome were the models for teaching in every European school of architecture. In 1745, however, appeared an extraordinary series of etchings—the *Carceri d'invenzione*, or *Imaginary Prisons*. Tradition has it that they were the product of visions seen in the delirium of a fever.

Six years later, when at the height of his career, Piranesi returned once again to the *Carceri* and brought out a second edition in which the fantastic prisons are even more eloquently inhuman, vast and sinister than before. This juxtaposition of belligerent impetuousness, violent energy and preoccupation with human despair and hopelessness suggests very strongly that Piranesi was a manic-depressive who experienced episodes of melancholia.

The great Spanish painter Francisco Goya (1746–1828) was another man in whom spells of furious energy alternated with fits of black despair. Like Piranesi, he was an impetuous quarrelsome man, involved in duels and pursued by irate husbands. He is remembered for his ruthlessly candid appraisal of the pride and folly of the very society of which he was an idol. At times he was seemingly almost overwhelmed by the malignant folly of mankind, as when he created his series of etchings *The Disasters of War*, a sardonic commentary on the Napoleonic invasion of Spain; at times too in his *Caprichios* he hinted at disturbing personal visions, as in the title page "The Sleep of Reason begets Monsters". Goya lived to be over eighty, and even in his old age he was beset by fits of melancholy, during one of which he painted the series of Pinturas Nigras, of which one of the most terrible is *Chronos Devouring His Children*: with macabre humour, Goya chose to hang this picture in his dining-room.

Melancholia is a condition which we can readily understand: we have all sometimes felt depressed. But schizophrenia brings about bizarre and quite unfamiliar distortions of reality. In its early stages it can sometimes stimulate a more intense though usually rather sinister awareness of the mystery behind normal phenomena. One is compelled to wonder in what does this 'mystery' lie: perhaps it is an attribute of the beholder. Earlier in the present century painters of the surrealist school—men like Dali, Magritte and Yves Tanguy—were quite frankly envious of the schizophrenic's faculty of living in a dream-like state, even though the dream should often prove a nightmare. In the early 1920's the term 'paranoid' had a positive value in æsthetic parlance, and surrealists made it their aim to paint frankly psychotic imagery. This was their tribute to the 'magical' quality of schizophrenic phantasy, a quality which was attributed to its origin in the unconscious mind.

The onset of an acute schizophrenic reaction can be accompanied by distortions of perception. Patients will describe strange lights in the sky, a changed appearance of familiar objects. Volunteer subjects who have taken hallucinogenic drugs such as mescalin or lysergic acid diethylamide have described a rainbow-like appearance around the edge of things. Perhaps this is what Edvard Münch saw when he painted his *Madonna* and *The Shriek*. A similar vision is apparent in the early stages of the remarkable series of paintings of cats executed by Louis Wain in the course of his schizophrenic illness. Wain's cats undergo remarkable transformations under the influence of his mental disorder: at first realistic, charming and full of life, they become stylized, fragmented into angular symmetrical patterns, horrific and bizarre, and finally disintegrate into a shapeless kaleidoscopic mass.

Another item in the Guttmann–Maclay collection provides an involuntary record of a violent schizo-affective episode in the life of an anonymous Victorian flower-painter, between the years 1863 and 1865. His paintings are at first meticulously drawn, studied and cold. Then, in May 1864 they change; warm colours and ripe sensuous forms appear, while on the facing page of his book he apostrophizes the woman he loves. The succeeding paintings become more and more ecstatic and confused: a woman's form appears among the foliage, a snake and a solitary eye. The confusion reaches a climax—and then quite suddenly it is over: a new series of neat, dispassionate flower-paintings (dated 1865) supervenes.

Another patient from Maudsley Hospital was an art student who already showed considerable technical skill: but during her schizophrenic illness her paintings became slapdash, hasty, almost incoherent: she began to write in phrases and words to emphasize her fear of overwhelming disintegration. Later, as her personality rallied again, she expressed herself much more coherently in a finger-painting of two nightmare faces.

These series of paintings have shown the artists' struggle with the illness which threatened to overwhelm them. In a lesser degree, perhaps, all art is an attempt to exorcise an inner disease; certainly Freud was not alone in his experience that a period of restlessness and minor ill-health seemed to be the prelude to all his bursts of creative work.

Some of the greatest art has been the fruit of suffering: never more so perhaps than in the tortured magnificence of the works of Van Gogh's last four years.

There are a number of defences against the schizophrenic nightmare. One of these is to rally one's intellectual resources in an attempt to define and contain the threats which arise in phantasy: this is the obsessional defence. Few painters have been so constantly assailed by those monsters begotten in the sleep of reason as Hieronymous Bosch. In painting after painting executed with astonishing precision of detail he has conjured up a whole universe of demons. His bestiary, of course, is drawn largely from the traditions of the Middle Ages; but he depicted them with a new sense of urgency because he was persuaded that the fate of the world and the destiny of mankind hung in the balance. It has long been known that he believed the alchemists to be in league with the devil to overthrow the world, hence the profusion of alchemical symbolism in his works; but recent research has revealed that he was a member of a secret millenial cult, the Brethren of the Free Spirit, and their counter-symbols can also be found in his paintings.

A few years ago I had occasion to treat a young, self-taught Canadian painter, whose pictures showed certain affinities with those of Bosch, except that where Bosch was obsessed with the imminent destruction of humanity, this patient was for a time pre-occupied exclusively with his own tortured ruminations, his own phantasies and his sense of being trapped and helpless. He depicted these feelings eloquently in a series of paintings, particularly in one entitled *The Maze*, in which he drew his own prostrate form with his skull sawn open to reveal a maze, enclosed with no escape. In each compartment of the maze he showed one of his recurrent, usually painful, obsessive memories.

This patient won through, after some years, to a relative peace of mind. He is still painting, but his work has lost its former tragic intensity. Bosch, if one can judge by his works, never ceased to be tormented by his acute awareness of the peril which threatened mankind. His favourite image, to be found in many of his works, is the owl which represents human folly.

Where, I wonder, is the contemporary artist who can turn his "innocent eye" on the nightmare realities of this era with its threat of nuclear annihilation? We need a Goya or a Hieronymous Bosch to-day to quicken our sense of the urgency of the human predicament before it may prove too late.

DETERMINATION OF THE HELICAL CONFIGURATION OF RIBONUCLEIC ACID MOLECULES BY X-RAY DIFFRACTION STUDY OF CRYSTALLINE AMINO-ACID–TRANSFER RIBONUCLEIC ACID

By Dr. M. SPENCER, Dr. W. FULLER, Dr. M. H. F. WILKINS, F.R.S., and Dr. G. L. BROWN

Medical Research Council Biophysics Research Unit,
King's College, London, W.C.2

CRUCIAL steps in protein synthesis appear to involve interaction between transfer ribonucleic acid (RNA), to which amino-acids are attached, ribosomes, and the messenger or informational RNA which determines the amino-acid sequence of the protein[1-4]. More information about the 3-dimensional configuration of RNA molecules and the base sequences in them would greatly help these processes to be understood. In elucidating the structure of deoxyribonucleic acid (DNA), X-ray diffraction analysis was indispensable: it guided the building of the Watson–Crick model[5], and detailed diffraction

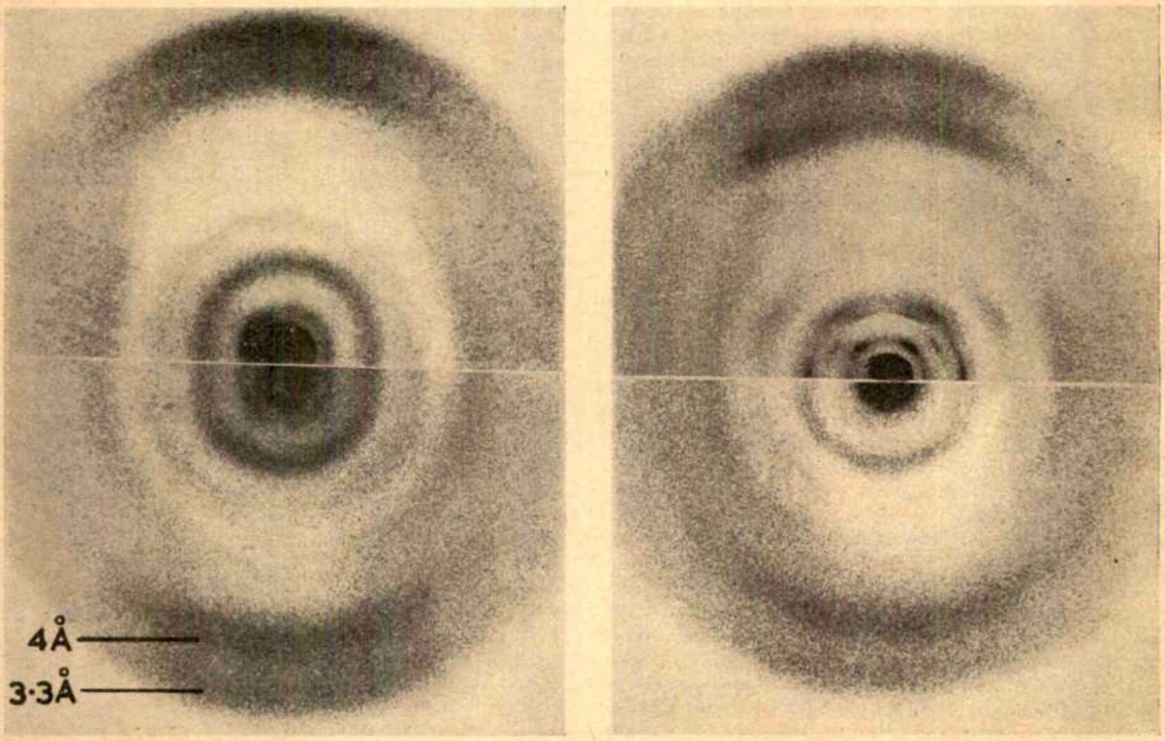

Fig. 1. Similarity of X-ray diffraction patterns of RNA. Top left, ribosome RNA from rabbit reticulocytes (supplied by Dr. R. A. Cox); bottom left, RNA from tobacco mosaic virus (supplied by Dr. H. Schuster); top right, crystalline yeast transfer RNA; bottom right, non-crystalline yeast transfer RNA (the innermost ring is missing from this pattern, which is taken at 57 per cent relative humidity, whereas the others are at 75 per cent)

data from crystalline fibres of DNA enabled the structure in its various configurations to be established[6-10]. The Watson–Crick hypothesis of DNA replication[11] was thus placed on a firm stereochemical base. In the case of RNA, however, X-ray diffraction has been of little use because the RNA was amorphous and the diffraction patterns were too diffuse to be interpreted[12].

Although the diffraction patterns of fibres of RNA had a broad similarity to those of DNA, it could not be established with certainty that the molecules were helical, whether there were one, two or three polynucleotide chains twisted together in helices, or whether there was more than one type of helix.

X-ray diffraction studies of synthetic ribopolynucleotides were less help than was hoped. The relation of the carefully established helical structure of polyadenylic acid[13] to that of RNA was not clear. Various complexes of polynucleotides gave DNA-like patterns[14]. The complex of polyinosinic and polycytidylic acids was of special interest because it gave a crystalline diffraction pattern resembling that of DNA and a non-crystalline pattern like that of RNA (ref. 15). This suggested that RNA might have a structure like DNA. The same conclusion was drawn from X-ray studies of soluble RNA (ref. 16) and from molecular model-building[17]. However, the most commonly found RNA pattern looked different from DNA patterns and no molecular model could be constructed which would correlate with it. On the other hand, nucleotide compositions of amino-acid transfer RNA from a wide range of sources[18-22] are very similar, and compatible with a DNA-like structure.

Physico-chemical investigations of RNA solutions[23-25] also provided much evidence that RNA molecules were probably helical. It was shown that RNA molecules contained hydrogen-bonded regions in which the bases were stacked on each other. Close correspondence of the behaviour of optical rotation for DNA, synthetic ribopolynucleotides and RNA strongly suggested that these regions were helical. Such investigations, however, gave little precise information about the helical regions; and, since the correlation of optical properties with configuration was largely empirical, the very existence of helical regions could not be established with certainty.

We have now obtained conclusive evidence that RNA molecules are helical and have determined the structure of the helix. This has been achieved by crystallizing yeast transfer RNA and by obtaining from it X-ray diffraction patterns of quality comparable to those of DNA. We give here a preliminary account of this work and of light microscope observations of liquid-crystalline forms of the RNA. We have concentrated on transfer RNA because the molecule was small and likely to have a regular structure, and because the prospects of isolating it intact seemed greater than with other types of RNA.

Preparation and Crystallization of Transfer RNA

Amino-acid transfer RNA was prepared from baker's yeast by the method of Brown, Kosinski and Carr[18,19]. Low-molecular weight RNA was extracted from the cells with 1 per cent 'Cetavlon' in 0·45 *M* sodium chloride; transfer RNA was purified by fractional precipitation with 'Cetavlon'–sodium chloride mixtures, and 'Duomeen 12'–$Mg(CH_3COO)_2$; residual protein was removed by treatment with phenol. Most of our observations have been made on preparations which were not fractionated with 'Duomeen'. The binding of amino-acids to the RNA was dependent on the presence of cytidine triphosphate, indicating that at least part of the terminal trinucleotide[26] was missing. The DNA content was found to be less than 0·1 per cent by the diphenylamine reaction[27]. 'Cetavlon' content was estimated as less than 0·1 per cent by Mr. P. J. Cooper, using a modification of a method for detecting quaternary ammonium groups[28].

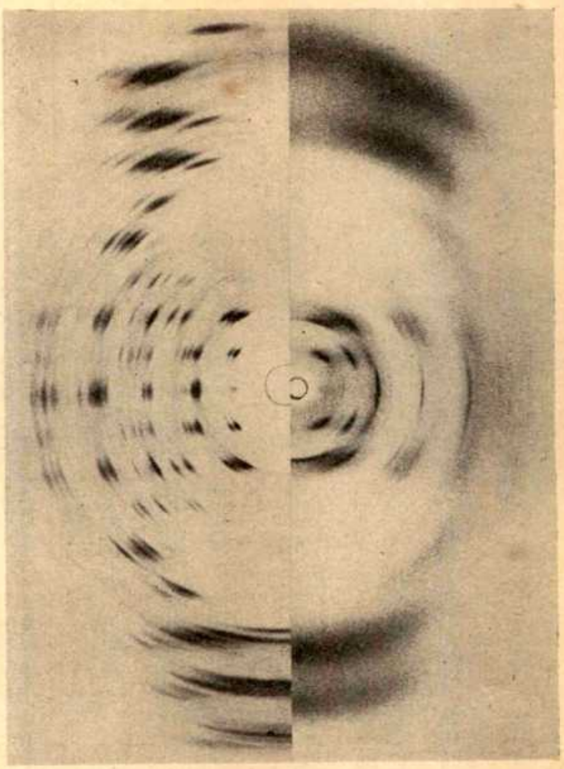

Fig. 2. Comparison of diffraction patterns of (left) DNA in the *A* configuration (supplied by Dr. L. D. Hamilton) and (right) crystalline yeast transfer RNA. Both are taken at 75 per cent relative humidity, with the fibres tilted 14° from the perpendicular to the X-ray beam. The patterns are joined along their meridians. Layer lines are horizontal, the equatorial layer line passing through the centre of the picture

Crystallization was induced by allowing a concentrated solution of RNA to dry in a controlled manner over a period of hours. Rapid drying, which does not inhibit crystallization of DNA, completely prevented crystallization of RNA. Only the sodium salt has so far been successfully crystallized. Excess sodium chloride prevented crystallization. Potassium and rubidium salts gave some crystallinity but the lithium salt did not. Magnesium inhibited crystallization. The best patterns were obtained by crystallization at about 0° C.; it was found possible at this temperature to obtain oriented fibres by drawing them from the material before it had completely solidified. With specimens prepared at higher temperatures, the overall distribution of intensity in the patterns was the same, but orientation was inferior and the positions of the sharp reflexions indicated that a mixture of two lattices was present.

X-Ray Diffraction Patterns of RNA

Fibres of all types of RNA which we have examined —RNA from tobacco mosaic virus, *E. coli* and rabbit reticulocyte ribosomes, and non-crystalline transfer

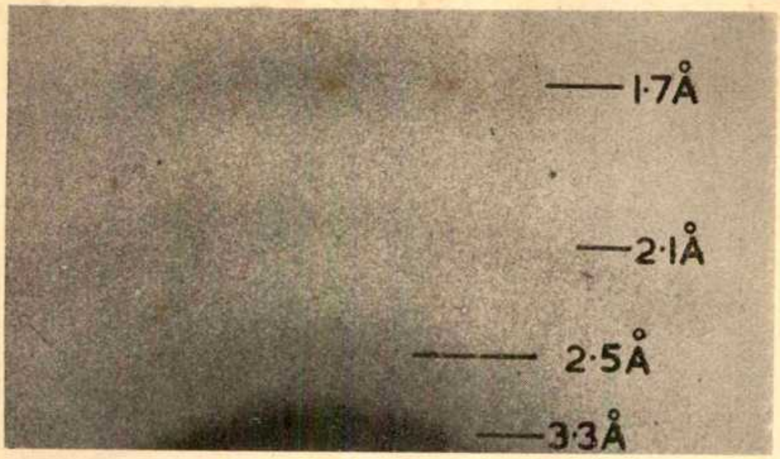

Fig. 3. Part of a heavily exposed diffraction pattern from crystalline transfer RNA, showing the eleventh layer line. The faint reflexion on this line appears to be meridional, and corresponds to 2·5 Å., the internucleotide spacing along the axis of the molecule. A similar reflexion is observed with *A* type DNA

RNA from yeast—give almost identical diffraction patterns (Fig. 1). When transfer RNA crystallizes, the pattern is better oriented, more clearly defined and, in the central part, the diffraction is split into sharp crystalline reflexions (Fig. 2). However, the broad distribution of intensity remains the same, showing that the molecular configuration has not been altered by the crystallization.

The crystalline pattern has a striking resemblance to the *A* type pattern of DNA (Fig. 2). This resemblance was not apparent when diffuse patterns alone were available. The positions of the sharp reflexions differ from those in DNA, because the crystalline packing is different; but it is clear that the broad distribution of intensity, which is determined by the molecular configuration, has maxima and minima closely corresponding to those of the DNA pattern on the various layer lines. This means that the two structures are essentially the same.

The diffuse patterns of RNA could not be interpreted without comparison with the crystalline patterns, because several basic features of the pattern could not be distinguished. The diffraction pattern of a helix may be recognized by absence of diffraction on the meridian on all layer lines, except for an upper layer line reflexion corresponding to the separation of nucleotides along the helix axis. In the diffuse patterns, lack of orientation prevented it being seen that meridional diffraction was absent on the first and second layer lines, obscured the fact that the strong outer reflexions at 3·3 Å. and 4 Å. were non-meridional, and made it impossible to distinguish equatorial reflexions from those on the first layer line. Another difficulty was that the 3·3 Å. and 4 Å. reflexions did not appear to lie on layer lines. With the crystalline patterns, these difficulties are very largely removed and the 3·3 Å.–4 Å. reflexions are seen to be resolved into several overlapping components which correspond roughly to those of the DNA *A* pattern (Fig. 2). When the fibre is inclined to the X-ray beam so that higher layer lines are recorded, the RNA and DNA patterns are very similar: no tenth layer line is seen but a reflexion on the eleventh at 2·5 Å. (Fig. 3) is present (the numbering of layer lines is taken from the *A* pattern). We believe that this reflexion corresponds, as in DNA, to the separation of nucleotides along the helix axis. Still higher layer lines are not seen separately, but the general intensity distributions for RNA and DNA are very similar (Fig. 4).

The relative intensities of diffraction on the sixth, seventh and eighth layer lines are for RNA somewhat different from those for DNA. In poorly defined patterns the seventh layer line appears to be weak; but in the best patterns there are indications that the intensity maximum on the seventh layer line has moved outwards so that it tends, owing to disorientation, to overlap with the maximum on the eighth layer line. This kind of overlap gives the impression in the poorer patterns that the reflexions do not lie on layer lines. Preliminary model building shows that the differences between the outer regions of the RNA and DNA patterns, as well as some differences in the central region, may be accounted for by a twisting of the *A*-type model of DNA about the helix axis and by a small movement of the phosphate groups relative to the base and sugar groups. Moreover, when DNA (sodium salt) is dried, the maximum on the seventh layer line moves in the way we describe (Fig. 5). At 10 per cent relative humidity the intensity distribution is very similar to that of RNA, the maxima not lying on layer lines. Dr. D. R. Davies directed our attention to the fact that unpublished patterns of dried DNA, obtained by Drs. Franklin and Gosling (see also ref. 29), had, on the higher layer lines, an intensity distribution like that of RNA.

Structure of the Transfer RNA Molecule

Intensity measurements of the diffraction patterns of transfer RNA indicate that, as with DNA, at least 50 per cent of the material is crystalline. The clarity and sharpness of the patterns suggest that most of the molecules have, apart from base sequences,

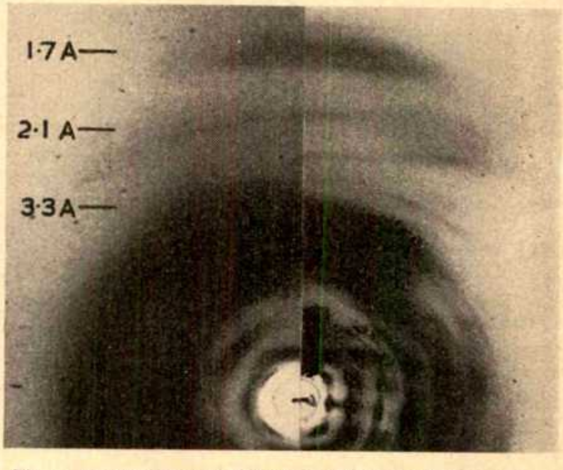

Fig. 4. Heavily exposed diffraction patterns of (left) crystalline transfer RNA, and (right) DNA in the *A* configuration, the fibres being tilted to record diffraction on higher layer lines. The diffraction in the upper region corresponds to smaller spacings and is similar in both patterns

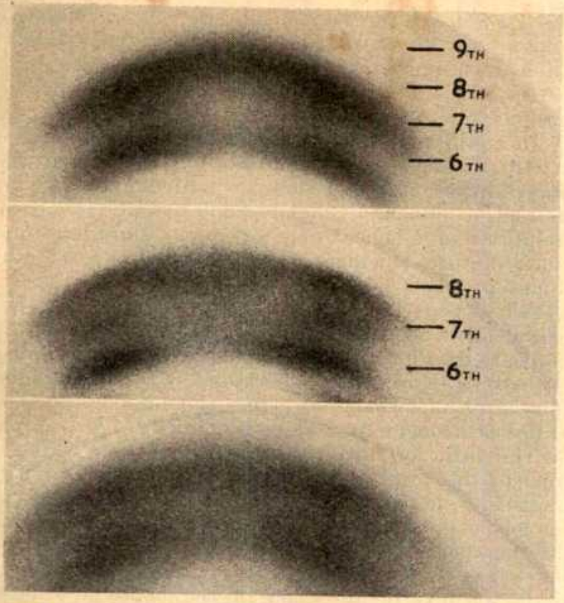

Fig. 5. Diffraction on sixth to ninth layer lines from (top) crystalline yeast transfer RNA at 75 per cent relative humidity, (middle) sodium DNA at 32 per cent relative humidity, and (bottom) sodium DNA at 10 per cent relative humidity

identical and highly regular structures. The fact that the transfer RNA molecule has a structure like DNA implies that the RNA molecule contains Watson–Crick pairs and complementary sequences. The sharpness of the patterns is not sufficient to exclude the possibility that there are minor deviations from complementarity. However, we think it likely that the sequences in the molecule are exactly complementary from one end of the helix to the other.

It is known that each molecule consists of one polynucleotide chain of about 80 nucleotides[19,22]. The most likely structure consistent with our results is therefore one in which the polynucleotide chain is folded back on itself[16] so that the sequence of atoms in one-half of the chain runs in the opposite direction to that in the other, the two halves of the chain thus being equivalent to the two 'anti-parallel' chains in DNA. The molecule is about 100 Å. long and contains roughly $3\frac{1}{2}$ helix turns. The pitch-length varies with humidity from about 28 Å. to 30 Å. The separation of nucleotides along the helix axis direction is 2·5 Å. The base pairs are tilted about 20° from the perpendicular to the helix axis. The distance between two ribose groups at the end of a molecule is about 12 Å. Model building shows that the portion of polynucleotide chain joining these groups, and forming the bend at one end of the molecule, need contain no more than three nucleotides. Also there is no difficulty in accommodating in the structure the hydroxyl group of the ribose. It is very likely that there is a hydrogen bond from the hydroxyl, either to the ring oxygen atom of the neighbouring ribose or to an oxygen atom of the adjacent phosphate group. Such an extra bond should help to stabilize the structure. This may explain our observation that the structure is largely unchanged over a wide range of relative humidity (32–92 per cent).

Base analyses of the RNA preparation support the proposed structure. Because of base-pairing there should be equal numbers of adenine and uracil groups and of guanine and cytosine (if we ignore the bases at the folded end of the helix and the remnant of trinucleotide tail). These equalities are observed[19]. Investigations of the properties of transfer RNA in solution suggest that 70–75 per cent of the material is helical[30]. We believe all the molecules are similar, and, because there is no evidence of uncoiling in the crystallites, our results suggest that the overall helical content in the solid state is higher. It may be that the molecules partly uncoil in solution but are entirely helical in the solid state because the high concentration of sodium ions present gives the helices extra stability.

It is not clear at present how our results relate to those of Brown and Zubay[16] on soluble RNA, with amino-acids attached, from *E. coli*. Their X-ray data indicated that a proportion of the molecules were in a configuration resembling the *B* form of DNA. It is, however, apparent in the light of our recent work that the patterns indicate also the presence of molecules with a structure like the one we describe here. Moreover, it has since been shown[19] that soluble RNA preparations of the kind studied by them contain only 65 per cent transfer RNA.

Crystalline Arrangement of Transfer RNA Molecules

The sharp reflexions in the crystalline pattern of RNA can be indexed on a hexagonal lattice and the indices of absent reflexions show that each molecule is surrounded by six neighbours each of which is displaced, in the helix axis direction, by one-third the pitch-length. When crystallinity is optimum, at 75 per cent relative humidity, the unit cell dimensions are $a = 40{\cdot}7$ Å., $c = 29{\cdot}0$ Å., the c axis being in the helix axis direction.

It is noticeable that, whereas the crystalline reflexions in the central region of the pattern are sharply defined, diffraction on higher layer lines is diffuse. DNA patterns of this kind are referred to as semi-crystalline. The explanation of the sharpness of the central reflexions is that the molecules interlock to form a highly regular arrangement of helices (Fig. 6). The diffuseness of the outer reflexions is apparently due to each helix being turned like a

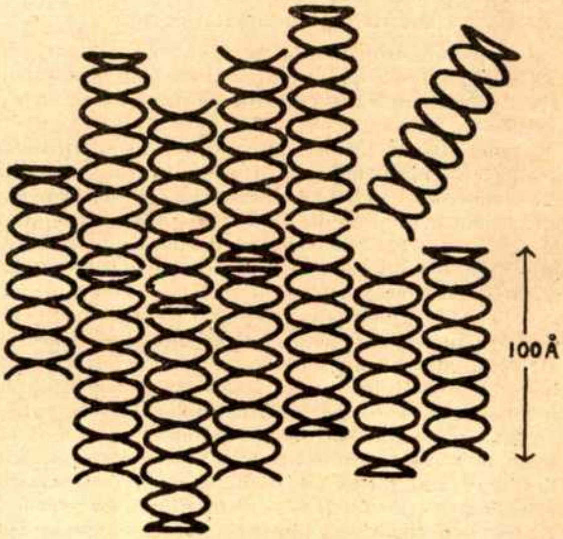

Fig. 6. Diagram of the arrangement of double-helical transfer RNA molecules in a crystal. The lines represent polynucleotide chains. A single molecule is shown at top right

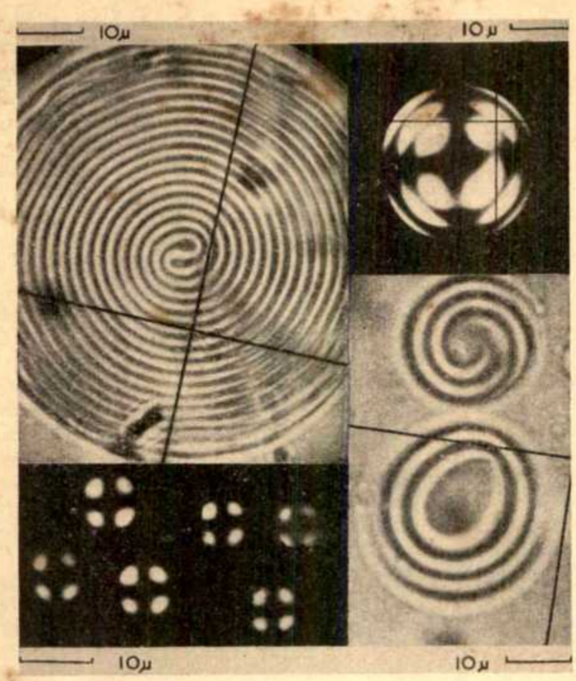

Fig. 7. Liquid crystal forms of transfer RNA. Top left, large spherulite showing double spiral contour due to variation of refractive index (unpolarized light). Bottom left, a group of simple spherulites (crossed nicols). Top right, spherulite showing circular contours of refractive index (crossed nicols). Bottom right, the same in unpolarized light, compared with a small spherulite of spiral type

screw about its axis by a random amount. In addition the short length of the molecules, 3½ helix turns, would cause the upper layer lines to spread vertically over a width one-third of their separation. It is possible that slight irregularities in the structure also contribute to the diffuseness.

If there were appreciable gaps between the ends of the molecules one would expect diffraction at angles corresponding to the length of the molecules; no such diffraction has been observed up to 200 Å.

Polarizing Microscope Studies of Transfer RNA and its Liquid Crystal Forms

Solutions of transfer RNA, on drying, show in the polarizing microscope a number of striking phenomena which corroborate the conclusions drawn from X-ray studies.

A dried layer formed at an interface with air is negatively birefringent. This indicates that the molecules are rod-shaped, negatively birefringent, and orient, as one would expect, parallel to the interface. Similarly, the sheared material in a drawn fibre of the kind used in the X-ray experiments has negative birefringence. The value of the birefringence is 0·07, which is consistent with the fibres consisting entirely of helical molecules like those of DNA in the *A* configuration, the high birefringence being due mainly to the bases lying roughly perpendicular to the length of the molecule.

The rod shape and negative birefringence of the molecules are confirmed by the properties of various liquid crystal forms which develop in concentrated solutions of transfer RNA on standing. As expected, tactoids are negatively birefringent and, in spherulites, the direction of the greater refractive index is radial. Furthermore, the small axial ratio of the tactoids (~ 1·5 : 1), and the very small difference of refractive index between ordered and disordered regions, both indicate that the axial ratio of the molecules is not large. In agreement with this, the structure we propose has an axial ratio of 5 : 1.

In addition to simple spherulites (Fig. 7), there is a remarkable type of spherulite which, viewed from most angles, shows a double-spiral due to varying refractive index. Similar bodies were found in solutions of α-helical poly-γ-benzyl-L-glutamate and their nature elucidated[31–33]. A similar form was found in gels of DNA[32].

A new type of spherulite is found in the RNA, the spiral form being replaced by concentric circles. It appears that both types of spherulite contain similar structures, except that the spiral type has a radial line of disinclination[34], whereas the circular type has a line of disinclination along a diameter.

The variation of refractive index in these bodies is due to the varying direction of the molecules. The molecules lie parallel in layers with the length of the molecule in the plane of the layers. The direction of the molecules in one layer is, however, inclined at a small angle to that in the neighbouring layer. As a result, the direction of the molecule rotates on passing through a succession of layers, so that the whole assembly is twisted. The inclination of the molecules in one layer to those in the next shows that the packing forces between the molecules must be asymmetric and therefore that the molecules are asymmetric. A helical molecular structure has the required asymmetry.

The twisted liquid-crystalline structure appears to be essentially the same as that found in cholesteric liquid crystals[35]. With RNA the regularity of the twisted structure and the perfection of the spherulites indicate a high degree of molecular homogeneity in the preparations.

The homogeneity of the preparations is also indicated by the finding that, when the RNA dries between microscope slide and coverslip, solid birefringent domains form in which the optic axis is often exactly parallel over an area of many square microns (Fig. 8). The parallelism suggests that these areas are single crystals; presumably they correspond to the microcrystals that give the crystalline X-ray patterns. In agreement with this, some unoriented specimens of crystalline RNA give diffraction rings in which the spots corresponding to individual crystals can be seen separately (Fig. 8).

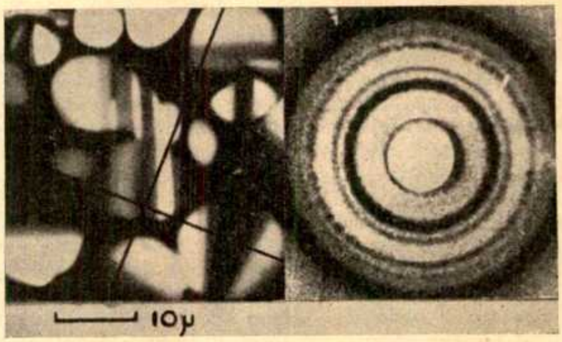

Fig. 8. Left, birefringent crystalline regions in a thin film of dried transfer RNA (crossed nicols). Right, central region of diffraction pattern from an unoriented specimen of crystalline transfer RNA. The third ring from the centre consists of spots corresponding to separate crystals in the specimen. The second ring from the centre is from another crystalline phase and shows no spots

This effect has not been observed with unoriented DNA; the diffraction rings are uniform and the crystallites very small.

Relation of the Structure of the Transfer RNA Molecule to its Function

Various speculations may be made about the transfer RNA molecule. (1) Molecular model-building shows that the fold at the end of the molecule must consist of at least three nucleotides with free hydrogen-bonding sites on the bases. These might be the nucleotides (probably three[36]) which specify each amino-acid in the code for amino-acid sequence, since their bases could form hydrogen bonds with coding RNA. (2) The crystalline packing we observe for RNA molecules in the solid state might be operative during protein synthesis, by packing transfer RNA molecules with helical regions of ribosomal or coding RNA. (3) The probable function of many of the nucleotides in the molecule is to react specifically with an amino-acid-activating enzyme so that the correct amino-acid is attached to the RNA molecule. The specific pairing in the molecule might serve to prevent the bases, which react with the enzyme, from hydrogen bonding to the coding RNA and thus interfering with the functioning of the adaptor. The role of pseudo-uridylic acid in the molecule is obscure; it could form a Watson–Crick pair with adenine in the double helix[17]. (4) The deduction of complementary sequences within each molecule suggests the molecule might be self-replicating. To replicate, the molecule would unfold and a second polynucleotide chain would form on the parent chain. If the two halves of each chain contained complementary sequences, both chains would be identical in their helical regions. After separating, each chain would fold into a double helix. However, the three or more unpaired bases in the folded ends of the parent and daughter molecules would not necessarily be identical.

Structure of the Helical Regions in Virus and Ribosome RNA

When we obtained crystalline diffraction patterns from transfer RNA, the nature of the diffuse patterns obtained from other types of RNA became clear. There is no doubt that they are essentially the same as the crystalline pattern, although there are minor variations: every feature of diffuse patterns can be accounted for in terms of the crystalline pattern, and the small though characteristic changes with humidity are the same. We are confident, therefore, that all types of RNA so far studied contain helical regions with a configuration essentially similar to that of *A* DNA.

The base compositions of virus and ribosome RNA are such that at least 10 per cent of the material cannot exist in a DNA-like structure with complementary sequences. In agreement with this, solution studies[25] indicate that the helical content of tobacco mosaic virus RNA is 88 per cent and that of ribosome RNA is 77 per cent. These studies also indicate that the molecules consist of single polynucleotide chains and that, where parts of the chain contain approximately complementary sequences, these parts may fold back on themselves to form double helices in which the two parts of the chain are anti-parallel[37]. The X-ray results show that the chains are anti-parallel. This provides further evidence that the helices in virus and ribosome RNA are formed by folding back of the chain.

It might be thought that the diffuse nature of the virus and ribosome RNA patterns was evidence that the helical regions were not regular. This is not necessarily so, for the patterns of virus and ribosome RNA are no more diffuse than that of non-crystalline transfer RNA. The differences between the non-crystalline and crystalline patterns of transfer RNA appear to be due to improved orientation and regular packing of molecules in the crystalline material, and not to increased regularity of the molecule. There is therefore little to suggest from the X-ray results that the helical regions in virus and ribosome RNA are less regular than those in transfer RNA.

It is therefore possible that the base sequences in the helical regions are exactly complementary. However, in the absence of crystallinity, the X-ray evidence is not adequate to decide between three possibilities for the structure of virus and ribosome RNA. (1) The helical regions might consist entirely of Watson–Crick pairs, separated by non-helical regions (which could prevent crystallization). (2) The base sequences in the helical regions might contain, in addition to Watson–Crick pairs, other base-pairs, some joined by only one hydrogen bond[37–39]. These pairs would cause minor irregularities in the helix, because their dimensions would differ from those of the Watson–Crick pairs. (3) Where there are deviations from complementary sequence in the folded regions of virus and ribosome RNA, the non-pairing part of the polynucleotide chain might form a small loop projecting from the double helix, all the bases in the helix forming Watson–Crick pairs[40]. Such loops would interfere with regular packing of one helical region with another. Some degree of regular packing does occur; this is shown by the presence of a fairly well-defined ring near the centre of the patterns of virus and ribosome RNA. While the X-ray evidence does not prove that there are no loops containing unpaired bases, it is probably not in favour of their existence. The diffraction patterns of random polynucleotides could cast light on these problems[14] but a difficulty is that the degree of randomness is seldom precisely defined.

Can X-ray Diffraction Analysis provide the Base Sequence of Transfer RNA?

The number of bases in a DNA molecule is too large for a determination of base sequence by X-ray diffraction to be feasible. However, in transfer RNA the number of bases is not too large. The size of the crystals observed by means of X-ray diffraction and polarization microscopy suggests that it should not be too difficult to grow crystals large enough for single-crystal X-ray analysis. If a pure preparation of transfer RNA specific for one amino-acid were used, one might expect that the crystals would be free of the disorder at present found and would be as perfect as those in microcrystalline DNA. If such crystals were obtained, and provided that all the molecules had identical structure and base sequence, a complete analysis of the primary structure of the molecule could be made, including the sequence of the bases and the form of the fold at the end of the helix.

We thank Prof. J. T. Randall, Drs. R. A. Cox and S. Arnott for advice and discussion; Mr. Z. Kosinski for help in preparing RNA; Mr. P. J. Cooper for technical assistance; Mr. Z. Gabor and Mrs. F.

Collier for photographic help; Drs. R. A. Cox, H. Fraenkel-Conrat, M. Grunberg-Manago, L. D. Hamilton, S. Osawa, H. Schuster, B. Singer and G. Zubay for sending us material for trial; the Rockefeller Foundation for a grant, and the University of London Computer Unit for facilities.

NEWS and VIEWS

Food Science and Technology at the Food and Agriculture Organization : Dr. Z. I. Kertesz

Dr. Z. I. Kertesz (United States) has been appointed chief of the Food Science and Technology Branch of the Nutrition Division of the Food and Agriculture Organization. He succeeds Dr. A. G. van Veen of The Netherlands, who has been appointed to the new chair of international nutrition, Cornell University, Ithaca, New York. Dr. Kertesz joined the Food and Agriculture Organization in September 1961, following more than thirty years with the Department of Food Science and Technology, Cornell University. During the past fifteen years he has also carried out surveys of the food industries in Europe and Australia, and in Ceylon, Korea, Turkey, Libya, Ethiopia, Taiwan, and Thailand. During 1952–53 he was nutrition officer for the Organization in Ceylon. During 1950–52, Dr. Kertesz was editor of the journals *Food Technology* and *Food Research*.

Applied Mathematics at Nottingham :

Prof. R. Hill, F.R.S.

Prof. Rodney Hill was appointed professor of applied mathematics at the University of Nottingham in 1953 after holding a research fellowship and readership at Bristol. His research has been mainly in the field of continuous mechanics of solids and has been concentrated in recent years on the fundamental questions of uniqueness and stability, especially for materials of non-linear type. His researches have been published in a large number of important papers in scientific periodicals and in his book on plasticity, which has been recognized since its publication as a standard work on this subject. He has also been editor of the *Journal of Mechanics and Physics of Solids* since 1952. He gained the degree of Sc.D. in Cambridge in 1959, and the distinction of his contribution to applied mathematics was recognized by his election to the fellowship of the Royal Society in 1961. Prof. Hill has resigned his chair at Nottingham to devote the year 1962–63 to writing and studying without academic responsibilities. Although his plans after that year are still uncertain, he will certainly be working and carrying out research at the University of Nottingham during the year, and he will also continue as editor of the *Journal of Mechanics and Physics of Solids*.

Prof. G. G. Hall

Dr. George Garfield Hall, lecturer in mathematics in the Imperial College of Science and Technology, London, has been appointed to succeed Prof. Hill. Dr. Hall graduated with first-class honours in both mathematical physics and mathematics at the Queen's University, Belfast, in 1946, and a year later gained a third degree with first-class honours in physics. From Belfast he went to Cambridge and began research on the orbital theory of chemical valency, for which he was awarded the degree of Ph.D. in 1951. In 1950 he was appointed assistant in research in theoretical chemistry and three years later was elected to a Fellowship in St. John's College, Cambridge. He was appointed to his present position in 1955, and was granted leave of absence to spend the session 1957–58 in the University of Uppsala on research. In 1961 he spent two months at the Institute of Theoretical Physics, Naples, and this year was in Florida for a shorter period. The principal field of Dr. Hall's recent research has been that of quantum mechanics as applied to problems of atomic, molecular and crystal structure, but he has also published papers on programming for an electronic computer and in the field of theoretical biology.

Expenditure by Colleges of Advanced Technology in Britain

In a written answer in the House of Commons on May 21, the Minister of Education, Sir David Eccles, estimated the total amount of tuition and residential fees receivable in 1962–63 from students at the colleges of advanced technology to be £660,000. He estimated net recurrent expenditure after allowing for income receivable from fees and sources other than Ministry grant was £7,532,107, besides capital expenditure on new buildings and equipment, towards which a grant from the Ministry was estimated to be about £2 million. For the individual colleges the figures are: Battersea College of Technology, £753,116; Birmingham College of Advanced Technology, £1,274,790; Bradford Institute of Technology, £1,040,060; Bristol College of Science and Technology, £440,205; Brunel College, Acton, £523,205; Chelsea College of Science and Technology, £526,160; Loughborough College of Technology, £501,307; Northampton College of Advanced Technology, London, £735,392; Royal College of Advanced Technology, Salford, £1,147,270; Welsh College of Advanced Technology, Cardiff, £590,702.

Power from Gas-cooled Reactor Stations

In a written answer in the House of Commons on May 21, the Parliamentary Secretary for Science, Mr. D. Freeth, stated that, assuming a 20-year life, 75 per cent load factor and 6 per cent interest charge, the Atomic Energy Authority estimated that an advanced gas-cooled reactor station of two 500-MW. reactors would produce electricity at rather less than 0·5*d*. per unit, excluding the recovery of development expenditure. This should fall to 0·45*d*. per unit and probably lower as the reactor system is developed further and larger reactors are built. If the load factor is taken as 85 per cent, the unit cost would be reduced by about 0·04*d*. and in addition a station life of 30 years would give a further reduction of 0·03*d*. These estimates assume that the overheads of industry and the Authority in connexion with these reactors are spread over a series of stations.

British and American Industrial Research

The industrial pattern of research and development expenditure is strikingly similar in Britain and America. In both countries, the same group of industries—mainly capital goods and chemicals—account for more than nine-tenths of research expenditure although they employ less than half the total labour force engaged in manufacturing industry. The story is very different, however, when total and relative expenditures are compared. A comparative study of the subject published in the May issue of *Economic Review* shows that after allowing for differences in salaries and other factors, the American effort is more than five times as big as in Britain. In terms of real expenditure per employee, it is about three times as big and as a percentage of output about twice as high. The economy of the United States benefits from more research per worker as from more capital per worker and both contribute to high productivity. There is a marked correlation between research and growth in both countries and this appears to have a common cause. Fundamental discoveries in science and technology dictate the areas in which research and development are likely to be fruitful. Though more expenditure on research will not necessarily yield faster growth in any particular industry, yet it seems certain that any programme for faster growth in Britain must include provision for more research expenditure, especially as growth in Britain is inexorably linked with exporting. British industry cannot hope to rival American industry in the absolute volume of industrial research, but *Economic Review* suggests that to some extent British industrialists might be able to compensate for their smaller total resources by greater concentration of effort. Copies of *Economic Review* are obtainable from the National Institute of Economic and Social Research, 2 Dean Trench Street, Smith Square, London, at 12*s*. 6*d*. each.

Management Training Techniques

The management training techniques used by different organizations vary widely, and, over the past three years, the Management Development Schemes Sub-Committee of the British Institute of Management has been examining the training philosophy and management selection and development policy in a large number of commercial and industrial concerns. At a conference held in London last year under the chairmanship of Mr. C. G. Simpson, director-general of staff, National Coal Board, people individually concerned with four particular training techniques were brought together and asked to explain them. The papers they gave, together with the summing up by Mr. A. R. N. Roberts, are reprinted in *Management Training Techniques* (Pp. 68. London: British Institute of Management, 1962. 9*s*. 6*d*.). The four principal papers given were: Dr. W. D. Hargreaves (Richard Thomas and Baldwins Ltd.), "Case Studies and Projects"; Mr. B. Eldon (Shell International Petroleum Co. Ltd.), "The Business Game"; Mr. K. D. O. Cole (Westminster Bank Ltd.), "Role Playing"; and Mr. R. J. Hacon (Joseph Lucas Ltd.), "Group Dynamics".

Physics Letters

Similar in aim, size and format to *Physical Review Letters*, published by the American Institute of Physics, is the new international letter journal, *Physics Letters*, which is issued bi-monthly commencing with the April number (1, No. 1. Pp. 32. Subscription price per vol., 36 guilders; 62*s*.; 10 dollars; 40 D.M. Amsterdam: North-Holland Publishing Co.). The editors are G. E. Brown (Copenhagen) and D. Ter Haar (Oxford). Members of the advisory editorial board are drawn from twenty-five countries, including Australia, Canada, France, Great Britain, India, Japan, the United States, the U.S.S.R. and Yugoslavia, but not China. Contributions can be written in English, French or German. The April number contains thirteen letters, two in French and the others in English, which bear dates of communication between January 28 and March 13. They include letters from CERN on a new measurement of the anomalous magnetic moment of the muon; and from CISE (Milan) on an application of silicon detectors to measurements of monoenergetic neutron beams, and on (n, α) reactions in heavy elements.

Photochemistry and Photobiology

A revival of interest in photobiology in the past few years has resulted in the birth of a new periodical, *Photochemistry and Photobiology*, the first issue of which has recently appeared (1, January–March 1962. Approx. 70 pages. Published quarterly by Pergamon Press, Ltd., Oxford, New York. Annual subscription for personal use 70*s*., or 10 dollars). The object of this international journal is the publication, in English, French or German, of "papers concerning all aspects of photochemistry and photobiology but will be primarily concerned with articles of an analytical nature dealing with the photochemistry of organic substances and the action of infra-red, visible and ultra-violet light on biological systems". Papers dealing with ionizing radiations are specifically excluded. Members of the editorial board are Dr. E. J. Bowen, University of Oxford; Prof. S. Claesson, Institute for Physical Chemistry, Uppsala; Dr. A. Hollaender, Oak Ridge National Laboratory, United States; Prof. A. O. McLaren (executive editor), University of California; and Prof. D. Shugar, Institute of Biochemistry and Biophysics, Warsaw. These are supported by an international group of leading workers forming an editorial advisory board of thirty-three. Although duplicating, to some extent, the aims of *Radiation Research*, the institution of a separate journal devoted to the physical, chemical and biological aspects of non-ionizing radiations seems justifiable at the present time. The contents of the first issue (mainly concerned with nucleic acids and related substances) show a high standard of editorial policy; in particular, citations of recent literature in the field—as a regular feature—should be of great value to research workers involved.

Large-Scale Mach-Zehnder Interferometer

The new large-scale Mach-Zehnder interferometer recently announced by the Carl-Zeiss Foundation of Oberkochen, Western Germany, is a further development of the well-known single-mirror focusing model, and incorporates optical systems and focusing mechanisms of very high standard. The total deviation from parallelism and straightness in the interference fringes is less than one-tenth of a fringe width throughout, even though the light beam is reflected four times and passes through two glass plates before the measurements are made. The need for two cameras has been obviated. By shortening the focal length of the objective it has been possible to unite the cameras and, whereas previously the former intermediate image was barely 1 cm. in diameter, it is now of a size to be directly photographed. The interference image is very bright and the exposure time required for a photographic record is extremely short. By means of a large 13 × 18 cm. ground-glass screen it is possible for the interference fringes to be viewed simultaneously by several viewers. The agents in the United Kingdom are Degenhardt and Co., Ltd., 6 Cavendish Square, London, W.1, from whom a coloured illustrated booklet can be obtained in which is given full details of the interferometer, associated camera and other accessories for various applications in the fields of aerodynamics, fluid dynamics, thermodynamics and ballistics.

Solvents in Dry Cleaning

Risks of fire and explosion from the use of solvents in dry cleaning processes, and the precautions that should be taken to reduce such hazards, are discussed in *Dry Cleaning Plant: Precautions Against Solvent Risks*, a booklet in the Safety, Health and Welfare, New Series, published by the Ministry of Labour (No. 15. Pp. 20. London: H.M.S.O. 1*s.* 3*d.* net). Solvents in general use are divided into two categories—flammable and non-flammable. The former are white spirit and petroleum distillate, and the latter mainly chlorinated hydrocarbons, such as trichloroethylene and perchloroethylene. When dry cleaning was first introduced, highly flammable solvents such as benzine or petrol were used. Fires and explosions causing serious injury and damage resulted. The introduction, in 1949, of the Dry Cleaning Regulations, which restricted the use of petrol and other liquids with a flash-point below 90° F., has greatly reduced risks from fire and explosions in the washing and hydro-extraction stages. There is still a risk of serious fires and explosions in tumblers used for drying articles cleaned in white spirit or petroleum distillate. Flammable solvents now being used have a flash-point of about 100° F. At atmospheric temperatures these do not give off vapour in concentrations high enough to form flammable or explosive mixtures. In some processes, such as tumbling, temperatures of about 150° F. are usual, giving rise to explosive concentrations of solvent vapours unless adequate precautions are taken.

Hydrology in Great Britain

Because of the ever-increasing demand for water there is increasing need for information about the quantity and quality of supplies available. Data on the flow of many rivers in Britain are given annually in *The Surface Water Year-Book of Great Britain*, issued by the Ministry of Housing and Local Government and the Scottish Office. In the latest issue, that for 1959–60, for the first time graphs are given which show, for selected stations, the frequency of discharges above given values (*Hydrometric Statistics for British Rivers, together with Related Rainfalls, for the year ended 30th September, 1960.* Pp. xiv+113 (2 maps). London: H.M.S.O., 1961. 22*s.* 6*d.* net). Information of a different kind is collected in the *Selected Bibliography of Hydrology*, prepared on behalf of the International Association of Scientific Hydrology of the International Union of Geodesy and Geophysics by the Hydrology Sub-Committee of the British National Committee for Geodesy and Geophysics (*Selected Bibliography of Hydrology (with abstracts), United Kingdom, for the years 1955–59 inclusive.* Pp. 52. London: The Royal Society, 1961). This contains references, with brief abstracts, of publications which appeared between 1955 and 1959 on many aspects of hydrology of both surface and ground waters. References to overseas work are included if it has been published in the United Kingdom. It is hoped that further bibliographies, dealing with later years, will be published periodically.

Geological Atlas of British Guiana

Few regions in the world are more inhospitable to the geological surveyor than is British Guiana. Throughout about nine-tenths of the country access is greatly hindered by swamps and forest; and over much of the remainder exposures are scanty, the bedrock being hidden by deep tropical weathering and by Tertiary to Quaternary sands and clays. But despite these adverse field conditions, the post-war years have seen a great expansion in the work of the local Geological Survey, financed largely by Colonial Development and Welfare grants from the British Government; and there is now a staff of fifteen field geologists engaged in exploration, aided by a team of specialists centred in Georgetown. In 1957 a new programme of geological mapping was initiated, with the objective of covering the whole of British Guiana in seven years; and from this effort there has recently resulted a new series of black-and-white geological maps on a scale of 1 : 200,000, each sheet covering one-quarter of a degree square and bearing about 1,500 words of explanatory text. Twenty-one sheets were published in 1961 and about three-quarters of the country will be covered by this series by the end of 1962. Although the maps are necessarily only of a reconnaissance character, the rapidity of production has been remarkable and the series should do much to guide and promote the future economic development of British Guiana. Copies of the Survey maps are available from the Geological Survey of British Guiana, Georgetown.

Progress in Botany

THOSE who were present at the ninth International Botanical Congress, held in Montreal in 1959, know that it was a largely attended and well-managed affair. It was the occasion for a great outpouring of new scientific work on virtually every aspect of plant life. This, too, was well ordered in that the main work of the Congress had been organized into a comprehensive system of symposia, each of vital contemporary interest. There were also special lectures on selected topics given by distinguished exponents. All this material has now been made available in two large volumes, amounting to 1,766 pages (*Recent Advances in Botany.* Vol. 1: Pp. xvi + 1–948. Vol. 2: Pp. xiv + 949–1766. Toronto: University of Toronto Press; London: Oxford University Press, 1961. 320*s.* net the set).

There can, of course, be no question of 'reviewing' these volumes for, in a sense, they are in themselves reviews. But it should be said that they constitute unusually valuable and stimulating works of reference for research workers and teachers, providing as they do representative and coherent treatments of major topics by those most actively engaged in their investigation. The two volumes will certainly repay the general botanical reader who takes the time and trouble to browse through them; as for the research worker in any particular field, they seem likely to give him the assurance that he is at least reasonably *au fait* with what has been achieved to date. They are, indeed, the kind of books that might well be made available in departmental libraries for general reference and perusal. As to the title *Recent Advances*, what appears to emerge from this large collection of original papers is that contemporary botanical science has not only important salients but is also advancing on a broad front.

Publications of the Organization for European Co-operation and Development

THE Organization for European Co-operation and Development (O.E.C.D.) has issued a general catalogue which covers all works published since its inception. Publications have been classified under two main headings: "Economics" and "Technology and Organization", with many sub-headings. Under each heading there is an introductory note showing the connexion between the works published and the activities of the Organization in the sector concerned. Most of the publications of the European Productivity Agency will be found under the heading "Technology and Organization". O.E.C.D. publications are printed in the two official languages of the Organization. Each work therefore appears as two separate editions, one in English and the other in French. Certain works, however—statistical publications, glossaries, bibliographies—are produced in a single bilingual edition, which can be used equally well by either English or French readers. In order to give the fullest possible information, the catalogue also lists the documents which can be obtained on request, free of charge, or consulted at the Organization, as distinct from publications offered for sale. Applications for copies should be made to the Distribution and Sales Section of the O.E.C.D., 2 Rue André Pascal, Paris.

The Linnean Society of London

AT the anniversary meeting of the Linnean Society of London, held on May 24, the following were elected officers for the session 1962–63: *President*, Prof. T. M. Harris; *Treasurer*, The Earl of Cranbrook; *Secretaries*, Prof. C. T. Ingold, Dr. H. G. Vevers, Dr. J. Smart (editorial); *Vice-Presidents*, The Earl of Cranbrook, Dr. C. R. Metcalfe, Dr. Sydney Smith and Mr. P. R. Bell. *New Members of Council*, Dr. Eric W. Baxter, Dr. A. McClean Bidder, Prof. C. T. Ingold, Mr. N. W. Simmonds and Dr. E. I. White. Prof. George Ledyard Stebbins and Kurt Wein were elected Foreign Members.

The Institution of Metallurgists

AT the eighteenth annual general meeting of the Institution of Metallurgists the following officers were elected: *President*, Dr. E. G. West, technical director, Aluminium Development Association; *Senior Vice-President*, Dr. L. Northcott, principal superintendent, Materials Division, Armament Research and Development Establishment, Fort Halstead, War Office; *Vice-Presidents*, Prof. J. G. Ball, head of the Department of Metallurgy and professor of physical metallurgy, Imperial College of Science and Technology, and L. Rotherham, member for research, Central Electricity Generating Board; *Honorary Treasurer*, L. W. Derry, head of the Department of Metallurgy, Battersea College of Technology; *Ordinary Members of Council*, G. T. Harris, assistant managing director, Jessop-Saville, Ltd., J. M. Mowat, director, Wm. Beardmore and Co., Ltd., Parkhead Steelworks, Glasgow, and G. R. Morton, senior lecturer in metallurgy, Wolverhampton and Staffordshire College of Technology.

Alfred P. Sloan Awards

THE first Alfred P. Sloan Awards in cancer research have been conferred on: Dr. Oscar Bodansky, chairman, Department of Biochemistry, Memorial Hospital for Cancer and Allied Diseases, for his contributions to the advancement of biochemistry and its applications to the problems of patients with serious disease, especially cancer; Dr. Felix Wróblewski, associate of the Memorial Hospital for Cancer and Allied Diseases, for his contributions to the knowledge of enzymes in the blood tissues and their usefulness in medical diagnosis; Dr. Charlotte Friend, associate member of the Sloan-Kettering Institute for Cancer Research, for her contributions to cancer research, particularly through her discovery of and continuing studies on a virus which will induce leukæmia in mature mice; Dr. Lloyd J. Old, associate of the Sloan-Kettering Institute for Cancer Research, for his work on the role of specific and non-specific immunological factors in cancer development and growth.

Postgraduate Course in Nuclear Technology (Chemical)

APPLICATIONS are invited from graduates in chemical engineering, chemistry or metallurgy, or persons with equivalent qualifications, for a one-year course leading to the D.I.C. at the Department of Chemical

Engineering and Chemical Technology, Imperial College of Science and Technology. The course includes lectures in fundamental and applied radiochemistry and radiation chemistry; process chemistry and technology of reactor fuels; nuclear criticality and plant design; reactor fuel element technology; and radiological protection. Practical work includes participation in a design study or in a research programme. Further information can be obtained from the Registrar, Imperial College of Science and Technology, Prince Consort Road, London, S.W.7.

University News :

Birmingham

THE following titles have been conferred: that of reader in mathematical physics on Dr. G. V. Chester, senior lecturer in the Department of Mathematical Physics; that of reader in chemical engineering on Dr. C. W. Nutt, senior lecturer in the Department of Chemical Engineering; that of deputy director of the Institute for Engineering Production on Mr. F. Edmondson, assistant director of the Institute; that of head of computing services on Mr. K. A. Redish, lecturer in computing in the Department of Mathematical Physics; that of reader in medicine on Dr. J. M. Bishop, senior lecturer and first assistant in the Department of Medicine; that of University Research Fellow on Dr. P. Hele, during the tenure of her appointment in the Department of Physiology. The following appointments are announced: Prof. T. Ganea, to be Senior Research Fellow in the Department of Pure Mathematics; Mr. C. E. Gough, to be Research Fellow in the Department of Physics; Dr. M. P. Osborne, to be Research Fellow in the Department of Comparative Physiology.

Edinburgh

THE following appointments have been announced: *Senior Lecturer*, Dr. G. R. Hervey (physiology); *Lecturers*, Dr. J. E. Dale (botany), A. J. Tulett (botany), Miss J. Marrian (organization of industry and commerce), Dr. D. S. Saunders (zoology).

London

PROF. P. R. OWEN, professor in the mechanics of fluids in the University of Manchester, has been appointed to the Zaharoff chair of aviation, tenable at the Imperial College of Science and Technology, from January 1, 1963. The title of reader in experimental physiology has been conferred on Dr. A. F. Cobbold, and that of reader in biology on Dr. A. G. Hamilton, in respect of their posts at St. Thomas's Hospital Medical School; the title of reader in biochemistry has been conferred on Dr. A. E. Kellie, in respect of his post at the Middlesex Hospital Medical School. Dr. J. F. Fowler has been appointed to the readership in physics tenable at St. Bartholomew's Hospital Medical College.

Sussex

DR. T. BARNA, assistant director of the National Institute of Economic and Social Research, London, has been appointed to the chair of economics, and Mr. T. H. Elkins, lecturer in geography at King's College, London, has been appointed to the chair of geography. The following appointments have also been announced: *Reader*, Dr. W. Ledermann (mathematics); *Senior Lecturers*, Dr. D. F. Brewer (experimental physics), Dr. J. P. Elliott (theoretical physics); *Lecturers*, Dr. E. Mathieson (experimental physics), Dr. W. D. Hamilton (experimental physics), Dr. L. Allen (experimental physics), Dr. R. E. Turner (theoretical physics), Dr. C. N. Banwell (chemistry), Dr. E. O. Bishop (chemistry), Dr. R. A. Jackson (chemistry), Dr. J. D. Smith (chemistry), Dr. Ruth M. Rogers (mathematics), Mr. G. B. Trustrum (mathematics).

Announcements

THE Drummond Managing Trustees have awarded a Drummond Senior Fellowship in nutrition for the year 1962–63 to Mr. E. R. Humphreys, of the Royal Free Hospital School of Medicine. The Fellowship, valued at £1,100, is tenable for two years.

THE Trustees of the Plastics Industry Education Fund are offering a limited number of training grants towards the cost of full-time study on an approved course leading to a degree or other equivalent diploma in science, technology or industrial design. Grants are usually made for periods of one year at a time, but applications for the renewal of grants are considered provided the candidate is making satisfactory progress. Further information can be obtained from the Secretary, Plastics Industry Education Fund, 6 Mandeville Place, London, W.1.

THE 1962 international conference on "Precision Electromagnetic Measurements", sponsored by the Radio Standards Laboratory of the National Bureau of Standards, the Institute of Radio Engineers and the American Institute of Electrical Engineers, will be held in Boulder, Colorado, during August 14–16. Further information can be obtained from James F. Brockman, National Bureau of Standards, Boulder, Colorado.

THE second annual meeting of the Plant Phenolics Group of North America, under the auspices of the American Institute of Biological Sciences, will be held in Oregon State University during August 24–25. The programme will include a symposium on "Plant Phenolics and their Industrial Significance". Further information can be obtained from Dr. V. C. Runeckles, Imperial Tobacco Company of Canada, Ltd., P.O. Box 6500, Montreal, Quebec.

THE eleventh Canadian High Polymer Forum, sponsored by the National Research Council of Canada together with the Chemical Institute of Canada, is to be held at Essex College, Assumption University, Windsor, Ontario, during September 5–7. Further information can be obtained from the secretary-treasurer, Dr. L. Breitman, Research and Development Division, Polymer Corporation, Ltd., Sarnia, Ontario.

THE eighth international congress for microbiology, organized by the Canadian Society of Microbiologists under the auspices of the International Association of Microbiological Societies, will be held in Montreal during August 19–25. The programme will be divided into five sections, two or more symposia being arranged in each section: structure and function; agricultural microbiology; industrial microbiology; medical and veterinary microbiology; virology. Further information can be obtained from Dr. N. E. Gibbons, Eighth International Congress for Microbiology, National Research Council, Ottawa, 2.

ERRATUM. In the communication entitled "Coccolith Formation" (*Nature*, 193, 1094; 1962), by E. Paasche, the second half of the first sentence in the third paragraph should read: ". . ., it was found that the calcium content of one *Coccolithus huxleyi* coccolith is $5 \cdot 5 \times 10^{-13}$ gm. calcium".

INHIBITION OF GASEOUS FREE RADICAL REACTIONS

AN informal discussion on the inhibition of gaseous free radical chain reactions was held during April 12 and 13 in the Department of Physical Chemistry, University of Cambridge (by kind permission of Prof. R. G. W. Norrish), under the auspices of the Faraday Society. About 120 were present. On the afternoon of April 12, six papers were presented and discussed, under the chairmanship of Prof. F. S. Dainton (Leeds).

The first paper, on the "Mechanism of Inhibitor Action for Chain Processes", by H. Eyring, T. Ree and K. Yang (University of Utah), was presented by Prof. H. Eyring. The authors considered the classical theories of inhibition, where inhibitory action is explained by consumption of inhibitor (I). As consumption of I is often not observed, it is proposed that I destroys the chain carriers and is also regenerated. Denoting by β the radical which reacts bimolecularly in the chain propagation steps of the Rice–Herzfeld mechanism and by μ the radical which reacts unimolecularly, the complexes βI and μI formed regenerate I, either by reaction with the substrate *M* or by direct dissociation. Thus, a hyperbolic function is obtained for the variation of rate with inhibitor pressure. Good agreement is observed between this function and the literature data for the effect of nitric oxide and propylene on the decomposition-rates of hydrocarbons, aldehydes and ethers. It must be noted that this agreement is dependent for the nitric oxide inhibition of propane decomposition on the occurrence of such equilibria as:

$$CH_3NO \rightleftarrows CH_3 + NO$$

(forward reaction = 'saloon effect', backward reaction = 'chaperon effect'); or the participation of bimolecular reactions such as:

$$CH_3NO + C_3H_8 \rightarrow CH_4 + C_3H_7 + NO$$

Such reactions were questioned by some.

Mr. D. R. Blackmore (Oxford) presented a paper entitled "Inhibition and Acceleration by Nitric Oxide of the Decomposition of a Series of Paraffins". It is considered that, in inhibition, both the chain-carrying radicals combine with nitric oxide and, on the basis of the mechanism employed, the individual rate constants of some of the free radical reactions involved are evaluated. Three quantities are measured, namely: (*a*) the degree of inhibition by nitric oxide as a function of paraffin pressure; (*b*) the rate of the induced decomposition at much higher pressures of nitric oxide; (*c*) the rate of the uninhibited chain reaction. It is shown (from (*b*)) that the induced reaction is first order in both paraffin and nitric oxide, approximately equal molar quantities of nitric oxide and paraffin being consumed. Therefore, the following mechanism is proposed:

$$RH + NO \rightarrow R + HNO \text{ (slow, rate determining)}$$
$$R + NO \rightarrow \text{products (fast)}$$

Six rate constants are required to specify three experimentally observed quantities: thus the numerical values of three of these being assumed, the remaining three are evaluated. In discussion, some attention was directed to the wide differences between these rate constants and those obtained by other workers.

The next paper was given by Dr. B. W. Wojciechowski and Prof. K. J. Laidler (Ottawa) under the title "The Inhibition of Organic Decompositions", in which the effect of inhibitors in pyrolytic mechanisms is considered to be the establishment of chain processes, in which the inhibitor is involved in both initiation and termination, rather than the suppression of all chain processes. Thus, in the case of the pyrolysis of ethane and other hydrocarbons, of aldehydes and ethers, a hydrogen atom is abstracted by nitric oxide:

$$RH + NO \rightarrow R + HNO$$

Chain termination is achieved by reaction between the most plentiful chain carrier and either HNO or nitric oxide, depending on whether or not hydrogen is a chain carrier. In the particular case of ethane pyrolysis, it is proposed that the two equilibria:

$$C_2H_6 + NO \rightleftarrows C_2H_5 + HNO$$

and

$$HNO + M \rightleftarrows H + NO + M$$

participate, that is, nitric oxide catalyses the equilibrium:

$$C_2H_6 \rightleftarrows C_2H_5 + H$$

It is proposed that this hydrogen abstraction is general for any inhibitor (for example, propylene). and also for surface sites. Similar mechanisms are proposed for the decomposition of alkyl halides and, for the ethyl bromide pyrolysis in the presence of nitric oxide, the important reactions are:

$$C_2H_5Br + NO \rightarrow C_2H_5 + NOBr \text{ (initiation)}$$
$$C_2H_5 + NOBr \rightarrow C_2H_5Br + NO \text{ (termination)}$$

Surface control (that is, initiation and termination at the surface) in the pyrolysis of isopropylbromide is discussed on the similar basis:

$$Pr^iBr + S \rightarrow Pr^i + SBr$$
$$SBr \rightleftarrows S + Br$$

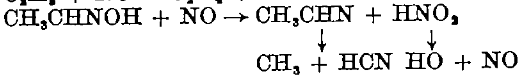
followed by chains initiated by bromine atoms and terminated by reactions of the radical having the odd electron on the terminal carbon atom.

Dr. G. L. Pratt (Cambridge) presented his paper (with Dr. J. H. Purnell) on "The Thermal Decomposition of Lead Tetraethyl in the Presence of Nitric Oxide". In the temperature-range, 235°–265° C. with excess nitric oxide, the pyrolysis-rate is reduced by a factor of 3–4, *n*-butane formation is entirely suppressed, ethane and ethylene still appeared in the products, and the predominant products formed are methyl cyanide and water. The latter products are explained by the sequence:

$$C_2H_5 + NO \rightarrow C_2H_5NO \rightarrow CH_3CH{=}NOH \xrightarrow{\text{surface}} CH_3CN + H_2O$$

No evidence for the addition of more than one nitric oxide molecule to each ethyl radical is obtained, although some reduction of nitric oxide to nitrous oxide by reaction with lead is observed. The small amounts of C_2 hydrocarbons may be explained by reactions such as:

$$C_2H_5 + NO \rightarrow C_2H_4 + HNO$$



$$\begin{array}{lll} CH_3CHNOH + NO \rightarrow & CH_3CHN & + \; HNO_2 \\ & \downarrow & \quad\;\; \downarrow \\ & CH_3 + HCN & \;\; HO + NO \end{array}$$

The acetaldoxime is decomposed very rapidly.

Dr. Margaret I. Christie (Oxford) then discussed her paper (with Mr. J. S. Frost) on "Kinetics of the Association of Alkyl Radicals with Nitric Oxide and of Subsequent Reactions", the relative rates of the reactions:

$$R + NO \rightarrow RNO$$
$$R + I_2 \rightarrow RI + I$$

being obtained from quantum yields of iodine produced in the gas phase photolyses of alkyl iodides in presence of varying concentrations of nitric oxide. It is shown that for R = Et, Pr^n, Pr^i, the ratio is about 0·1, independent of pressure, and the second order character of the association is thus demonstrated. In addition, reaction of an initial photolysis product (presumably RNO) with nitric oxide to form a brown substance Y is observed and $\mathrm{d}Y/\mathrm{d}t = k(R\mathrm{NO})^1(\mathrm{NO})^2$. At 25° C., it is shown that k increases in the order Me < Et < Pr^i < Pr^n, and, from the temperature dependence, negative activation energies ($-2{\cdot}8 \leftrightarrow -5{\cdot}9$ kcal. mole^{-1}) are measured. The product Y is decomposed on condensation and re-heating. In the absence of excess nitric oxide, the rate of disappearance of the monomer due to:

$$2RNO \rightarrow (RNO)_2$$

is measured, the activation energy being about 5 kcal. mole^{-1} and the steric factor about 10^{-8}. Discussion centred on the nature of Y and the negative activation energy. It was suggested that this explained the failure of this reaction to participate at higher temperatures. A suggested mechanism was:

$$RNO + NO \rightleftarrows R(NO)_2 \xrightarrow{NO} R(NO)_3$$

The paper "Free Radical Scavengers in Gaseous Radiolysis Systems" was given by Dr. L. J. Stief (Sheffield). It is shown that four criteria for ideal scavenging in any particular system are available, namely: (*a*) lack of appreciable isotopic mixing in the presence of scavengers; (*b*) independence of non-scavengable or 'molecular' yields of products with temperature, pressure, or particular scavenger used; (*c*) identification of the products of the inhibition reaction and comparison of these product yields with the yields of radiolysis products believed to have a particular free radical precursor; (*d*) the accuracy of rate constants, pre-exponential factors, and activation energies for free radical reactions obtained from radiolysis systems, when corrections for molecular contributions, based on scavenger experiments, are applied.

On the morning of April 13, five papers were presented and discussed, under the chairmanship of Prof. K. J. Laidler (Ottawa). The first paper in this session was "Inhibition by Nitric Oxide of some Reactions of Nitrogen Dioxide", by Dr. P. G. Ashmore (Cambridge). For the reaction:

$$H_2 + NO_2 \rightarrow H_2O + NO$$

nitric oxide acts as an inhibitor, probably due to the reaction:

$$NO + OH + M \rightarrow HNO_2 + M$$

the hydroxyl radical being a chain carrier. The reaction is also catalysed by nitric acid and nitrosyl chloride and both these reactions are inhibited by nitric oxide. It is likely that nitrosyl chloride initiates chains by the sequence:

$$NOCl + M \rightarrow NO + Cl + M$$
$$Cl + H_2 \rightarrow HCl + H \text{ (chain initiated)}$$

and that nitric oxide has little effect on this. The fast reversible reaction:

$$NO_2 + NOCl \rightleftarrows NO_2Cl + NO$$

followed by:

$$NO_2Cl + M \rightarrow NO_2 + Cl + M$$

is mainly responsible for the catalysis (nitryl chloride dissociation is faster than nitrosyl chloride). Reaction is inhibited by nitric oxide because of the reverse reaction and diminished nitryl chloride concentration in addition to the normal inhibition reaction with hydroxyl radicals.

Dr. P. J. Thomas (Imperial Chemical Industries, Ltd., Widnes) then discussed "The Effect of Nitric Oxide and of Olefinic Inhibitors on the Free Radical Chain Decompositions of the Lower Aliphatic Alcohols". It is shown that nitric oxide can both inhibit the thermal decomposition of alcohols (500°–600° C.) and also induce decomposition. Thus the rate/inhibitor concentration curves pass through a shallow minimum. This minimum rate is observed to be independent of nitric oxide concentration over a limited range only, and this range is varied in extent and concentration for different alcohols. When either propylene or isobutene are used as inhibitors (0–300 mm. added), the reaction rates are reduced to well-defined limits, which for sec-propanol and tert-amyl alcohol coincide for the minimum rates observed with nitric oxide addition. However, for ethanol, *n*-propanol, *n*- and iso-butanol the limiting rates observed with propylene and iso-butene are two- to three-fold greater than the minimum nitric oxide rate. The limiting rates observed with propylene are reduced by the addition of nitric oxide and therefore must be predominantly free radical chain reactions. *Cyclo*pentadiene is intermediate in inhibiting power to nitric oxide and propylene, and is similar to nitric oxide in that a marked increase in overall rate is observed at the high inhibitor concentrations. The results are interpreted in terms of concurrent inhibition and induced decomposition reactions: at maximum inhibition it is suggested that in addition to molecular decomposition modes, a limited amount of free radical decomposition of the alcohol also occurs. Discussion centred largely on the meaningfulness of the assumption of the molecular modes of decomposition, and on the determination of the orders of the reactions at all stages of addition of inhibitor.

Mr. R. A. Ross (University College, London) presented his paper (with Dr. A. Maccoll) on "Inhibition and the Unimolecular Pyrolysis of Organic Bromides". The homogeneous gas phase elimination reactions of organic bromides and chlorides are divided into two groups: (i) those that are inhibited by propylene and *cyclo*hexane, and (ii) those which show no inhibition. Group (i) are characterized by (*a*) induction periods, (*b*) 1½ order kinetics (in some cases), (*c*) difficulty of obtaining reproducible results, (*d*) acceleration by stimulants, and (*e*) the ability to produce chains in a substrate that can sustain them. Group (ii) are characterized by (*a*) first order behaviour and 'fall-off', (*b*) no acceleration by stimulants (in some cases), and (*c*) no ability to induce chains in a substrate that can support them. In support of the assumption of complete inhibition, it is shown for both group (ii) and the maximally inhibited group (i) that (1) decompositions have all the characteristics of unimolecular reactions, and that (2) the effects of structural variations are comprehensible within the framework of present-day chemical theory. Discussion centred on the effect of surfaces, and the variations between the experimental fall-off characteristics and those predicted by Slater and Kassel theories.

The paper "The Inhibition of *n*-Butane Pyrolysis by Propylene" by Mr. C. P. Quinn and Dr. J. H. Purnell (Cambridge) was presented by the former. The kinetics of the formation of the products of the pyrolysis of *n*-butane in the presence and absence of propylene are studied by means of high-speed gas chromatography. It is shown that the product ratio $C_2H_4 : C_2H_6$ is greater than unity, a function of temperature and pressure, and increases linearly with inhibitor pressure. It is concluded that this is incompatible with the hypothesis of two concurrent processes, one of which (free radical) is halted by the inhibitor and the other of which (molecular) is unaffected. It is therefore proposed that the fully inhibited reaction proceeds by a modification of the free radical chain mechanism which is responsible for the whole of the uninhibited reaction. Competition between the two reactions:

$$C_2H_5 + C_4H_{10} \rightarrow C_2H_6 + C_4H_9$$
$$C_2H_5 \rightarrow C_2H_4 + H$$

is found to play an important part in both the uninhibited and the fully inhibited processes. The increase in the activation energy for *n*-butane pyrolysis at low pressures is thus explained, and the classification of paraffins on the basis of changes with pressure of the order and activation energy of the fully inhibited pyrolysis (due to Peard, Stubbs and Hinshelwood) is interpreted in terms of the classes of hydrocarbons which do and do not give the competitive reactions listed above.

The final paper on "The Effect of Surface and Nitric Oxide on the Pyrolysis of Isopentane" was given by Prof. W. A. Bryce (University of British Columbia, Vancouver). The effect of surface : volume ratio and nitric oxide pressure on the decomposition-rate and product distribution of isopentane is studied. It is shown that alteration in the surface : volume ratio alters the rate at any fixed pressure, and the rate/nitric oxide pressure curves for the inhibited reaction. The main products of pyrolysis are methane, propylene and iso-butylene; the latter is unaltered by increase in pressure of nitric oxide, whereas the other two products are increased. Ethylene and ethane are minor products and the ratio increases with nitric oxide pressure, and with decrease in surface : volume ratio. The observations are interpreted on the basis of heterogeneous initiation of the pyrolysis. It is shown that *n*-pentane and neopentane behave differently from isopentane, and that di-allyl sensitizes the rate of decomposition of *n*-pentane, presumably by the reaction:

$$C_3H_5 + n\text{-}C_5H_{12} \rightarrow C_3H_6 + C_5H_{11}$$

The discussion covered many issues and there was no general agreement on inhibition mechanisms. The following brief summary from the discussion indicates some of the important questions to which answers should be sought in any examination of the effect of inhibitors on gas phase decomposition reactions: (1) the order of the reaction in both substrate and inhibitor; (2) consumption (or otherwise) of inhibitor; (3) the nature of the reaction(s) between radical and inhibitor, and substrate and inhibitor; (4) subsequent reactions of the products of these reactions; (5) the effect of surface; (6) the effect of different inhibitors; (7) the effect of adding a second inhibitor to a maximally inhibited reaction; (8) the assumption of molecular decomposition mechanisms; (9) comparison of product analysis/time curves with pressure/time curves; (10) the effect of temperature variation on reaction possibilities.

It is hoped that this discussion, by revealing the scope of the many kinetic problems involved in an understanding of inhibition mechanisms, will lead to an advance in our understanding of a theme that can be as complex as oxidation. B. G. GOWENLOCK

CELL DIFFERENTIATION AND INTERACTION

THE annual research conference of the Biology Division, Oak Ridge National Laboratory, was held at Gatlinburg, Tennessee, during April 9–12. The subject was "Specificity of Cell Differentiation and Interaction", and a mixed gathering of bacteriologists, biochemical cytologists, embryologists, geneticists and immunologists, including a small number from Europe and Sir Macfarlane Burnet from Australia, attended.

After introductory remarks by Dr. A. Hollaender, head of the Biology Division, Oak Ridge National Laboratory, and Dr. A. Weinberg, director of the Oak Ridge National Laboratories, Dr. J. Brachet (Université Libre de Bruxelles) gave the opening talk in which he outlined results of measurements of deoxyribonucleic acid and ribonucleic acid on amphibian oocytes and embryos. New methods have confirmed that there is little or no DNA synthesis before the late blastula stage in the embryo, so that pre-existent cytoplasmic DNA evidently contributes to the nuclei during cleavage. This probability was used by Dr. J. A. Moore (Columbia University, New York), the second speaker, to explain the results of interspecific nuclear transfers in amphibian embryos that he reviewed, in which the nuclei seem to undergo more or less permanent genetic change after dividing a few times in foreign cytoplasm. In discussion, Dr. R. W. Briggs (Indiana University) mentioned that chromosomal translocations have been detected in diploid nuclei after transplantations of this kind. Brachet described nuclei with various staining peculiarities, suggestive of abnormal DNA and RNA content, that arise in some lethal hybrid embryos. He also mentioned new work on *Acetabularia*, including indications that some low-molecular forms of DNA may be synthesized in the cytoplasm in the absence of the nucleus.

Cell-interaction during embryonic differentiation was discussed from various angles by Drs. T. Yamada (Oak Ridge), C. Grobstein (Stanford University) and A. A. Moscona (University of Chicago). Dr. Yamada had achieved the conversion of explanted amphibian gastrula ectoderm into mesoderm, after contact for 3 hr. with a protein fraction from guinea-pig bone marrow. He was studying the mechanism of this conversion, and also of the regeneration of lens from iris cells, by autoradiography, fluorescent antibody techniques and electron microscopy. Dr. Grobstein pleaded for a distinction between 'heterotypic' and 'homotypic' control of cell differentiation, to interpret the dependence of pancreatic epithelium not only on the presence of mesenchyme but also on integrity of reasonably large epithelial pieces, for good differentiation of acini. Dr. Moscona, describing the ability of mixed cultures of dissociated mouse and chick tissues to form composite organs whereas cells of different tissue types from the same animal do not combine, pointed out that after an initial non-selective phase of reaggregation the cells sort out into distinct tissue types by a process which he believes may depend on a molecular fit between protein and carbohydrate at the cell surfaces. The problem he raised of how embryonic cells recognize each other needs linking up with theories about the development of immune mechanisms in embryos, but in an evening round-table discussion on this topic the cellular embryologists failed to get to grips with the immunologists. Immunologists who spoke at the conference were Dr. T. Makinodan (Oak Ridge), who emphasized the importance of plasma-cell differentiation during immune response, and Dr. G. Möller (Karolinska Institutet), who described brilliantly the use of tumour-cell strains to study tissue antigenicity and pointed out discrepancies that had arisen in dating the earliest appearance of transplantation antigens in developing animals by different methods. Dr. R. E. Billingham (The Wistar Institute, Philadelphia) brought together genetical and immunological considerations in reviewing the different abilities of bone marrow and lymph-node tissues to induce tolerance of skin grafts, when different strain crosses of rats and mice were used.

Another aspect of cell differentiation was dealt with by Prof. C. H. Waddington (University of Edinburgh), who showed electron micrographs of developing amphibian notochord cells, and of ommatidia of normal and eye-mutant strains of *Drosophila*. He also showed a film illustrating the different behaviour of myoblast and neural cells in culture, even before they are structurally distinguishable. Any theory of differentiation controlled by genes has to account for the regional differentiation within cells that is now visible in electron micrographs, as well as how such differences are established when the cell-contents are in constant commotion as the ciné pictures show.

In his final summary of the conference, Sir Macfarlane Burnet (The Walter and Eliza Hall Institute of Medical Research, Melbourne) reiterated that genetic information must control all types of differentiation, and he called for an intensified study of gene-controlled immunological anomalies, such as human a-gammaglobulinæmia. He also pointed out our complete ignorance of whether systemic immune mechanisms exist in invertebrates, which do not appear to possess gamma-globulins.

Other speakers at the conference were Drs. L. Herzenberg (Stanford University) and A. J. Riker (University of Wisconsin), who described differentiation in cultures of mouse lymphoma, and gall-infected plant tissues, respectively, and Dr. V. Hamburger (Washington University, St. Louis), who reviewed evidence for cell-specificity in the development of the nervous system. The full proceedings, including discussions, will be published as a supplement to the *Journal of Cellular and Comparative Physiology* later this year.

E. M. DEUCHAR

GRAZING IN TERRESTRIAL, FRESHWATER AND MARINE ENVIRONMENTS

THE fourth symposium to be arranged by the British Ecological Society was held at the University College of North Wales, Bangor, during April 11–14. The subject was treated in the broadest sense, and included not only pasture and range grazing by terrestrial herbivores but also planktonic grazing and other grazing-like phenomena of freshwater and marine environments.

In the first contribution to the symposium, Mr. A. Macfadyen, Zoology Department, University of Swansea, classified the main routes through which matter and energy can flow in a model ecosystem, and discussed the magnitudes of the main trophic components in several contrasting systems, including grassland and plankton. The relationship between stock and productivity can vary over several orders of magnitude, according to the biology of the organisms concerned. Thus the standing crop of plant material in the marine environment is very small compared with that in terrestrial environments, although the energy-flow is of similar magnitude. Grazing yields can be reduced by energy-flow into unproductive pathways, such as ungrazed organic matter by plants, and inefficient utilization of plant material by herbivores. It is therefore clearly important to have a framework within which to compare present performances of ecosystems with potential yields.

Mr. M. B. Alcock, Department of Agriculture. University College of North Wales, Bangor, discussed the problem of achieving maximum output of animal products from grassland. The responses of the plant to defoliation may be due to changes in root growth and uptake of minerals, to utilization of carbohydrate reserves, or to changes in the interception of light energy.

Dr. J. D. Ovington, Nature Conservancy, St. Ives. Huntingdonshire, described work carried out at the University of Minnesota in which he compared the productivity of prairie, savanna and oakwood. The presence of woody plants greatly increases the nutrient circulation and utilization of the site, with the result that the primary productivity of the oakwood almost reaches that of intensively managed fields of maize nearby.

Prof. L. B. Slobodkin, University of Michigan. discussed grazing phenomena in fresh-water, and emphasized that the limited extent and uniformity of most freshwater environments leads to unstable relationships between planktonic species and, in consequence, to wide fluctuations in population numbers.

Dr. Cushing, of the Fisheries Laboratory, Lowestoft, summarized existing knowledge bearing on one of the economically important food chains in the North Sea. He compared the efficient utilization of the planktonic herbivore *Calanus* by the herring with the apparently wasteful feeding on diatoms by *Calanus* itself. In certain years at least, zooplankton grazing limits the growth of phytoplankton. More detailed information on the nutrition and reproduction of *Calanus* obtained from laboratory work was given in a later contribution by Dr. Marshall and Dr. Orr, of the Marine Station, Millport. Dr. D. T. Gauld, Zoology Department, University of Aberdeen, described a second mode of feeding by means of which certain copepods, including possibly *Calanus*, can augment their diet. The maxillæ can be used by the larger copepods not only as passive filtering organs but also as an active 'sweep net' to catch the larger diatoms, dinoflagellates and even animal food.

A further session was devoted to examples of the activities of organisms which occupy a significant place as 'grazers' in various marine habitats. Fortunately, the discussion provoked by the fascinating problems which the speakers introduced took precedence over any consideration of what phenomena should properly be regarded as 'grazing'. Dr. D. J. Crisp, Marine Biology Station, University College of North Wales, considered how the food requirements of barnacles, as measured from growth-rates and feeding-rates, can be met from the amount of suspended matter in sea-water, and concluded that growth is usually limited by the availability of food. Mr. P. R. Walne, of the Fisheries Laboratory, Conway, emphasized the importance of the quality and concentration of phytoplankton cells constituting the food of marine bivalve larvæ. In the laboratory, good growth necessitates a higher concentration of cells than normally occurs in the sea, and it is possible therefore that some other source is available to naturally occurring larvæ. Grazing by limpets was reviewed in the contribution from Dr. A. J. Southward, of the Laboratory, Plymouth. The grazing-rate of the common limpet was measured by observations on algae-covered aquarium surfaces; however, under natural conditions, limpets remove not merely algae but also considerable quantities of the softer rocks such as chalk and limestone. Dr. T. E. Thompson, Department of Zoology, University College, Cardiff, directed attention to the very specialized diet of many nudibranchs; it is possible that the veliger larvæ of some nudibranchs can recognize the presence of their prey and respond by settling on it. Nudibranchs which pass through several generations in a season are prodigal feeders of transitory prey, whereas those with annual life-cycles browse more sparingly on stable and abundant populations of food organisms. Mr. P. J. S. Boaden, Department of Zoology, Queen's University, Belfast, dealt with food relationships within sand and gravel. The interstitial fauna consumes dead organic matter, bacteria, and autotrophs such as diatoms, sometimes removing them individually from grains of sand. The number of animals found in the interstitial spaces indicates that coarse sands contain a fairly rich source of food for the large indiscriminate sand grazers.

Several papers were devoted to the influence of grazing animals, both indigenous and introduced, on terrestrial vegetation. Dr. D. F. Costello, of the U.S. Department of Agriculture, Portland, Oregon, described how ecological research has led to improved practices in range management, especially with regard to re-vegetation, eradication of harmful species, prevention of land erosion and controlled grazing. Dr. J. W. Marr, of the Institute of Arctic and Alpine Research, University of Colorado, and Dr. D. R. Flook, of the Canadian Wildlife Service, Edmonton, Alberta, described the soil conditions, the natural vegetation and the dominant herbivores of the Alpine tundra of the Front Range, Colorado, and of the Banff and Jasper Natural Parks, Alberta. Mrs. D. J. Carr, Department of Botany, Queen's University, Belfast, described degenerative changes and the early stages of accelerated erosion in certain areas of the Bogong High Plains, Victoria, which are believed to be a consequence of their use for summer grazing by the European settlers. Changes extending over a much longer time-scale were described by Dr. R. L. Dix for the North American grassland. The original grassland was traced from its formation in the central Great Plains area during the late Oligocene or Miocene to the present century.

Prof. F. A. Pitelka, and Dr. A. M. Schultz, of the University of California, Berkeley, introduced evidence obtained at the Arctic Research Laboratory, Barrow, Alaska, on the well-known cyclic fluctuations in the populations of the brown lemming, *Lemmus trimucronatus*. These regular changes can be explained on the basis of a simple interaction between herbivore and vegetation with a three-year nutrient cycle. Following overgrazing in a peak year, the nutrients are only slowly recovered and made available again by the third year, and by this time the plant cover has reached a sufficient quantity and quality to support another rapid population increase. Cycles in plant production and in soil nutrient-level were found to correlate with population changes in the lemmings.

The last session of the symposium dealt with the effects of animal behaviour on grazing. Dr. G. W. Arnold, of the Commonwealth Scientific and Industrial Research Organization, Division of Plant Industry, Canberra, discussed the importance of the animal's behaviour in selecting and harvesting its food to its nutrition and to the productivity of the system. Decreasing the availability of suitable pasture, though at first compensated by an increase in the time of grazing, eventually leads to a reduction in the total intake of food. Dr. R. Elfyn Hughes, of the Nature Conservancy, Bangor, described experiments on productivity in which the sheep were allowed to distribute themselves voluntarily between richer and poorer mountain pasture.

A technique for analysing sheep diet from epidermal plant fragments identified from fæces, which has a distinct advantage over fistula sampling methods, was described by Dr. D. J. Martin, West of Scotland Agricultural College. A surprising observation, which was confirmed by others taking part in the discussion, was reported by Dr. R. F. Hunter, of the Hill Farming Research Organization. Sheep do not appear to roam freely, but form family groups which restrict themselves to certain territories differing in altitude, aspect and vegetation. This finding is of obvious importance to management of hill sheep. It may also vitiate attempts at breeding by simple selection if the desirable characteristics are attributable more to the home range environment of the sub-flock than to genetic differences.

The proceedings of the symposium will be published and will represent the fourth of the series published by the Society. D. J. Crisp

DEVELOPMENT OF RESEARCH IN NORTHERN AUSTRALIA

AN important advance in the development of northern Australia occurred recently when the Minister-in-Charge of the Commonwealth Scientific and Industrial Research Organization, Senator Gorton, opened a new research laboratory at the C.S.I.R.O.'s Coastal Plains Research Station. The Station is situated forty miles east of Darwin, close to Humpty Doo.

The aim of the research workers in this laboratory, in collaboration with Northern Territory authorities, is to develop agricultural procedures for the development of the coastal plains in the Northern Territory. The crop plant receiving major attention is tropical rice. The breeding of special rice varieties, the determination of planting, harvesting and fertilizer techniques to meet the particular conditions of the area, form an important part of this work. The possibility of forms of agricultural development other than rice are also to be examined.

Work commenced at the Station in 1959 when the Commonwealth Government, through the Northern Territory Administration, provided £124,000 for its capital development and £50,000 per annum for running costs. Since that time it has been possible to provide accommodation and special facilities to enable research workers to carry out their programme under tropical conditions. These facilities have attracted a staff of fifteen officers to the Station.

The agricultural development which has so far taken place in Australia has mainly evolved from European agricultural practices although Australian scientists have solved many of the problems peculiar to the Australian environment, particularly in tropical Queensland. The essential European temperate agricultural background has resulted in greater development of the southern areas of Australia, and only within the past decade or two has Australia been able to divert its scientific effort to the less-developed areas of the northern environment.

More than half a million square miles of northern Australia have now been surveyed and mapped by C.S.I.R.O. scientists. Large areas have also been examined for possible mineral development by the Bureau of Mineral Resources.

The development which is now occurring at the Coastal Plains Research Station is a further step forward in the essential advances of this vast area. The station is one of a number of C.S.I.R.O. units working on agricultural problems of the north. Others are located at the Ord River in the Kimberley region of Western Australia, at Katherine and Alice Springs in the Northern Territory, and at Mareeba, Ingham, Rockhampton, Brisbane and Cunnamulla in Queensland.

The proposed establishment of a new pasture research laboratory at Townsville also indicates the strong desire of the Government to provide a sound scientific basis for the development of these areas.

All these, in conjunction with the activities of the Northern Territory Administration Technical Services, will contribute to the eventual development of a vast region, the potential of which has scarcely been touched.

THE ARTHUR D. LITTLE RESEARCH INSTITUTE

THE annual report of the Arthur D. Little Research Institute for 1961 * also briefly reviews the first five years achievements of the Institute, and, besides a list of senior staff, includes a list of the Acorn Lectures delivered since January 1958. Lists of publications are included under the several sections. The Biochemistry and Biophysics Section is now well established, and during the year centred on isolated wheat gluten. Starch-gel electrophoresis has shown that there are at least 26 protein components and paper chromatography that the phospholipids of flour are present in the same complexity in isolated gluten. Equipment has been designed to study the fundamental properties of gluten as an elastomeric gel.

The Organic Chemistry Section has prepared a range of stable true sodium sucrates up to the hepta derivative and studied their reactions with more than 50 chloro compounds, particularly the reactivity of penta-sodium sucrate under mild conditions in the presence of dimethoxyethane. Other work has been concerned with the polymerization of glucose and its derivatives, the preparation of carbohydrate polyamides with viscosities comparable with that of nylon by interfacial polycondensation, polyglucoses and the chemical modification of wood, for example, its phosphorylation, the dimensional stability of wood, the preparation of chlorinated phenyl derivatives of cellulose and the emission of corrosive volatiles from wood, while early in 1960 the study of the chemistry of ethylene sulphide was begun.

In physical chemistry, the polymer group has been concerned with the mechanism and kinetics of formation of 'isotactic' polymers and with certain of their bulk properties with the view of a better understanding of the effect of structural and environmental parameters. The kinetics of the reaction between molten aluminium and water vapour at about 1,000° C. have also been studied, while the Metallurgy Section has attempted to establish relations between the effectiveness as corrosion inhibitor of an additive in aqueous solution and its molecular structure. Although 470 inhibitors were tested, no clearly defined relation was established between threshold concentration and molecular structure. A study was also made of the influence of additives on the relation between applied current and metal potential for both cathodic oxygen reduction and anodic metal dissolution. Investigations have commenced on the hydrogen embrittlement of very strong steels with the view of devising a procedure for acid pickling which avoids subsequent hydrogen embrittlement.

SCIENTIFIC AND TECHNICAL EDUCATION IN SCOTLAND

THE Staff Association of Paisley Technical College is to be commended for the way it has made a critical examination of the Scottish system of education with particular reference to advanced technical education. A memorandum submitted to the Robbins Committee on Higher Education is concerned mainly with the present system and the possible future structure of higher education in relation to the technological and technical training provided in Scottish Central Institutions. The Staff Association considers that there is no general lack of opportunity for higher education in science and technology as there appear to be only rare cases of qualified students not being accepted for the course of their choice. On the other hand, there is a distinct lack of information of the kind which would enable a potential student to make the most suitable choice.

The present courses in scientific and technological subjects are suitable, on the whole, for those attending them. If better guidance were available for students there would be fewer instances of students attending courses not suited to their abilities and inclinations. The ordinary B.Sc. in pure science, awarded by the Scottish universities, does not give a satisfactory qualification for teaching science, except at lower levels, nor does it provide a suitable qualification for any other career in science. Many students who are at present directed into pure science may have more aptitude and likelihood of success in a branch of applied science. There is insufficient opportunity for those who have demonstrated abilities above their chosen level to change to a higher level of education. The admission requirements and the exemptions allowed for entry to higher courses and professional institutions are unrealistic in some cases and should be rationalized.

The Association considers that there should be more opportunities for people who have already gained higher education qualifications to add to these; many older people who have not received any higher education could successfully complete courses in higher education if given the opportunity. Lack of information and guidance often prevent suitable people from starting on a new career. The various forms of membership offered by professional institutions safeguard the standards within the professions but, like educational institutions making external awards, they are slow to change syllabuses, examination procedures and admission qualifications to suit changing conditions.

There is sufficient freedom of academic and administrative policies at lower levels, but many higher educational establishments would function more efficiently if they had a greater degree of autonomy at the higher planning levels. This would encourage some much-needed integrative planning among higher education institutions and would lead naturally to over-all integration of the higher education system.

Copies of the memorandum are available from the Secretary, Staff Association, Technical College, Paisley.

WORLD-WIDE MICROSEISMIC STUDY

By DR. H. M. IYER*

Meteorological Office, Bracknell, Berks.

EVEN though the over-emphasized importance of microseisms for meteorological and oceanographical investigations has waned fast over the past decade the geophysical implications still remain interesting. The following are some interesting possibilities:

(1) The energy in microseisms is predominantly contained in the 0·25–0·1 c.p.s. band[1], with a peak in the neighbourhood of 0·15 c.p.s. Considering that microseisms contain an appreciable amount of surface waves of the Rayleigh type travelling in one or more directions[2] and in the frequency-range covered by them earthquake surface waves are seldom observed, it seems logical to use microseismic data to supplement investigations of earthquakes.

(2) The well-known idiosyncrasy of certain sources (usually intense storms) in the ocean giving entirely different microseismic intensities at two seismograph stations on the same coastline suggests strong refraction effects. When this observation is taken in conjunction with the characteristic peaking of the microseismic spectrum, it makes sense to postulate that the Rayleigh waves in microseisms are strongly affected by the transition from the ocean to the continent. The dispersion relation for such transition is very well known[3] even though its application to the examination of propagation of microseisms is often overlooked. I have suggested that the continental margin acts as a low-pass filter for microseisms[4]. The direct verification of this has to wait until a seismograph station is established in the deep ocean. However, a preliminary Russian experiment of recording microseisms on the floor of the Black Sea[5] and comparing it with simultaneous recording on land showed that 2-sec. microseisms were twenty times stronger under the sea than on land.

(3) The third interesting fact about microseisms is that they seem to be always present everywhere. In island stations like the United Kingdom, the basic background of microseisms is of the order of 2–3μ peak to peak, the activity rising to several times this value under certain meteorological conditions. On the other hand, there are places like California where the background of the order of 1-μ movement, with the usual spectral peak, occurs day after day with no specific source to which this could be attributed. The interesting possibility of the Earth being filled with 'seismic noise' cannot be over-ruled.

(4) For the very practically minded, the immediate problem of detecting low-level seismic signals calls for a knowledge of the directional spectrum of 'seismic noise'.

(5) Last, but not the least in importance, is the classical problem of the origin of microseisms. Several well-known theories of origin are in existence;

---

* Gassiot Fellow in Seismology.

but no one completely accounts for all the observations. However, I believe that postulation of new theories and modification of old ones are only of academic interest unless preceded by consistent detailed observation and analysis over several points of the globe for an appreciable length of time.

Hence, it appears that the war with microseisms is not over, and only considerable research spread over space and time can provide answers to all the questions.

During the International Geophysical Year a valuable amount of microseismic data was collected on this basis. But I contend that such information obtained from conventional earthquake seismographs with widely different characteristics is only of statistical interest. The present is the most opportune moment to think about a programme of international study of microseisms in line with the general renaissance in seismology and particularly because a world-wide network of standardized seismographs is coming into existence, for the first time in the history of seismology.

The aim of this article is to call for incorporating certain essential instruments with all good seismograph stations so that a detailed examination of microseisms on an international level can be made possible. The cost of such instrumentation is negligible compared with the overall expenditure incurred in establishing the station.

Theory of Microseisms

The first question is to decide what information is required from each seismograph station, and for this it is essential to understand some basic ideas on the nature of microseisms.

As in any geophysical time series, let us assume that microseisms consist of signal and noise. Very useful directional results have been obtained in the past[6] by assuming the signal to consist of Rayleigh waves coming from certain coherent direction or directions and noise confined mainly to the horizontal components and isotropic in nature. Based on this model, in the simple case of a source making an angle θ with the east–west axis, we can write for the three orthogonal components:

$$\text{east–west } x(t) = R(t) \cos\theta + \text{noise} \qquad (1)$$

$$\text{north–south } y(t) = R(t) \sin\theta + \text{noise} \qquad (2)$$

$$\text{vertical } z(t) = kR(t) \qquad (3)$$

where $R(t)$ is the Rayleigh wave time series and k is the polarization factor for Rayleigh waves (assumed to be independent of frequency over the range of interest). The problem is to estimate:

(1) Spectra of $x(t)$, $y(t)$, $z(t)$

(2) Spectrum of $R(t)$/noise

(3) θ and k.

As in any signal-to-noise problem, the solution is to make spectral and cross-spectral (cross correlation) estimates of the components at the same station and between different stations. For a single source of microseisms, assuming the vertical component to contain pure Rayleigh waves, by correlating each of the horizontal components in turn with the vertical, the Rayleigh wave part could be completely defined. The operation can be represented as follows:

$$\overset{(\tau)}{C}xz = \int_T x(t)z(t+\tau)\,dt \qquad (4)$$

$$\overset{(\tau)}{C}yz = \int_T y(t)z(t+\tau)\,dt \qquad (5)$$

$$\overset{(\tau)}{C}xy = \int_T x(t)y(t+\tau)\,dt \qquad (6)$$

where C is the correlation function, $\int_T$ represents integration over a time-interval T and τ is the usual time lag used in estimating the correlation function.

Let us confine our attention to a narrow band of mean frequency f_0 c.p.s. Since, for Rayleigh waves, the vertical component is 'in quadrature' with the horizontal components, maxima of $\overset{(\tau)}{C}xz$ and $\overset{(\tau)}{C}yz$ occur every time $\tau = \pm\,(2n+1)\,\frac{\pi}{2}\,\frac{1}{f_0}$ where $n = 0$, $+1$, $+2$, etc.

From equations 1, 2, 3 we can thus write:

$$C_{xz}^{\max} \alpha k\overline{R^2(t)} \cos\theta \qquad (7)$$

and:

$$C_{yz}^{\max} \alpha k\overline{R^2(t)} \sin\theta \qquad (8)$$

Therefore:

$$\tan\theta = \frac{C_{xz}^{\max}}{C_{yz}^{\max}} \qquad (9)$$

Once θ is estimated the other unknowns can be evaluated from a knowledge of the spectra of $x(t)$, $y(t)$ and $z(t)$.

Techniques

(1) The most obvious way of evaluating the parameters already mentioned is to start from the analogue records produced by the instruments and analyse them either directly or after digitization, depending on available resources. In any event, a good record is a prerequisite. Unfortunately, the drum recorders used in most seismograph stations do not provide sufficient resolution either in time or in amplitude to perform this analysis. Since microseismic samples need be taken only for half an hour or so for twice a day, the ideal thing would be to incorporate a sensitive three-channel strip chart recorder at the output of the seismographs. Most of the long-period seismographs in use nowadays have a sensitivity of more than 25 μv./μ movement near the microseismic peak frequency and it is not difficult to visualize a suitable recorder with least resolution of about 0·5μ and dynamic range of 100.

Even at a speed of recording of 1 mm./sec., in half an hour it will produce only 6 ft. of record. Such a system should not cost more than 2 per cent of the cost of overall equipment layout. The records thus collected could be sent to a few experimental centres where reading facilities and computer time are available for spectral and cross-spectral studies. In certain areas, a few neighbouring stations can join together and produce time-synchronized records leading to very valuable studies of spacial distribution of microseismic sources and propagation problems. This type of collection of data takes off the limitation of the simple model outlined so far and lends itself to more general analysis.

(2) For certain stations (isolated island stations in hurricane belts) immediate knowledge of the direction of arrival of microseisms is of great interest. In any event, a quick and easy way of directly obtaining this information from seismograph signals is desirable rather than waiting for the results of detailed analyses of the type outlined in the previous paragraph. The most practical way of handling this problem is to

estimate $C_{xz}^{\max}$ and $C_{yz}^{\max}$ (equations 7 and 8) or their nearest approximations using a simple analogue 'in line' correlator. A method already used[7] employs simple contact galvanometers at seismograph outputs to estimate correlation co-efficients using Tomoda's zero crossing principle. The contact galvanometers are used to examine at successive intervals of time whether the two outputs used are both deviated on the same side or opposite sides of zero. From this 'in phase' and 'out of phase' information, taken over a sufficient length of time, the correlation coefficient (maximum) between the two outputs can be computed.

A much more elegant method will be to compute $C_{xz}^{\max}$ and $C_{yz}^{\max}$ directly and feed them simultaneously to the two deflexion systems of an X–Y plotter. The position of the point vectorially represents the direction of arrival θ. If such an instrument is in operation during a 'microseismic storm' the scatter diagram of θ on the X–Y plotter should indicate the average direction of the source. A type of automatic direction finder as above can be easily made by subjecting suitably amplified and filtered signals from seismographs to addition, squaring, integration and plotting. Squaring can be easily carried out using a simple thermal square law unit and integration by a low leakage capacitor of the plastic film type. In fact, the instrumentation could be made very compact, cheap and simple.

Another basis for designing a direction-finder is to use a technique similar to that used by Jensen[8]. Since Rayleigh waves in the vertical are in quadrature to those in the horizontal components, it is seen that every time the vertical crosses zero the Rayleigh waves in the horizontal should reach a theoretical maximum in the positive or negative direction. Thus by estimating the deflexion of the east–west and north–south components at the zero crossing times of the vertical, for a sufficient length of time, it is possible to make a statistical estimate of the ratio of the north–south to east–west component of Rayleigh waves, which is $\tan\theta$. It could be easily arranged so that every time the vertical component crosses zero, a simple unit can be made to generate a pulse and this pulse could cause the instantaneous values of east–west and north–south deflexions to be plotted on an X–Y plotter. The series of points thus obtained should indicate the mean value of θ.

Conclusion

In conclusion, it is proposed that all modern seismograph stations take an active interest in microseismic study as well, and:

(1) Produce a good microseismic record with sufficient amplitude and time resolution for detailed study, twice a day.

(2) That groups of interested workers join together to analyse such records in places where analogue or digital analysers are available.

(3) Simple direction finding instruments be incorporated in the seismograph stations to provide scientific and utilitarian data on the relation between storms and microseisms.

The foregoing programme, or a better alternative, if carried out at least over a selected number of stations for an experimental period of time, should provide solutions to the many unsolved problems in microseismic science and prove a valuable tool in geophysics and in the meteorology of remote island stations.

RADICAL PRODUCTION AND ENERGY TRANSFER IN RADIATION CHEMISTRY AND IN PHOTOCHEMISTRY

By DR. GISELA KALLMANN OSTER and PROF. HARTMUT P. KALLMANN

Department of Physics, New York University

ONE of the most interesting questions in the radiation chemistry of organic substances is which of the excited states of the solvent is involved in radical production and in energy transfer. It has been demonstrated with organic scintillators[1] that up to 5 per cent of the absorbed ionizing radiation energy (γ-radiation) appears in the first excited singlet electronic state, either due to direct excitation to this state or due to cascading down from higher states. Radical yields in benzene–carbon tetrachloride mixtures are in excess of those expected from direct absorption by the constituents which should be proportional to their mass ratios[2]. This excess radical production has been attributed to energy transfer from the benzene to the carbon tetrachloride molecule[3]. We have determined which excited states of benzene are involved in this process by comparing radical production by optical excitation and by ionizing excitation particularly in the crucial region of low carbon tetrachloride concentration.

The radical concentration was determined by scavenging the radicals with the stable purple free radical diphenyl picrylhydrazyl (DPPH). The disappearance of the scavenger was followed by measuring the decrease in optical density at 546 mμ where the absorption of the yellow scavenger product is insignificant. All samples were thoroughly degassed by five-time freezing and thawing under high vacuum. The ionizing radiation source was a tungsten target X-ray tube operated at 250 kV. and 15 m.amp. with an output at the sample of 30,000 r./hr. as measured with a calibrated ionization chamber. The photochemical reactions were carried out using an 8-W. mercury resonance lamp producing mainly

254 mμ, the 185 mμ line being filtered out. The quartz reaction cell (1 cm.^{2} cross-section) which was fitted for degassing was placed at a distance of 30 cm. from the lamp, where it received 2·45 × 10^{-8} einsteins/min./c.c. as shown by uranyl oxalate actinometry. Care was taken to ensure that the overwhelming absorption was due to benzene by making the concentration of benzene so large that its optical density at 254 mμ was at least ten times higher than the sum of the optical densities of all other constituents. In separate experiments it was established that DPPH in carefully degassed solutions is not photolysed by 254 mμ radiation. In order to avoid local depletion of the scavenger at the front surface of the cell, vigorous stirring by means of a magnetic stirrer was utilized. Without stirring it was noticed that a slow disappearance of the scavenger occurred after illumination. This dark reaction, which does not occur when the system is stirred, is attributed to the reaction of DPPH with chlorine produced from chlorine radicals when scavenging is incomplete. All rates of radical production are initial rates in order to assure that DPPH was always present in excess. The rates only decreased somewhat after 70 per cent of the scavenger has been consumed.

We have found that free radicals are also produced when benzene is irradiated with 254 mμ light in the presence of small amounts of carbon tetrachloride. This radical production can only be caused by energy transfer from the first excited state of benzene to a carbon tetrachloride molecule. Trivial re-absorption is ruled out since benzene is only weakly fluorescent, yet the quantum yield of radical production may be as high as 0·66. On comparing the formation of radicals by ionizing radiation and by 254 mμ radiation, we notice some significant differences. In Fig. 1, the excess radical formation with ionizing radiation due to energy transfer from benzene to carbon tetrachloride is computed by deducting from the observed rate of radical production the rates of radical production due to primary decomposition of either benzene or carbon tetrachloride. These latter rates were determined by measuring the rates of radical production in the pure solvents and assuming that in a mixture these rates are proportional to their relative masses when equal amounts of energy are absorbed.

It is seen that in the ionizing radiation case (Fig. 1) considerably higher concentrations of carbon tetrachloride are required to reach a plateau as compared with the rapid rise of curve *A* of Fig. 2. This demonstrates that shorter lifetimes of excited states, presumably higher electronic states, are involved in the ionizing radiation case. When certain substances, such as phenylbiphenylyloxadiazole, *o*-terphenyl or fluoranthene, which are known to deactivate the first excited state of benzene and the fluorescence of which is not quenched by carbon tetrachloride[3] are added to the benzene–carbon tetrachloride mixtures, they markedly reduce the rate of radical production under ultra-violet excitation but have absolutely no effect under ionizing radiation excitation. The concentration of these substances was of the order of 0·1 *M* corresponding to their maximum solubility, and the carbon tetrachloride concentration was varied from 0·1 *M* to 0·005 *M*. This finding further substantiates our conclusion that only higher excited electronic states of benzene contribute to radical production under high-energy excitation.

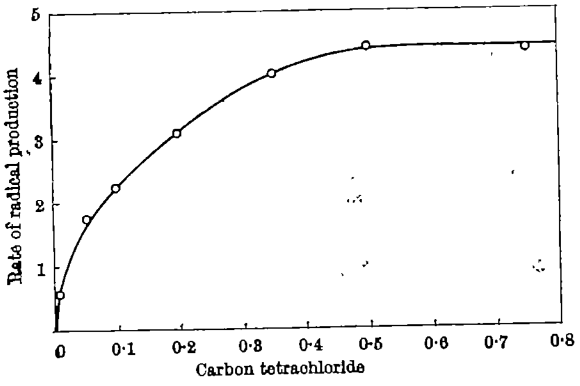

Fig. 1. Rate of excess radical production (moles/l. min. × 10^{6}) as a function of carbon tetrachloride concentration (moles/l.) using ionizing radiation (30,000 r./hr.). Initial DPPH concentration 5 × 10^{-4} moles/l.

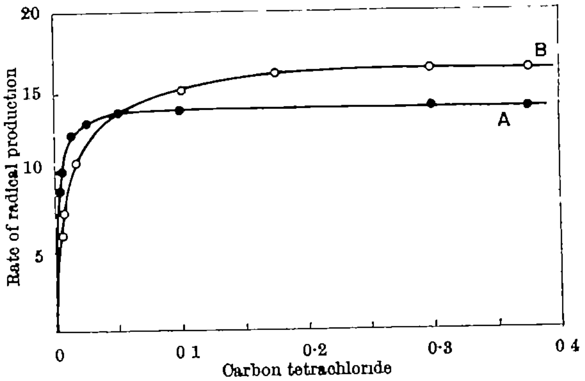

Fig. 2. Rate of radical production (moles/l. min. × 10^{6}) as a function of carbon tetrachloride concentration (moles/l.) using 254 mμ source (2·45 × 10^{-8} einsteins/c.c./min.). Initial DPPH concentration 2 × 10^{-4} moles/l. Curve *A*, solvent pure benzene, curve *B*, solvent *cyclo*hexane/benzene (5 × 10^{-3} moles of benzene/l.)

The region above 1 *M* carbon tetrachloride (approximately 0·1 mole fraction), corresponding to the condition where each benzene molecule is in contact with at least one carbon tetrachloride molecule, is just the region where we see the curve of Fig. 1 approaching a plateau. Apparently for ionizing radiation only those excited benzene molecules contribute to radical production which have a carbon tetrachloride molecule as a nearest neighbour. The concentrations used in the aromatic quencher experiments make it unlikely that any excited benzene is being simultaneously surrounded by both carbon tetrachloride and aromatic quencher; hence no competition will occur between quencher and carbon tetrachloride. This situation is completely different from the case of light excitation where energy migration is involved. With 254 mμ radiation only the lower state of benzene is excited the energy of which migrates because of the relatively long lifetime of this state and reaches in this manner the carbon tetrachloride molecule.

The difference of curves *A* and *B* of Fig. 2 at low carbon tetrachloride concentrations can be attributed to energy migration which would only occur to a significant extent in pure benzene (curve *A*). In curve *B* the energy reaches the carbon tetrachloride molecule only by material diffusion, which is not as fast as energy migration and therefore requires larger carbon tetrachloride concentrations. The difference of curves *A* and *B* at high carbon tetrachloride concentrations may be ascribed to two different reactions between carbon tetrachloride and excited benzene molecules, one leading to the formation of radicals, the other just to a deactivation of excited benzene. The relative extent to which these two reactions occur may be affected by the solvent. We have evidence from other experiments for the existence of these two types of reactions. It may be further noted that the relatively high quantum yield of radical production (0·66 for the plateau of curve *B*) indicates that the excitation energy of benzene is relatively easily transferred to the atomic vibrations of the carbon tetrachloride molecule, where it results in dissociation into free radicals.

Under excitation by ionizing radiation the first electronic state of benzene is also excited, but since this excitation amounts to not more than 3 per cent[1], its contribution to radical production is insignificant compared to that by higher excited states.

Grateful acknowledgment is made of the support of this investigation by the United States Army Signal Corps, under contract No. *DA* 36–039 *SC*–78056 and by the Aeronautical Research Laboratory, under contract No. *AF* 33(616)–8317.

VERY LOW COERCIVE FORCE IN NICKEL–IRON FILMS

By H. CLOW

Research Laboratories, Electric and Musical Industries, Ltd., Hayes, Middlesex

THIN films of evaporated 80–20 nickel–iron alloy, 1000 Å. thick, normally exhibit domain wall coercivities of 1·5–2·5 oersteds, depending on the experimental conditions. I have recently prepared laminated films, with a total nickel–iron thickness of 1000 Å., with coercitivities of about 0·2 oersted[1].

Fig. 1 shows the magnetization curves, obtained with a 500 c./s. loop tracer, of a normal film in the easy and difficult directions (H_C = 2·0, H_K = 3·5 oersteds), and underneath are shown the corresponding magnetization curves for a composite, laminated film prepared in the same deposition (H_C = 0·2, H_K = 3·5 oersteds). There is, therefore, a 10 : 1 change in domain wall coercivity, whereas the hard direction magnetization curve is unaltered.

The low coercivity film consists of ten laminations of nickel–iron, each 100 Å. thick, interleaved with silicon monoxide layers of comparable thickness. The silicon monoxide and nickel–iron layers were deposited alternately in the same vacuum, using a differential shutter, starting and finishing with the silicon monoxide. The pressure in the vacuum system was about 1 × 10^{-6} mm. mercury during the deposition of nickel–iron, and the substrates were glass microscope slides heated to 320° C.

The coercivity of a magnetic material can be reduced by relief of stress, or by the reduction of the impurity content. The isotropic stress in the laminated films may have been reduced in the manner described by Blois[2]. By laminating nickel–iron, which has a thermal expansion coefficient larger than that of his glass substrates, with a material of low thermal expansion, he could reduce the stress in his layers. However, in the present experiments, laminated layers of silicon monoxide and nickel–iron deposited on copper substrates had the same low coercivity as layers made in the same deposition on glass.

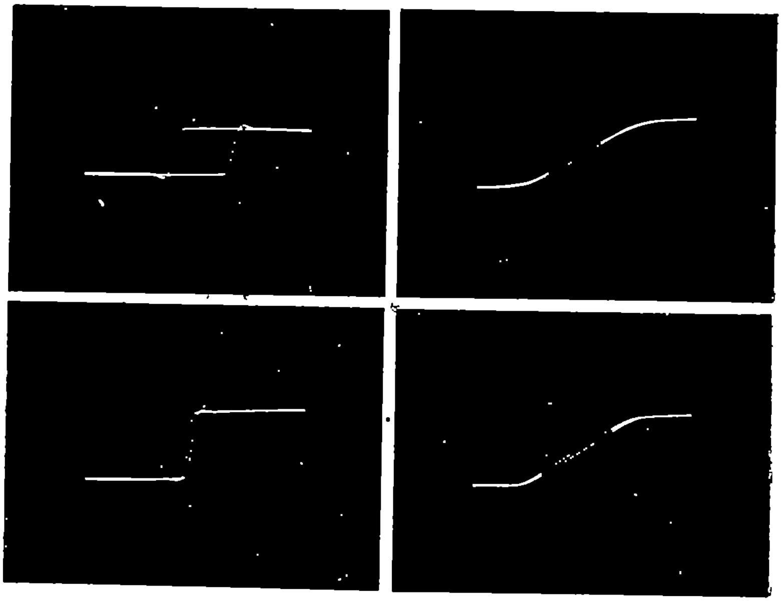

Fig. 1. Top left, longitudinal *I–H* loop 1,000 Å. solid nickel-iron film; top right, transverse *I–H* loop 1,000 Å. solid nickel-iron film; bottom left, longitudinal *I–H* loop 1,000 Å. composite nickel-iron film; bottom right, transverse *I–H* loop 1,000 Å. composite nickel-iron film

Further, it seems unlikely that laminating a nickel–iron film with silicon monoxide could improve its purity, especially as nickel–iron laminated with calcium fluoride also has low coercivities. Again, a single lamination of nickel–iron does not have a low coercivity whereas several laminations do produce this effect, as described.

A more likely interpretation of the effect may be that the reduction of coercivity is due to a reduction of the domain wall energy, γ. The coercivity of a thin film may depend on either the domain wall energy itself or on its variation with wall position, $\frac{d\gamma}{dx}$ (ref. 3). To account for a reduction of coercivity in this way it is then necessary to assume that $\frac{d\gamma}{dx}$ is itself dependent on γ.

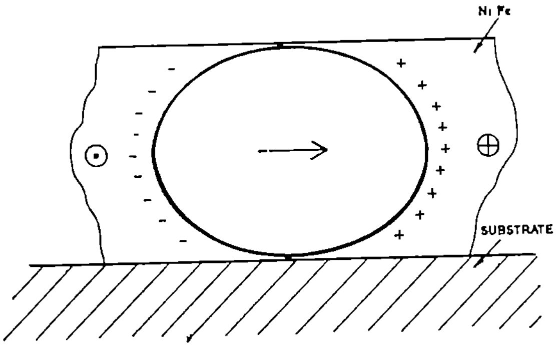

Fig. 2. Néel wall

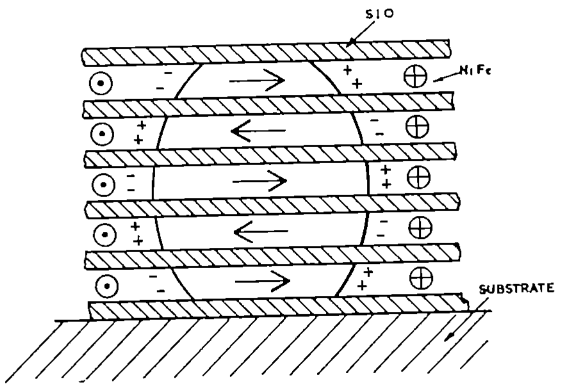

Fig. 3. Proposed wall structure in composite film

Fig. 2 shows diagrammatically a cross-section through a Néel wall in a thin film. (The cross-section is here shown as elliptical, but the actual shape is unimportant.) Exchange interaction causes the whole of the magnetization inside the wall to lie in essentially the same direction, as shown by the arrow in Fig. 2, giving rise to a large free-pole energy.

In a laminated film there can be no exchange interaction through the silicon monoxide separating neighbouring nickel–iron layers. Hence there appears to be no reason why the magnetization within the Néel wall should not reverse its direction at every lamination, thus reducing the magnetostatic energy, as shown in Fig. 3. The surface energy density γ of such a configuration would be much smaller than that of a conventional Néel wall, and this reduction may account for the very low coercivities observed here.

Using a dried colloid technique, domain walls were readily observed on solid nickel–iron layers 1000 Å. thick covered with silicon monoxide. However, no domain walls were seen on laminated layers with a total nickel–iron thickness of 1000 Å. This is at least an indication that there are smaller stray fields associated with domain walls in laminated layers than there are with those in solid layers, as would be expected from the above model.

KARST MORPHOLOGY IN AUSTRALIAN NEW GUINEA

By J. N. JENNINGS
Australian National University, Canberra
AND
M. J. BIK
Commonwealth Scientific and Industrial Research Organization, Division of Land Research and Regional Survey, Canberra

THE increasing interest in recent years in the climatic morphology of limestone[1-3] has been chiefly directed at discerning the different karst styles associated with horizontal climatic variation. Fewer attempts[4] have been made as yet to see what happens to limestone land-forms as they are traced through height, though the principle that morphoclimatic systems are storied is well established[5]. In a further approach to this question during 1960 and 1961, we made reconnaissance studies of a number of karst areas in Australian New Guinea. These range in height from sea-level to well above 3,000 m. and are developed in limestones which vary considerably in age and in lithology (Fig. 1).

(*a*) *Low levels* (cf. *tierra caliente*). In the lower Kikori area (Gulf District) at heights mainly below 200 m., Lower Miocene limestones subject to 5,000–7,500 mm. annual rainfall give rise over wide areas to typical 'Kegelkarst' of Lehmann's Goeneng Sewoe type[6]. The relief consists of a sea of roughly hemispherical hills with enclosed star-shaped depressions —the 'cockpits' of tropical karst[7]. There is some orientation, apparently joint-controlled. This 'Kegelkarst' is developed in different lithologies—in white chalky limestone, cream algal limestone and brown crystalline limestone.

Additionally, there is what the oil geologists call 'crevice' country; this is level or gently undulating in overall relief but intricately cut up in detail by irregular fields of close-set solution corridors. It resembles most closely the 'giant grikeland' phase of

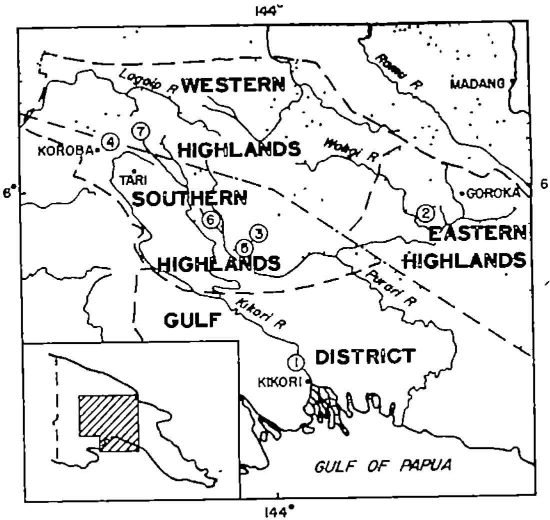

Fig. 1. Location of the Karst areas discussed. 1, Lower Kikori R.; 2, Yandimi; 3, Tualamara; 4, Paru R., Kambe Ck., and Tabaiya Mabu; 5, Sugu R.; 6, Nembi R.; 7, Mt. Kaijendi. Stippling denotes mountainous country

the tropical semi-arid karst of the Limestone Ranges of West Kimberley in Australia[8], though lacking its larger dimensions and greater rectilinearity through joint control.

Since the two sorts of terrain can be found on the same limestone and since 'crevicing' can occur within 'Kegelkarst', an explanation in terms of lithology for the two does not seem possible. In some cases crevice karst appears to be formed in flat erosion surfaces along major valleys, perhaps formerly alluviated, but this association is not invariable.

(*b*) *Intermediate levels* (cf. *tierra templada*). In some areas doline karst prevails, that is, the relief is dominated by enclosed depressions of moderate dimensions and rounded contour, ranging from conical to dish shape. Such karst around Tualamara (Southern Highlands District) about 1,580 m. high and with approximately 3,100 mm. rainfall occurs on an impure Miocene limestone formation with interbedded siltstones, whereas in the neighbourhood of Yandimi (Eastern Highlands District) it is found on the pure Chimbu Limestone of Upper Cretaceous–Eocene age (height 1,500 m., annual rainfall 2,200 mm. with a short dry season). Around Korenda and Tabaiya Mabu (Southern Highlands District) doline karst seems to be located synclinally where Orubadi Mudstone has recently been stripped from Darai Limestone.

Equally widespread at the intermediate levels, however, is limestone terrain dominated by projecting residual hills, which nevertheless overlook conical or bowl-shaped dolines. The hills assume either a blunted pyramidal form with slopes about 40° or else a tower form, conical at the top but with vertical or nearly vertical sides. Both appear to be fashioned by the deepening and inosculation of the dolines. The towers seem to have evolved from the pyramids by the development of high free faces. Examples of such kinds of karst are: (1) Sugu R. area, height 1,400–1,650 m., rainfall 3,100 mm.; (2) Nembi R. area, height 1,400–1,750 m., rainfall 2,700 mm.; (3) Paru R.–Kambi R. area, height 1,600–2,000 m., rainfall 2,400 mm. All these are developed in the pure Darai Limestone of Miocene age in the Southern Highlands District. Within them occur large enclosed depressions elongated along the strike, the floors of which consist of fields of dolines, for example, Pewa depression west of the Nembi valley.

(*c*) *High levels* (cf. *tierra fria*). In the one high-lying area examined, between the Porgera–Lagaip drainage and the Tari Basin at elevations of 2,600–3,700 m., three karst types were found in limestones probably Upper Cretaceous–Eocene in age. On the Nia alpine grassland (3,100 m.) is a limited area of doline karst associated with pure limestone being stripped of a siltstone cover. This is surrounded by higher forested karst of the pyramid-and-doline type. The third type consists of vertically walled, knife-edged arêtes and pinnacles of bare limestone standing like battlements around dolines covered by montane forest of mossy aspect. This occurs on the south flank of Mt. Kaijende (Fig. 2) and in two other areas southwards towards the Tari basin.

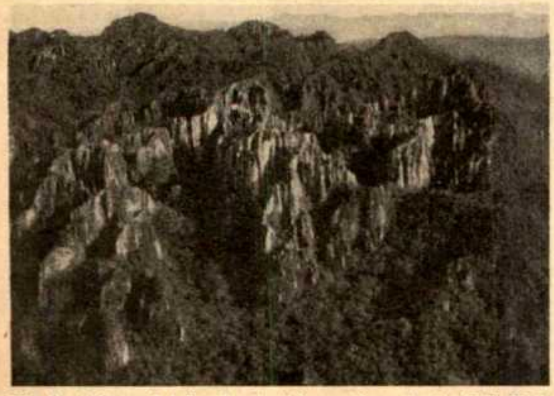

Fig. 2. Arête-and-doline karst of the southern flank of Mt. Kaijende, Western Highlands District, Australian New Guinea

Though these observations pose many questions as yet unanswerable, they bear significantly on some of the issues much discussed recently by students of karst.

(1) In the humid tropics, 'Kegelkarst' has been related to pure limestones, whereas doline karst has there been thought to be associated with impure calcareous formations[7,9]. Although no doline karst at low levels has yet been encountered in Australian New Guinea, doline karst at intermediate levels is definitely not restricted to impure calcareous facies.

(2) Lehmann[10] has shown how geomorphologists were confused by established terminology based on classical studies of the Yugoslavian karst when they first came to consider tropical humid karst. Observers such as Daněs[11] failed to recognize some of the significant differences between temperate dolines and tropical cockpits, between temperate hums and tropical residual limestone hills. Through their transference without much qualification of the classical karst terminology to these different tropical land-forms, these early authors who described tropical humid karst misled theorists such as Grund in Europe[12]. The latter consequently regarded the tropical 'Kegelkarst' as a more advanced stage of a single karst cycle, representing the further evolution of doline karst. Largely as a result of Lehmann's and von Wissmann's work in the 1930's, the misconceptions were recognized and the idea that tropical 'Kegelkarst' developed in a separate manner altogether was established.

However, though the New Guinea low-level observations seem to sustain the modern point of view, the data from intermediate and high levels call for an elaboration of it. Much of the karst here is dominated by fields of residual limestone hills, but these are genetically associated with dolines clearly of European type. In fact the relief resembles most closely, not tropical 'Kegelkarst' as described more precisely by modern workers, but the false picture Alfred Grund conceived of it in his attempt to put tropical and temperate forms into one evolutionary sequence. His theoretical block diagram[12] sketches hollow-chested, horn-like peaks rising between inosculating, flat-floored dolines. These imagined residual projections correspond in large measure with the pyramidal hills of much of the karst at intermediate levels in New Guinea. However, the dolines associated with the latter have not developed significant flat floors. The Davisian deductive approach has been adversely criticized recently, but certain virtues may be demonstrated in that something very close to Grund's mature karst, which was at least as much the product of his theoretical deduction as of Daněs's observations, occurs in New Guinea.

(3) It is to be noted, however, that the pyramid— or tower-and-doline—karsts occur at higher levels in climates resembling European temperate climates more closely than do the full tropical conditions of the lower Kikori 'Kegelkarst'. At higher levels still the Mt. Kaijende karst departs even more completely from 'Kegelkarst', the residual hills being hollowed

out on their flanks until they are often reduced to arêtes with gendarmes. Thus, there seems to be an altitudinal climatic zonation of karst in New Guinea, though at each level the picture is not a simple one, complicated as it is by the cross-cutting influences of lithology, structure and evolutionary history (cf. Verstappen[13]).

It has been found that the periglacial phenomena of high tropical mountains do not match completely those of sub-polar regions but have their own character. It is apparent from the data presented here that the same lack of full parallelism between the effects of latitudinal and of altitudinal climatic gradients applies also to karst.

(4) Within tropical 'Kegelkarst', two major categories have been recognized by many authors, characterized by the hemispherical residual hill ('Kugelkarst') and by the tower ('Turmkarst'). Lehmann[14] and others have associated the latter with lateral solutional undercutting in association with the development of alluvial covers at some local rest-level of ground-water or else close to sea-level. The same factor, though locally operative at intermediate levels in New Guinea, for example, near Nanje in the lower Amia valley (Southern Highlands District), does not generally explain the differentiation of pyramids and towers there. The very steep walls of these towers usually rise from footslopes which correspond in angle and nature to the slopes of the pyramids without any intervention of lateral solutional undercutting or association with horizontal surfaces at all.

(5) Coleman and Balchin[15] have recently produced a strong case for regarding all the dolines of the Mendip Hills as stages in the evolution of collapse dolines and for rejecting the idea of solution dolines entirely for that area. They extend this finding to maintain that collapse dolines and their derivatives alone enter into 'the' karst cycle, which from their examples is implicitly regarded as applying to tropical as well as to temperate regions. This extension does not seem justifiable. In New Guinea, fields of evenly scattered dolines, both in normal doline country and in association with pyramids and towers, cover large areas, on divides as well as in valleys. It seems unlikely that all these dolines could be due to regular collapse patterns into underground river systems. Surface solution must be dominant here.

(6) Finally, a problem of great controversy has been the relative rate of limestone solution and of karst development in different climatic conditions. Lehmann, Bögli and Birot[1–3], among others, have maintained that in humid tropical lowlands conditions are optimal for these processes, relying chiefly on the *a priori* reasoning that chemical reactions will proceed fastest in accordance with Arrhenius's equation and that water going underground will have the greatest amounts of carbon dioxide in solution through the high rate of vegetation growth and decay, and of microbiological activity in the soil.

Corbel[16], on the other hand, has argued that cold temperate zones with high precipitation are the loci of most rapid limestone solution and land-form evolution. This is on the grounds of the higher saturation equilibria of carbon dioxide in water at these lower temperatures, of the high carbon dioxide content of the air in snow and so of meltwater. He has further[17] produced empirical evidence in support of his thesis, notably in a detailed comparison of the actual amounts of calcium carbonate carried out in solution from a catchment in Florida and one in Alaska, a comparison greatly in favour of the latter.

He has also maintained that tropical limestone streams are frequently saturated at low bicarbonate contents. Determinations in New Guinea show lower contents from the lower Kikori and its tributaries than in rivers at higher levels there; but the lowland streams remain very aggressive and discharges are enormous because of the amount and intensity of the rainfall.

Moreover, the rate of removal of limestone in solution from a limestone area must not be equated with the rate of limestone solution or of karst landform development[18,19,8]. In New Guinea re-deposition within the limestone areas of tufa along the rivers has already been noted[20] and our own observations suggest it is a widespread phenomenon.

Part of Corbel's thesis has been that cold temperate karsts have in most cases had little time for their development because of the interruptions of Pleistocene glaciations, whereas tropical 'Kegelkarsts' have had a much longer evolution. New Guinea can add many examples, however, to the tally of 'Kegelkarsts' which have been elaborated in a very short space of time. In the lower Kikori, Pliocene rocks are folded and the karst must have developed within the Pleistocene. There the major relief is tectonic; but in the Southern Highlands, though folding and uplift may be older (probably Pliocene), there is relief inversion and much of the highly developed karst lies in synclines.

Nevertheless, this controversy can as yet scarcely be said to be resolved. New Guinea suggests a complication to this question. The vigour of relief of the arête-and-doline karst at high levels is remarkable, surpassing in intensity even the 'biscuit-cutting' effects[21] of glacial cirque erosion, with which it has no genetic connexion however. The orogenic movements which raised these highlands are probably Pliocene. So this karst is a young one in terms of age, though not in geomorphological stage. The possibility needs to be considered therefore whether, at certain levels, high tropical mountains may not provide the optimal conditions for karst evolution, combining as they do lower temperatures, hence higher saturation equilibria for carbon dioxide, with a fairly high and an effective precipitation and with the prolific vegetation growth of mossy montane forest throughout the year.

CELL DIFFERENTIATION AND CARCINOGENESIS

By DR. DAVID STONE

Worcester Foundation for Experimental Biology, Shrewsbury, Mass.

THE mechanisms which determine the biological functions of the cell and govern the regulation of its activities are gradually being elucidated by various investigators. It is the purpose of this article to present some suggestions which might be related to cellular differentiation, dedifferentiation and carcinogenesis.

On the basis of the role of ribonucleic acids in protein synthesis and from the work on enzyme induction and antimetabolites in micro-organisms, it has been postulated that in the regulation of cellular activities, the activity of any enzyme in a metabolic sequence may be controlled through the stimulation or inhibition of the enzyme-forming systems (that is, the RNA 'templates') by substrate, metabolic intermediate or end-product[1]. Therefore, it is conceivable that in the multicellular organism, the activities of any one cell are influenced by the products of metabolism of the surrounding cells, and by alterations in the supply of nutrients, and in the rate of diffusion of its own end-products due to its environment of surrounding cells. Indeed, the literature on cell and tissue culture is well documented with the influences of environmental conditions on both the morphology and metabolic activities of mammalian cells in culture[2].

Consider a simple model system where a single cell forms a linear chain of cells: at the two-cell stage, the activities of either daughter cell will be altered by being in contact with the other. At the four-cell stage it might be expected that the inner two cells will have metabolic functions differing from the two outer cells, since in the former case each cell is bounded on two sides by other cells, whereas in the latter case, the outside cells are each adjacent to only one cell. Further, each of the inner cells will be bounded by two cells the activities of which are not alike, thereby allowing the possibility for even greater alterations in function as compared with the original cell. Whether such processes can lead to permanent changes, for example, differentiation or the formation of a blastula from a fertilized egg, is not known, although it is conceivable that when cytoplasmic activities have been altered for a long enough period of time this might occur. There are several examples in the literature regarding permanent changes which occur in cells in culture, for example, the production of cancer cells from long-term culture of cells derived from normal tissue, and the production of cells with altered numbers and morphological appearance of the chromosomes.

Such permanent alterations may be the result of changes in the pattern of activities of the ribonucleoproteins alone, or may reflect nuclear changes as indicated by the latter example. The possibility must not be ignored that the regulation of enzymatic activities of the cell is not confined to a closed cycle concerning only the ribonucleic acid enzyme-forming system alone, but might also involve an initial effect of cytoplasm on nuclear function, and then nuclear function on the enzyme-forming system. That is, in cellular regulation, the spectrum of metabolic activities of the deoxyribonucleoprotein molecules may fluctuate, perhaps by slight alterations in the spacial orientation of the molecules or by partial breakdown and re-synthesis. Long-term changes in environment might, therefore, lead to subtle and permanent alterations in the DNA.

It is of interest that recent work has suggested the possibility that different parts of the gene may have similar metabolic functions[3]. In this respect, it is easier to conceive of variations in combinations of activities as a result of the twisting or partial breakdown of the DNA molecules, when several polynucleotide groups have similar responsibilities.

Little is known of what is involved in the ultimate decision as to when and how a partly differentiated cell will differentiate. In the replacement of a dying differentiated cell, it might be considered that the final process in differentiation may depend on factors released from the dying cell. It is also possible that, in similar circumstances, the factors released may enter the recipient cell and upset the balance of its metabolic activities in such a manner as to give rise to a cancer cell. While there are no definitive data to support the above suggestions, the results of experiments being carried out in this laboratory are in accord with the above ideas. Several workers have shown that ribonucleic acid preparations are capable of influencing mitosis, morphology, and the re-aggregation of mammalian cells in culture. In this laboratory, saline extracts of fast-growing tissue (for example, chick embryo) have been shown to stimulate mitosis in polynucleated, amitotic cells of a hamster ascites population. Preparations of DNA and RNA obtained from chick embryonic tissue are also active in this respect. However, the influence of DNA is not transitory as compared with the action of the RNA and is suggestive of the transformations observed with micro-organisms. Similar activities of salt extracts are obtained from regenerating, but not from normal, rat liver, indicating that the amounts of active salt extractables vary with the metabolic state of the tissue[4].

In order to study further the possibility that mammalian cells are susceptible to alteration (for example, transformation) by materials from other cells, investigations were continued, using a HeLa cell strain sensitive to the growth inhibitory influences of small amounts of certain steroids, and steroid resistant sub-lines selected from it[5]. The sensitive strain was found to exhibit a stem-line containing 68 chromosomes, whereas the steroid resistant sub-lines showed a 74-chromosome stem-line[6]. Short-term culture of the sensitive strain in the presence of cell-free salt extracts obtained from the resistant lines resulted, in some cases, in significant increases in resistancy to the inhibitory action of the steroid. Further, after such treatment the cultures exhibited not only the 68-chromosome stem-line, but also a 74-stem-line characteristic of the steroid resistant sub-lines (Fig. 1). Such alterations are not

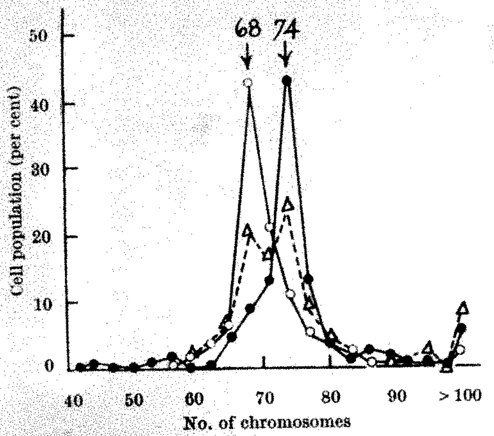

Fig. 1. Chromosome stem-lines of HeLa strain and sub-lines (a minimum of 200 metaphase cells counted in each case)
○, Steroid-sensitive strain; ●, steroid-resistant sub-line; Δ, altered HeLa line

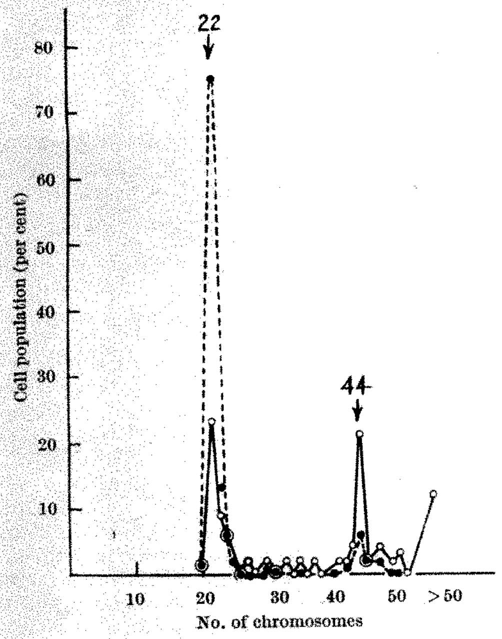

Fig. 2. Chromosomes of stable, classic diploid cells (*FAF* strain) and altered line (a minimum of 200 metaphase cells counted in each case)
●, Untreated *FAF* control; ○, altered *FAF* line

temporary; the bimodal character of the stem-line appears to be permanent, while increased resistancy to steroid lasted two to three months in actively growing cultures. It should be pointed out that neither of these characteristics is obtained when cell-free extracts of the steroid-sensitive strain itself is used. To obtain some information as to whether it is indeed possible to alter the metabolic and chromosomal characteristics of cells by materials obtained from identical cells, a normal cell strain with a more stable diploid character, and containing smaller numbers of chromosomes than the HeLa lines, was investigated (Chinese hamster cells, strain *FAF*, 22-chromosome classic diploid[7]). Fig. 2 shows the chromosome numbers in the normal *FAF* strain, and the *FAF* strain cultured for 4 weeks in rapidly growing culture after a short treatment with sterile-filtered salt extracts of its own cells; tetraploidy and polyploidy are greatly increased. Not only do the numbers of chromosomes change, but there are also significant changes in the idiograms (that is, the ratios of the various morphological species of chromosomes) within 80 per cent of the cells containing the same total number of chromosomes. Alterations in chromosome morphology also occur. That such changes are reflected by alterations in the metabolic characteristics of the cells has been indicated by variations in the growth-rates of the treated cultures as compared with untreated controls.

It has been well established that in some instances extracts of tumour cells passed through a bacterial filter have the capacity to produce tumours in normal tissue. The possibility that filtrates of normal cells themselves might be capable of producing alterations in the metabolic interrelationships of a similar normal cell, in such a manner as to produce a tumour cell, was tested. Normal untreated *FAF* cells and the normal *FAF* cells treated with sterile-filtered salt extracts of the *FAF* cells themselves (Fig. 2) were injected into the cheek-pouch of Chinese hamsters. Even though the opportunity for tumour-takes was negligible owing to the fact that the *FAF* strain is an F_1 hybrid derivative, and injections were made into adult, untreated hosts which are lacking in histocompatibility, the results in Fig. 3, nevertheless, demonstrate that the treated cells did not evoke a normal, immediate, antigenic response. This should not be confused with the delayed response observed with the Syrian hamster, and indeed is characteristic of the longer lag periods exhibited when cancer cells are injected. Similar studies are being undertaken with highly inbred cells and hosts.

In order to test this hypothesis further, and under *in vivo* conditions, the following experiment was carried out. Of 6 male adult rats, 5 were partially hepatectomized and the remaining lobes immediately injected with either saline (0·9 per cent) or sterile-filtered cell-free saline extracts of the removed lobe. Two rats received saline and three received cell

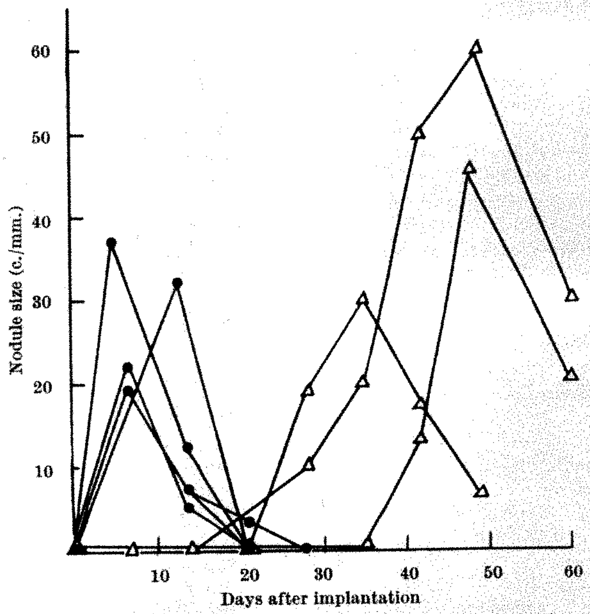

Fig. 3. Nodule formation in hamster cheek pouch after injection of *FAF* and altered *FAF* cells. (In some experiments 3×10^5 control and altered cells were injected; in other experiments 1×10^4 cells were used)
●, Normal *FAF* cells; Δ, altered *FAF* cells

extracts. A total of 1·0 ml. was used per animal, the injections being given in 0·1-ml. doses at ten different sites, and approximately two months later the rats were killed. Gross examination did not reveal any obvious signs of hepatoma, although it was noted that the livers from the liver-extract injected animals had greyish areas which were not seen in the saline-treated rats. Several samples of the liver tissue were taken from each animal and fixed in both absolute alcohol and formalin for histological study.

All histological and photographic procedures were identical for normal, saline control, and experimental animals. The photographs are × 970. Fig. 4 shows a section of a normal, untreated rat liver. The regenerated rat liver which received saline exhibits, in some areas (Fig. 5), degenerative and necrobiotic changes. In comparison, each of the livers injected with the liver extracts show remarkable alterations not associated with necrosis, as indicated in Figs. 6, 7, 8 and 9. Between the normal lobular arrangement of the cords of cells were present nodular-like areas exhibiting irregularities in structure. The epithelial cells of such areas have well-defined cytoplasmic membranes, are larger in size than the normal cells or the saline-treated controls, and show a granular cytoplasm containing a relatively large vesicular nucleus containing 1 to 3 large basophilic nucleoli. On each of these points, such cells bear a striking resemblance to hepatic tumour cells and are often

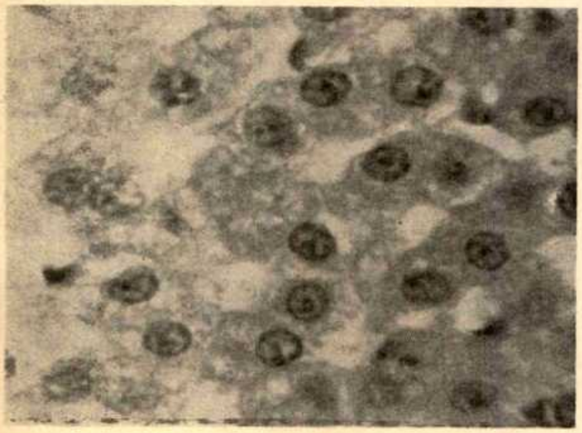

Fig. 4. Normal rat liver (× 970)

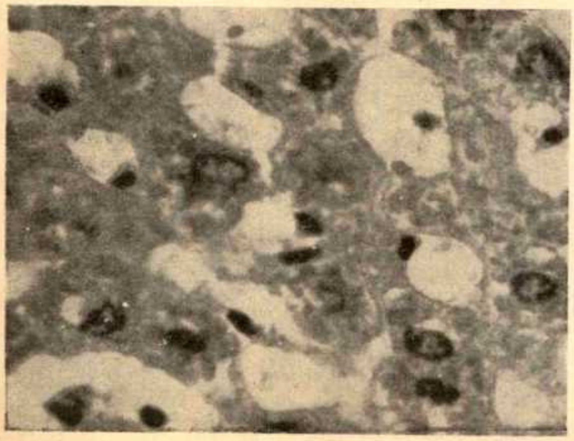

Fig. 5. Regenerated rat liver injected with sterile saline (× 970)

seen in acinar structures, similar to the glandular structures which occur not only in well-established tumours but also in hyperplastic atypical parenchymal nodules which appear to represent early neoplasm. In this respect, histological examination also indicates that in the livers treated with the test material, but not the saline, there are greater numbers of cells containing more than normal amounts of glycogen.

While no definite conclusions can be drawn from the foregoing results, they nevertheless are of interest with respect to possible mechanisms involved in differentiation and carcinogenesis.

I thank Prof. Y. S. Kang (Department of Zoology, Seoul National University, South Korea) for his kind co-operation with the chromosome studies, Dr. Likar (Mason Research Institute, Worcester, Mass.) for the histology, and to Dr. G. Yerganian (Children's Cancer Research Foundation, Boston, Mass.) for suggestions and for supplying both the cell strain and Chinese hamsters used in these investigations. This work was financially supported by the U.S. Public Health Services, the National Science Foundation, and the American Cancer Society (Mass. Division).

FUNCTION OF POLYURIDYLIC ACID AND RIBONUCLEIC ACID IN PROTEIN BIOSYNTHESIS BY RIBOSOMES FROM MAMMALIAN RETICULOCYTES

By DR. H. R. V. ARNSTEIN, DR. R. A. COX and DR. J. A. HUNT

National Institute for Medical Research, Mill Hill, London, N.W.7

THE importance of ribosomes to protein biosynthesis in both bacterial and animal cells is now well established[1]. In cell-free systems, consisting essentially of ribosomes, amino-acid activating enzymes, transfer ribonucleic acid (RNA) and an energy source, the incorporation of labelled amino-acids into polypeptide linkage has been studied in detail and experiments on the biosynthesis of hæmoglobin by ribosomes from rabbit reticulocytes[2] and of albumin by liver microsomes[3] have demonstrated the formation of specific proteins in such cell-free preparations.

The function of ribonucleic acid in protein biosynthesis has recently been clarified by experiments with similar cell-free systems from bacteria, particularly *Escherichia coli*. In addition to the relatively low-molecular-weight 'soluble' RNA which is involved in the transfer of activated amino-acids to ribosomes[4], a ribonucleic acid of higher molecular weight has been implicated in the polymerization of the amino-acids. This so-called messenger RNA is distinct from the bulk of the ribosomal RNA in nucleotide composition[5], rate of turnover[6] and metabolic activity[7].

The most striking demonstration of the role of a messenger in protein synthesis is, however, the discovery by Nirenberg and Matthaei that the addition of polyuridylic acid to *E. coli* ribosomes specifically brings about the biosynthesis of polyphenylalanine[7] and the extension of this work to synthetic co-polymers of uridylic, cytidylic, adenylic and guanylic acids which has resulted in the elucidation of a code for most of the 20 amino-acids which commonly occur in proteins[8-10]. Viral RNA also markedly stimulates incorporation of amino-acid and thus appears to function as messenger RNA[7,11].

No comparable evidence is, however, available concerning the function of ribonucleic acid in animal cells. It is also not known whether the genetic code as determined by the experiments with synthetic polynucleotides and *E. coli* ribosomes is generally applicable to other organisms.

In the work reported here, the function of ribosomes and their RNA in the biosynthesis of a specific protein, hæmoglobin, by cell-free preparations from reticulocytes has been investigated. It has been reported that, in cell-free preparations of reticulocytes from different animal species, the specificity of the hæmoglobin synthesized is determined not only by the ribosomes but also by the cell sap[12] or by the '*p*H 5 enzyme' fraction[13] after removal of the ribosomes by ultracentrifugation. We have not been able to confirm these observations. Using mixed systems from lysed rabbit and guinea pig reticulocytes, we have found that the specificity of synthesis of hæmoglobin is associated only with the ribosome fraction (Table 1), in agreement with the results obtained by Bishop, Favelukes, Schweet and Russell[14] with mixed cell-free preparations from rabbit and mouse reticulocytes. Our experiments

Table 1. SPECIFICITY OF HÆMOGLOBIN SYNTHESIS BY CELL-FREE PREPARATIONS FROM RABBIT AND GUINEA PIG RETICULOCYTES

	Origin of cellular components		Specific radioactivity (mμc./gm.)		
Exp. No.	*p*H 5 enzymes	Cell sap	Ribosomes	Rabbit hæmoglobin	Guinea pig hæmoglobin
1	Rabbit	None	930	601	47
			1,300	635	85
	Guinea pig	None	1,540	368	79
			1,410	516	124
2	Rabbit	Rabbit	1,150	1,005	114
	Guinea pig	Guinea pig	1,220	370	126
	Rabbit	Rabbit	1,000	1,040	94
	Rabbit	Guinea pig	1,060	900	92

Each tube contained (in 2·15 ml.) 400 μmoles sucrose, 40 μmoles potassium chloride, 13 μmoles magnesium chloride, 50 μmoles *tris*, *p*H 7·6, 5 μmoles glutathione, 20 μmoles phosphoenolpyruvate, 1 μmole adenosine triphosphate, 0·25 μmoles GTP, 150 μgm. pyruvate kinase, 0·3 ml. of an amino-acid mixture (ref. 2) containing L-[^{14}C] valine (1 μc., 15 μgm.) and L-[^{14}C] leucine (1 μc., 24 μgm.), 7·8 mgm. of *p*H 5 enzymes and 8·8 mgm. of rabbit reticulocyte ribosomes (ref. 2). Rabbit or guinea pig reticulocyte cell sap after removal of *p*H 5 enzymes (28 mgm. and 26 mgm., respectively) was added where shown. After incubation at 37° for 1 hr., the corresponding amounts of either rabbit or guinea pig cell sap, or both, were added as carrier, the ribosomes were removed by centrifuging at 100,000*g* for 1 hr. and the hæmoglobins were separated by Pevikon block electrophoresis (cf. ref. 13), precipitated by trichloroacetic acid, washed and counted.

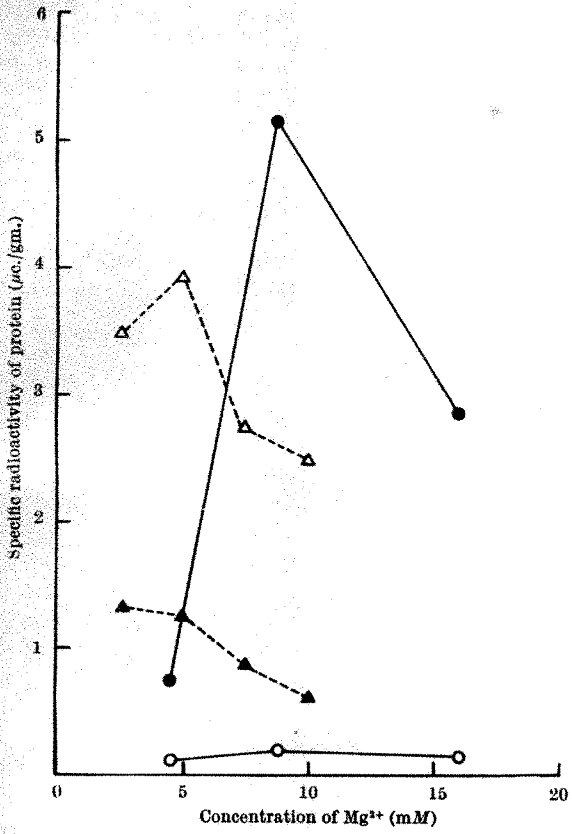

Fig. 1. Effect of magnesium on the incorporation of amino-acids by cell-free systems from rabbit reticulocytes. The cell-free preparation was similar to that of Schweet *et al.* (ref. 2). Pre-incubation and subsequent dialysis of the ribosomes (Exp. No. 2) were carried out essentially as described by Nirenberg and Matthaei (ref. 7). Exp. 1. Incorporation of L-[^{14}C]valine by fresh ribosomes. △, ribosome protein; ▲, soluble protein (hæmoglobin). Exp. 2. Incorporation of L-[^{14}C]phenylalanine by pre-incubated ribosomes into total protein. ○, in the absence of polyuridylic acid; ●, in the presence of polyuridylic acid (24 μgm./mgm. of ribosome)

suggest that the 'messenger' is already attached to the ribosomes and may be removed or inactivated either by pre-incubation or by mild treatment with ribonuclease. These treatments destroy the ability of reticulocyte ribosomes to incorporate amino-acids; but neither impairs the structural integrity of the ribosomes[15] nor leads to degradation of the ribosomal RNA, as judged by its sedimentation in the ultracentrifuge[16]. During treatment with the enzyme a relatively small proportion of ultra-violet-absorbing material is released, indicating the preferential destruction of a minor, but functionally important, component of the RNA[15]. Though this fraction may correspond to 'messenger' RNA in the bacterial system, it has not yet been possible to restore amino-acid incorporation by addition of high molecular weight RNA, which was extracted from reticulocyte ribosomes by either the phenol[17] or the guanidine[18] method. We have found, however, that rabbit reticulocyte ribosomes, like those from *E. coli*[7,9], can be induced to synthesize polyphenylalanine by the addition of polyuridylic acid (Table 2). The utilization of a mixture of 16 amino-acids labelled with carbon-14 and unlabelled phenylalanine was not affected by polyuridylic acid, demonstrating the specificity of polyuridylic acid for incorporation of phenylalanine. This result also shows that polyuridylic acid does not replace or inactivate existing 'messenger' RNA on the ribosomes since this would be expected to result in an inhibition in the incorporation of amino-acids other than phenylalanine.

Table 2. SPECIFICITY OF THE STIMULATION OF PHENYLALANINE INCORPORATION BY POLYURIDYLIC ACID

Exp. No.	Radioactive precursor	Additions	Specific radioactivity of protein (mμc./gm.)
1	Phenylalanine*	None	246
	Phenylalanine*	Polyuridylic acid (40 μgm.)	6,260
	Phenylalanine*	Polyuridylic acid (40 μgm.)	55†
2	Amino-acid mixture‡	None	1,422
	Amino-acid mixture‡	Polyuridylic acid (40 μgm.)	1,515

Ribosomes from rabbit reticulocytes were incubated (ref. 7), dialysed (ref. 7) and re-isolated by centrifuging. After suspension, they were incubated with fresh pH 5 enzymes, phosphoenolpyruvate, ATP and GTP, and either labelled phenylalanine and a mixture of unlabelled amino-acids (ref. 2) (Exp. No. 1) or unlabelled phenylalanine and a mixture of 16 labelled amino-acids (Exp. No. 2).

* 0·5 μc. of L-[^{14}C]phenylalanine.

† Phosphoenolpyruvate, ATP and GTP omitted.

‡ 0·5 μc. of each of the following ^{14}C-labelled amino-acids: L-alanine, L-arginine, L-aspartic acid, L-glutamic acid, glycine, L-histidine, L-isoleucine, L-leucine, L-lysine, L-methionine, L-proline, L-serine, L-threonine, DL-tryptophan, L-tyrosine, and L-valine.

The effect of polyuridylic acid is highly dependent on magnesium, about 0·01 *M* being the optimum concentration (Fig. 1). It is of interest that this concentration is considerably higher than that required for the maximum incorporation of valine into ribosomes and soluble protein in the absence of polynucleotide.

The effect of polyuridylic acid on polyphenylalanine synthesis was observed with freshly isolated ribosomes and with ribosomes which had been inactivated by either pre-incubation (cf. ref. 7) or mild treatment with ribonuclease[15]. Under comparable conditions, the stimulation of phenylalanine incorporation by polyuridylic acid was proportional to the incorporation of this amino-acid in the absence of polynucleotide (Fig. 2). It is concluded, therefore, that only active ribosomes can be induced to synthesize polyphenylalanine. The ratio of about 30 : 1 in incorporation of phenylalanine is consistent with the polyuridylic acid interacting to the same total length as a hæmoglobin messenger RNA.

In conclusion, our results indicate that the specificity of protein synthesis by the reticulocyte is determined by a fraction of RNA in the ribosomes. This

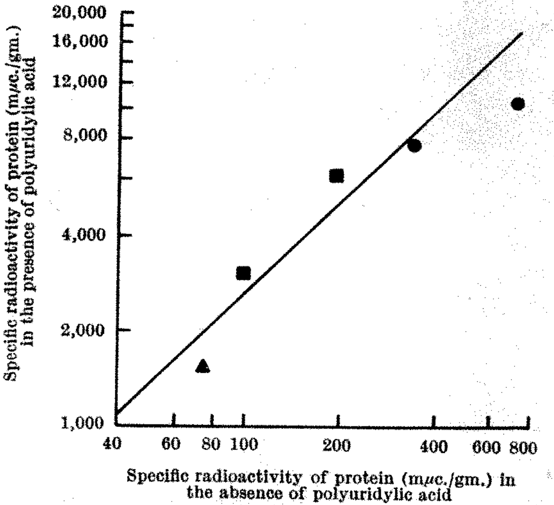

Fig. 2. Stimulation of phenylalanine incorporation by rabbit reticulocyte ribosomes in the presence of polyuridylic acid. ●, fresh ribosomes; ▲, ribosomes treated with ribonuclease (ref. 15); ■, pre-incubated ribosomes

RNA is readily destroyed by traces of ribonuclease and is not replaceable by added RNA, although we may not have achieved optimum conditions for the interaction of RNA and ribosomes. Polyuridylic acid is active as a specific 'messenger' for the biosynthesis of polyphenylalanine, but functions only in the presence of ribosomes which are active in protein synthesis. The polynucleotide and 'messenger' RNA apparently occupy different sites, both of which are equally susceptible to ribonuclease and pre-incubation, or alternatively occupy the same site consecutively.

TITRATION OF SOME COMMON COLD VIRUSES (RHINOVIRUSES) AND THEIR ANTISERA BY A PLAQUE METHOD

By Dr. J. S. PORTERFIELD

National Institute for Medical Research, Mill Hill, London, N.W.7

TYRRELL and Parsons[1] have described the conditions under which they were able to propagate in tissue culture cytopathic viruses from some persons with common colds. Certain agents multiplied in monkey kidney cell cultures and were designated *M* strains; others, known as *H* strains, failed to grow in monkey kidney cells but multiplied and produced a cytopathic effect in cultures of human embryonic kidney cells[2]. The general term 'rhinovirus' was suggested by Andrewes *et al.*[3] and has been used by workers at the Common Cold Research Unit, Salisbury, to include *M* and *H* strains which are clearly distinct from certain other viruses known to be capable of causing common colds[4]. The assay method devised by Parsons and Tyrrell[5] depended on the enumeration of small foci of degenerating cells seen when infected cultures were examined under the microscope. This approach has enabled the Salisbury group and others to examine many different rhinoviruses, but it has two major disadvantages. The first is that it is somewhat laborious involving the examination of the entire cell sheet of a number of replicate tubes for every specimen being tested. The second is that the end-point changes with time as virus released from cells infected initially enters further cells and gives rise to secondary foci. This difficulty is avoided by the use of an agar overlay, as first applied to animal viruses by Dulbecco[6], but Parsons and Tyrrell[5] were unsuccessful in their attempts to produce plaques under agar. This report describes the successful application of an agar overlay technique to rhinoviruses resulting in the development of plaques which can be counted by the naked eye and the use of this method in virus neutralization tests.

Preliminary experiments were carried out with *HGP* virus using monkey kidney cell monolayers. Some plaques were obtained, particularly in cultures overlaid with thin layers of agar, indicating that in these cells a high degree of oxygenation was necessary, as has been found with a number of other viruses[7]. Different batches of monkey kidney cells varied considerably in their sensitivity, using macroplaques as an indication of virus growth, and replicate cultures with a single batch of monkey kidney cells gave inconsistent results, there being no constant relationship between virus dose and plaque count. Attention was therefore directed to the use of cultures derived from human embryonic lung cells which were known to be capable of supporting the multiplication of certain common cold viruses[8]. Earlier difficulties over the availability of human embryonic material were overcome by the use of cells frozen in the presence of dimethyl sulphoxide[9]. The experiments described here were carried out with cultures derived from two ampoules each containing approximately 4×10^6 cells initially obtained from different embryos; both strains appeared to be equally sensitive to *HGP* virus, although most tests were carried out with one series of cultures.

The medium contained 0·25 per cent lactalbumin hydrolysate, 0·25 per cent peptone (Difco proteose peptone) and 10 per cent pre-colostral calf serum (obtained from new-born calves before suckling) in Gey's buffered salt solution containing 0·11 per cent sodium bicarbonate and 0·0025 *M tris* (hydroxymethyl)aminomethane. After thawing from the frozen state cells were diluted 1 : 10 in growth medium and distributed into 1-oz. bottles in 3-ml. volumes. These were incubated at 37° C. until a confluent cell sheet had formed; this took about ten days during which time the medium was changed twice. The growth medium was discarded, the cells were rinsed quickly with 0·25 per cent Difco trypsin, which was discarded, and the bottles were incubated without medium for 5–10 min. until the cells loosened[10]. Double the original volume of medium was added, the cells were dispersed by gentle pipetting and were then divided into equal parts in two new bottles. As the cells multiplied, stock cultures were passaged every 3–5 days using 10 ml. of medium in 4-oz. bottles. The yield of one 4-oz. bottle (20 ml.) was later divided into two 4-oz. bottles, six 1-oz. bottles or five Petri dishes. Bottles or Petri dishes for plaque tests were used when densely packed monolayers had formed; this took about five days, but commonly the medium was changed at this time and the cells were incubated for a further two or three days. Prior to infection, cells were washed once with diluent, which consisted of growth medium without calf serum, and buffered with *tris* only. Virus dilutions in this fluid were allowed to absorb for 2 hr. at 32° C. after which the cultures were rinsed once before overlaying. The overlay medium contained 0·25 per cent lactalbumin hydrolysate, 0·25 per cent peptone, 5 per cent pre-colostral calf serum in Gey's solution containing 0·11 per cent sodium bicarbonate without *tris* in bottles, or 0·0025 *M tris* without bicarbonate in Petri dishes. Noble agar was used at a final concentration of 1·5 per cent in bottles and 0·7 per cent in Petri dishes. The volume of the overlay was normally 2·5 ml. in 1-oz. bottles and 4 ml. in Petri dishes. Neutral red was added after 48 hr. incubation at 32° C. as 1·0 ml. of a 1 : 10 dilution of stock neutral red (1 : 1,000 in distilled water) in the peptone lactalbumin hydrolysate diluent.

Preliminary experiments were carried out using stock *HGP* virus in the form of monkey kidney cell culture fluid received from Dr. D. A. J. Tyrrell. Human embryo lung cells at the third passage-level were infected with serial dilutions of virus, one bottle being incubated with liquid medium while others were overlaid with agar. On the third day the liquid from one infected bottle was removed and frozen at − 70° C. for future experiments; no clear cytopathic effect was evident at this stage. By the fifth day small plaques were developing in bottles infected with undiluted and 10^{-1} dilutions of monkey kidney fluid inoculum, and by the twelfth day clearly defined plaques up to 3 mm. in diameter were present at 10^{-2} dilution of virus (Table 1).

Table 1. PLAQUES WHICH DEVELOPED IN HUMAN EMBRYO LUNG CULTURES INFECTED WITH MONKEY KIDNEY PASSAGED *HGP* VIRUS

Virus dilution	Day 5	7	12	15	21
10^{0}	??	?	confluent	confluent	lysed
10^{-1}	0	J	a50	> 50	> 50
10^{-2}	0	0	9	14	18
10^{-3}	0	0	0	2	2
Control	0	0	0	0	0

Later experiments, using the supernatant fluid from this experiment, showed that plaques were well developed at 48 hr. although they increase in size, and to some extent also in number, on further incubation (Fig. 1). When the titre of this material had been established, a neutralization test was set up as follows: to serial four-fold dilutions of a rabbit immune serum (kindly supplied by Dr. D. Taylor-Robinson) and to 1 ml. of a 1 : 50 dilution of a normal rabbit serum in 1 ml. volumes was added 1 ml. of a dilution of *HGP* estimated to contain about 200 plaque-forming units. Control tubes contained diluent mixed with the same virus dose, and with the virus diluted 1 : 4, 1 : 16 and 1 : 64. The mixtures were kept at bench temperature for 1 hr. and were then added in 1 ml. volumes to bottle cultures of human embryo lung cells. After adsorption for 2 hr., the cultures were washed twice, overlaid with agar and incubated at 32° C. Neutral red was added on the second day and plaques were counted on different days with the results given in Table 2. The virus control contained more plaques than could be counted, but on the basis of the 1 : 4 and 1 : 16 dilutions of virus, the challenge contained between 100 and 200 plaque-forming units of virus. From these results it is clear that the 50 per cent plaque neutralization titre is 1 : 3,200. The same serum gave almost complete neutralization at a dilution of 1 : 500 when examined by a generally similar technique but using microplaques as evidence of virus activity[11]. A final assessment of the sensitivities of the two methods must await more detailed comparative studies; these preliminary results indicate that the macroplaque technique is certainly not less sensitive than the microplaque method.

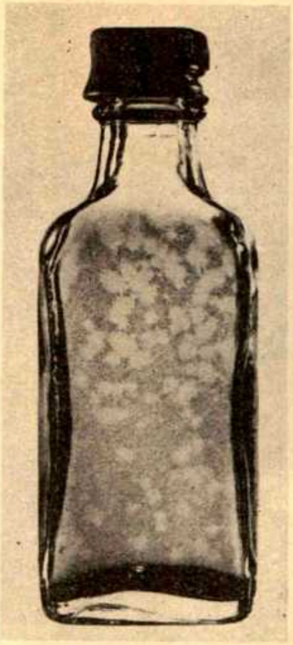

Fig. 1. Human embryonic lung fibroblasts infected with a 10^{-2} dilution of *HGP* virus. Photograph taken after six days incubation at 32° C.

Experiments were next carried out using the plaque inhibition test in which fish spine beads dipped in sera are applied to the surface of the agar covering virus-infected cells[12]. A zone of plaque inhibition 18 mm. in diameter was produced around a bead containing a 1 : 2 dilution of *HGP* immune serum. Later tests, using serial dilutions of *HGP* virus and a 1 : 5 dilution of *HGP* serum, are illustrated in Fig. 2. At a 10^{-1} dilution of virus, representing about 3,200 plaque-forming units of virus, the inhibition zone measured 16 mm. in diameter. It was slightly larger (18 mm.) with the next dilution of virus, estimated to contain 320 plaque-forming units, and the 10^{-3}

Table 2. PLAQUES DEVELOPING IN BOTTLE CULTURES OF HUMAN EMBRYONIC CELLS AFTER INCUBATION WITH MIXTURES OF *HGP* VIRUS AND HOMOLOGOUS RABBIT IMMUNE SERUM

Inoculum	Day 3	4	5	12
Virus and serum 1 : 50	0	0	0	2
Virus and serum 1 : 200	0	0	1	1

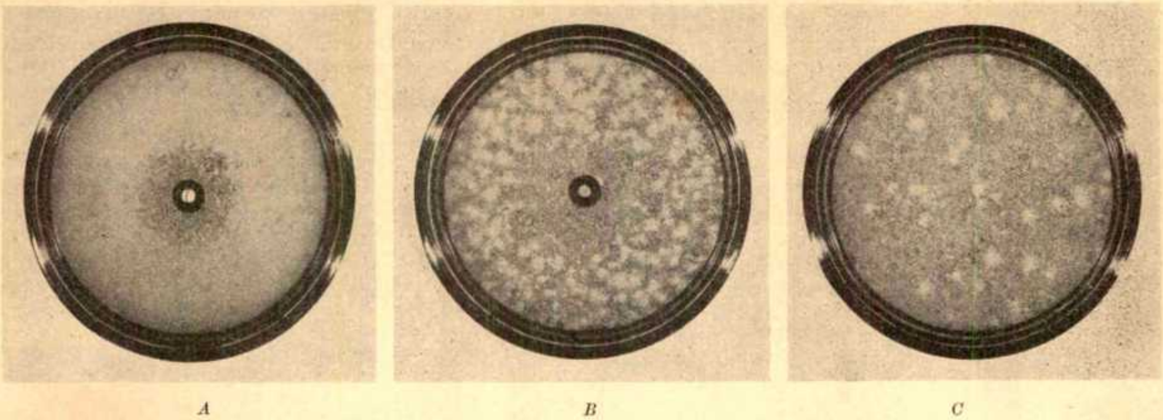

Fig. 2. The plaque inhibition test applied to *HGP* virus and homologous rabbit immune serum. *A*, virus 10^{-1} plus immune serum in central bead; *B*, virus 10^{-2} plus immune serum in central bead; *C*, virus 10^{-3}. Photographs taken after 6 days incubation at 32° C.

dilution gave 32 plaques. An immune serum prepared against another rhinovirus *B*632 gave no inhibition at 1 : 5 dilution of serum, although this material was slightly cytotoxic when used undiluted.

Less-extensive tests with two other rhinoviruses have also given positive results. An ampoule of a second *M* strain, *B*632, said by Dr. Tyrrell to contain about 1,000 microplaque-forming units per ml., produced 10 plaques in human embryo lung cultures infected with a 10^{-3} dilution of stock monkey kidney virus. These plaques were not clearly visible until the twelfth day and remained small and feathery in appearance, quite unlike the large clear plaques which developed with *HGP* virus but resembling those described by Ellem and Colter[13] produced by Mengo virus in human embryonic lung cultures. One *H* strain 'Norman', also produced small feathery plaques after an incubation period of fifteen days. Whether these strains will produce larger and clearer plaques more rapidly on further passage in human embryo lung cells is still to be determined.

The present article describes a technique for titrating the infectivity of some rhinoviruses based on the counting of macroscopically visible plaques of degenerated cells in a monolayer of human embryo lung fibroblasts covered by an agar overlay. The number of plaques bears a direct linear relationship to the dose of virus applied. Two *M* strains of rhinovirus gave plaque counts of the same order as those obtained by a microplaque technique in monkey kidney cells incubated under optimal conditions. The development of discrete plaques enables virus stocks to be purified by passage from single plaques. It also enables experiments involving infectivity titrations to be carried out with greater precision than has been possible so far. Virus plaques were inhibited by specific immune sera prepared against two different viruses before they had been passaged in human embryonic lung cells, thus excluding the possibility that a contaminating virus was responsible for the development of the plaques observed. Although the number of cells required to prepare one bottle for plaque titrations would prepare three tubes for microplaque studies, it is probable that the amount of information to be derived from the use of the former is greater.

A number of points of technique appeared to be important. It was essential to use densely packed monolayers, otherwise small areas of glass not covered by cells, or having only a very thin sheet of cells, might be mistaken for plaques. The medium described here gave better results than were obtained with Parker's solution 199 containing 10 per cent calf serum. Plaques developed when cells were overlaid with a peptone lactalbumin hydrolysate mixture without calf serum, although they were smaller than in comparable cells overlaid with the complete medium containing 5 per cent pre-colostral calf serum. Serum obtained from older calves inhibited plaque formation when incorporated in the overlay. It appeared that one passage of *HGP* virus in human embryo lung cells modified the virus so that it grew more readily in these cells than did monkey kidney stock material. This adapted virus gave approximately the same plaque count in two different human embryonic lung strains which had been preserved by freezing, the passage level in these tests varying from third to twenty-first. A third source of human embryonic lung fibroblasts was examined in secondary cultures prepared without freezing; plaques again appeared to a dilution of 10^{-3} of the stock virus, although they were less well defined than in cells which had been passaged regularly, probably because the cell sheet was more irregular.

Human embryo lung cells overlaid with agar appear to survive in bottles for two to three weeks without difficulty. In preparations containing two or three plaques only, these have increased in size to 8–12 mm. after incubation for 21 days at 32° C. In contradistinction to the first results obtained in monkey kidney cells, varying the volume of agar from 1 to 4 ml. did not decrease the plaque count; on the contrary, bottles containing the larger volume showed better survival of the cell sheets and at least as many plaques developed with 4 ml. as with 2 or 1 ml. of overlay.

The bead method of plaque inhibition has proved to be a convenient and economical method for carrying out serological typing of arthropod-borne viruses[14] and for detecting the presence of neutralizing antibodies in human sera following infection with arthropod-borne viruses[15]. The work reported here suggests that the method may have similar applications in the study of rhinoviruses.

I thank Drs. D. A. J. Tyrrell and D. Taylor-Robinson for the stocks of common cold viruses and antisera provided. The passage history of these strains was as follows: *HGP*, 6 passages in human embryo kidney followed by 12 passages in monkey kidney; *B*632, one passage in human embryo kidney followed by 6 passages in monkey kidney; 'Norman', 11 passages in human embryo kidney and one passage in human embryo lung cells.

ISOMERIC BILE PIGMENTS AS PRODUCTS OF THE *IN VITRO* FISSION OF HÆMIN

By Z. PETRYKA, D. C. NICHOLSON and PROF. C. H. GRAY

Department of Chemical Pathology, King's College Hospital Medical School, London, S.E.5

WHEN hæmoglobin is catabolized to biliverdin, the overall change is the removal of an iron atom from each of the four prosthetic hæm groups and the oxidative removal of one methene group from each of the resulting protoporphyrin IX molecules. IXα, IXβ, IXγ and IXδ bile pigments with different orders of their side chains will theoretically be formed according to whether the α, β, γ, or δ methene bridges are lost. The IXα and IXγ pigments may be differentiated by oxidation with permanganate, when they form respectively the αα′-pyrrole dicarboxylic acids (I) and (II) which can arise only from the two central pyrrole rings (Fig. 1). The other bile pigment isomers must give rise to mixtures of both these acids. The naturally occurring bile pigments have thus been shown to possess only the IXα structure[1]. No detailed examination of the bile pigments obtained in the *in vitro* oxidation of hæmin has yet been published. Lemberg[2] claimed that the dimethylester of the biliverdin formed by the coupled oxidation of protoporphyrin and ascorbic acid was wholly IXα in structure but esters of the 'green hæmins' formed by treatment of aqueous pyridine hæmochromogen with hydrazine sulphate had lower melting points than those of the natural bile pigments. Since much material remained uncrystallized in these experiments and no degradation investigations were made, Lemberg admitted that his product and mother liquors might contain other than IXα isomers. We now report evidence for the formation of such isomers under similar conditions.

In our experiments oxygen was passed through a solution of 0·5 gm. hæmin in 2 : 5 (v/v) pyridine/water at 50°–60°; 1·3 gm. hydrazine sulphate in 33 ml. 0·5 *N* sodium hydroxide was added, the temperature being maintained for about 5 min. The mixture was cooled and kept at 0° for 20 min. The aqueous pyridine hæmochromogen before oxidation absorbed maximally at 420 and 525 mμ. At the completion of oxidation a strong maximum at 650 mμ due to biliverdin had appeared. The pigment was then isolated by Engel's method[3]. Pigments were first extracted into ether, the extract showing maxima at 395 and 535 mμ with a particularly large maximum at 650 mμ. On continued washing with water these maxima changed to 380, 525 and 675 mμ, the aqueous washings acquiring maxima at 410 and 535 mμ due to the removal of residual hæmochromogen. Extraction of the ethereal solution with 5 per cent w/v hydrochloric acid caused almost complete transfer of the maximum at 675 mμ. The green pigment, now in the aqueous phase, was purified by partition five times between hydrochloric acid and ether, neutralizing the acid on each occasion with sodium acetate until the ratio of absorption 380 and 675 mμ in the ethereal solution became constant at 2·2. The ether solution then had the spectrum of pure biliverdin (Fig. 2) with no indication of the presence of porphyrin or of hæmin.

36 mgm. of porphyrin-free biliverdin from six such preparations was oxidized with alkaline permanganate and the resulting pyrrole dicarboxylic acids were analysed chromatographically by the method of Nicolaus[4]. Authentic acids (I) and (II) were used as chromatographic markers. Corresponding spots were obtained in all experiments and when these acids were included in the experimental chromatographic solutions they failed to produce duplet spots. The results are summarized in Table 1.

The formation of the acids (I) and (II) on permanganate oxidation of the biliverdin fraction

* Minor quantities of other, unidentified products were also present.

indicates that it contains not only IXα isomers but also other isomers. Thus the *in vitro* fission of the protoporphyrin of the hæmin under the conditions described must involve the loss of methene bridges other than that at the α position. During hæm catabolism the exclusive rupture of the protoporphyrin ring at the α methene bridge has been attributed to the electron density at that position being slightly higher than at other similar groups in the molecule[5]. The differences in electronegativities of the four bridge methene groups of protoporphyrin is small, however, and our present results suggest this is not the only factor responsible for the exclusive α fission which occurs under physiological conditions. The recently isolated enzyme catalysing the natural fission of protoporphyrin IX (ref. 6) may be more important and may specifically activate the α methene bridge.

We thank Dr. Aleksandra Kulczycka for a gift of samples of 3-methyl-4-carboxyethylpyrrole-2 : 5-dicarboxylic acid and 3-methylpyrrole-2 : 4 : 5-tricarboxylic acid.

EFFECT OF ENZYMES ON BLOOD GROUP ANTIGENS

By DR. M. YOKOYAMA and DR. E. G. TRAMS

National Institute of Neurological Diseases and Blindness, National Institutes of Health, Bethesda, Maryland

IN 1946, Pickles[1] reported that treatment of Rho(D) erythrocytes with a cholera culture filtrate, presumably containing various enzymes, induced agglutination by an incomplete type of anti-D antibody in saline. Since then, it has been reported that treatment with a number of enzymes, such as trypsin[2], papain[3], ficin[4] and bromelin[5], markedly increased erythrocyte agglutinability. These observations apparently were not due to an enhanced non-specific agglutinability of erythrocytes against the corresponding antibody often observed following prolonged incubation, and it has been suggested that an alteration of the blood group substances had occurred.

Recently, Hackel *et al.*[6,7] reported that the hæmagglutination with anti-Rh and anti-Lutheran sera was specifically inhibited by a number of ribonucleic acid derivatives such as cytidine sulphate, adenylic acid, uridylic acid and cytidylic acid. These authors suggested that the Rh and Lutheran antigens contained nucleotide moieties as part of their antigenic structure. In another communication, Hackel *et al.*[8] then described the effects of ribonuclease on the Rh and Lutheran antigens of human erythrocytes. They reported that the agglutinability of the enzyme-treated erythrocytes had decreased considerably when compared with the untreated controls. Mäkelä *et al.*[9] reported that trypsin destroyed M and N antigens and released *N*-acetylneuraminic acid (NANA) and hexosamine from the erythrocytes. They further stated that both the M and the N antigens were also destroyed by neuraminidase. A specific inhibition of anti-Rho(D) by the addition of *N*-acetylneuraminic acid and *N*-glycolylneuraminic acid to their test system was reported by Dodd *et al.*[10] and by Johnson *et al.*[11].

Some of the experiments already mentioned were repeated in this laboratory, and we would like to report our observations on the effects of trypsin, ribonuclease, neuraminidase, cellulase, hyaluronidase and lysozyme on the ABO, MN and Rh antigens of human erythrocytes.

Anti-A and anti-B sera were obtained from normal individuals of group B and group A, anti-M (human and rabbit) and anti-N sera (rabbit) from the Ortho Research Foundation, and both complete and incomplete types of anti-Rho(D) sera were given to us by the Ortho Research Foundation and Knickerbocker Biologicals, Inc.

Blood was obtained from normal individuals and was used immediately and also after 4 days storage at 5° C. Samples of blood were centrifuged and the erythrocytes washed 3 times with 20 volumes of 0·15 M sodium chloride solution. An aliquot of 1·0 ml. of washed, packed erythrocytes was then added to the following mixtures of 0·2 ml. each: (1) trypsin (Fisher Scientific Co.), 10 mgm. per ml.

Table 1. TITRATION SCORE OF TREATED ERYTHROCYTES WITH ENZYMES

Antiserum	Titration score: Original	Treated with trypsin	Un-treated control	Enzyme concentration (mgm./ml.)	Time for treatment
Anti-A (IHS)	55	78	52	10	4 hr.
		102	50		24 hr.
Anti-B (IHS)	32	64	30	10	4 hr.
		96	28		24 hr.
Anti-M (IHS)	36	0	36	10	1 hr.
		0	33		4 hr.
		0	16		24 hr.
Anti-N (IRS)	19	19	18	10	1 hr.
		24	16		4 hr.
		26	15		24 hr.
Anti-D* (IHS)	21	22	20	10	1 hr.
		23	17		4 hr.
		23	13		24 hr.

Antiserum	Original	Treated with neuraminidase	Un-treated control	Enzyme concentration (units/ml.)	Time for treatment
Anti-A (IHS)	65	64	65	100	30 min.
		62	62		3 hr.
		59	60		6 hr.
		55	57		24 hr.
Anti-B (NHS)	34	35	36	100	30 min.
		33	33		3 hr.
		30	31		6 hr.
		27	28		24 hr.

		20	20		4 hr.
		18	21		24 hr.
Anti-D* (IHS)	33	30	29	100	30 min.
		25	25		3 hr.
		21	21		6 hr.
		18	19		24 hr.

IHS, immune human serum; IRS, immune rabbit serum; NHS, normal human serum.

* Complete antibody which may contain a trace of incomplete antibody.

of 0·1 M phosphate buffer pH 7·7; (2) ribonuclease (Mann Research Laboratories), 4 or 10 mgm. per ml. of 0·1 M phosphate buffer pH 7·5; (3) cellulase (Worthington Biochemical Corp.), 10 mgm. per ml. of 0·1 M phosphate buffer pH 5·6; (4) hyaluronidase (Worthington Biochemical Corp.), 10 mgm. per ml. of 0·1 M phosphate buffer, pH 6·8; (5) lysozyme, 10 mgm. per ml. of 0·1 M phosphate buffer pH 6·5; (6) 0·35 ml. of neuraminidase solution (Behringwerke Marburg-Lahn), 100 units per ml., adjusted to pH 6·0.

All mixtures were made isotonic by the addition of the required amounts of sodium chloride solution. The mixtures were incubated at 37° C. for periods of 30 min.–24 hr. At the end of the incubation period the erythrocytes were washed with saline at 0° C. and a 2 per cent suspension of erythrocytes in saline was prepared. The control samples were prepared by incubation of the erythrocytes with the corresponding buffers.

Erythrocyte suspensions in saline were added to two-fold serial dilutions of anti-sera. For the determination of erythrocyte agglutinability against the incomplete Rh antibody, a 20 per cent bovine albumin solution was substituted for saline. Agglutination titres for A, B, M and N antigens were determined after incubation at 25° C. for 1 hr. Agglutination titres for Rho(D) antigen were read following incubation at 37° C. The agglutinability of erythrocytes was scored on the modified scale of Dunsford and Bowley[12] following centrifugation at $200g$ for 1 min.

The score for the agglutinability of A and B antigens against anti-A and anti-B sera, so-called naturally occurring agglutinins of the complete type of antibody, was not significantly altered by any treatment. As shown in Table 1, the titres of the immune human anti-A and anti-B sera were enhanced by the use of trypsin-treated erythrocytes. The agglutinability of M antigen, however, decreased rapidly after treatment, as compared with the controls. N antigen, in contrast, increased slightly by treatment with this enzyme. Ribonuclease did not affect either the M or the N antigen. With neuraminidase, a gradual decrease of the agglutinability against the M antigen was observed. A similar effect of neuraminidase on the N antigen was not detected.

Following the treatment of erythrocytes with trypsin for more than 1 hr., the non-specific agglutination with anti-Rho(D) sera containing an incomplete type of antibody was observed. This phenomenon was not detected with the complete type of anti-Rho(D) antibody. Erythrocytes treated with ribonuclease, neuraminidase, cellulase, hyaluronidase and lysozyme showed lower agglutinability against anti-Rho(D) sera after prolonged incubation. The score for treated erythrocytes was similar to that obtained for erythrocytes incubated in the absence of enzymes.

The amount of neuraminic acid released after incubation with various enzymes was determined by the method of Warren[13]. Following incubation with neuraminidase for 3 and 6 hr. respectively, between 0·348 and 0·381 μM of *N*-acetylneuraminic acid were released from a sample of 1·0 ml. of packed erythrocytes. Both Rho(D) positive and negative erythrocytes released similar amounts of neuraminic acid when incubated with this enzyme. Release of neuraminic acid after treatment with trypsin, ribonuclease, cellulase, hyaluronidase and lysozyme was not observed. Incubation of erythrocytes with neuraminidase for periods up to 24 hr. failed to affect the agglutinability against anti-Rho(D) sera.

Trypsin affected only the M antigen as demonstrated in the presence of both immune human and rabbit anti-M sera. Rosenfield *et al.*[14] obtained similar results with human anti-M serum. They also observed the non-specific agglutination similar to '*T*' agglutination (Huebener-Thomsen phenomena[15]) by using rabbit anti-M and anti-N sera. Our observations contrast with the findings of Mäkelä *et al.*[9] who reported that both M and N activity were destroyed by trypsin. On the other hand, erythrocytes treated with trypsin showed a slight increase in titre in the case of immune rabbit anti-N. It is suggested that different preparations of trypsin and the particular samples of anti-serum used may affect the results of such studies. The activity observed with neuraminidase appeared to be specific for the M antigen.

MITOSIS-STIMULATING PROPERTIES OF EMBRYONIC NUCLEO-PROTEIN CONSTITUENTS IN CELL CULTURE

By Dr. ROMAN J. KUTSKY and Dr. THOMAS V. FEICHTMEIR*

Veterans Administration Hospital, San Francisco, California

As previously reported, factors of high molecular weight found in chick embryo extracts (EE_{50}) stimulate growth of tissues in culture[1]. These factors have been segregated in a nucleo-protein fraction[2] and recently isolated in the protein moiety[3] of the nucleo-protein fraction, which contained most of the biological activity originally present in the parent embryo extract.

These embryonic factors were previously assayed by plasma clot culture methods[1] using increase in area of a tissue explant as an index of growth. This measure does not discriminate between the more basic growth parameters of cell size, cell number (mitotic stimulation), cell migration or extracellular deposition, all of which could be involved in tissue growth.

To determine if mitotic stimulation was involved, it was necessary to assay the effects of the embryonic fractions using quantitative cell enumeration techniques, following a direct (primary) culture of dispersed cells from the host animal. Previous experiments in another laboratory, using second-generation cell cultures, showed adult tissue nucleo-protein fraction and protein moiety to be active, but were inconclusive for embryonic fractions[4,5].

A more direct method for primary cell culture and quantitative cell enumeration was developed as described here, and comparisons were made of biological effects of the parent embryonic extract, embryo nucleo-protein fraction, embryo protein moiety and background medium.

All procedures are performed under sterile conditions in this method. Trypsin (Nutritional Biochemicals) and chicken serum (Microbiological Associates) solutions are made in Puck's saline[6]. Twelve- to fourteen-day chick embryo thighs are removed into 1 per cent chicken serum. Bone and skin are removed and the muscle tissue is transferred into a 12 ml. centrifuge cone. 2·2 ml. of 0·1 per cent trypsin per ml. of tissue are added. After incubating for 15 min. at 37° C. on a platform rotating at 70 r.p.m., most of the muscle cells will have settled. The supernatant containing some muscle cells, debris and red blood cells is aspirated off. An equal volume of fresh trypsin is added to the residue, which is incubated as before for 30 min.

The trypsinization is stopped by adding an equal volume of 5 per cent chicken serum. The cells are collected by centrifuging for 9 min. at 600 r.p.m. and the supernatant is discarded. The cells are re-suspended by gentle tapping in 5 ml. of fresh 5 per cent chicken serum and poured through a double layer of sterile gauze. An extra 5 ml. of fresh 5 per cent chicken serum is used for rinsing the tube and gauze and combined with the suspension. Hæmocytometer counts on the suspension from 2 ml. original tissue average between 1–5 million/ml. Aliquots are diluted to 75,000–100,000 cells/ml. using the basal nutrient medium. In this medium, penicillin–streptomycin–glucose contains 10 mgm. phenol red, 75 mgm. dihydrostreptomycin (Pfizer), 90 mgm. sodium penicillin (Merck) and 0·12 gm. glucose in 50 ml. of Earle's solution. $EE_{50}UC$ is 13-day chick embryo extract (EE_{50}) clarified by spinning for 1 hr. at 105,000*g*, and sterilized using ultra-fine filters. The composition by volume of the basal nutrient medium is: 80 per cent medium No. 199 (Microbiological Associates), 10 per cent penicillin–streptomycin–glucose, 1 per cent fœtal calf serum (Microbiological Associates) and 9 per cent Earle's solution in which growth factors ($EE_{50}UC$, nucleo-protein fraction[2], protein moiety[3]) are incorporated, on a dry weight basis.

Culture series are set up in *D*-3, 5 Carrel flasks, allowing several flasks for each count. A saline (basal medium) and an ultracentrifuged embryo extract ($EE_{50}UC$) control are incorporated in each experiment. 2 ml. of cell suspension in nutrient medium are added to each flask. Cultures are then gassed with 5 per cent carbon dioxide in air to a phenol red colour change at *p*H 7·6, closed with silicone rubber stoppers, and incubated at 37° C. The cells settle out and soon become attached to the glass surface, growing first as a monolayer culture, later becoming multi-layered.

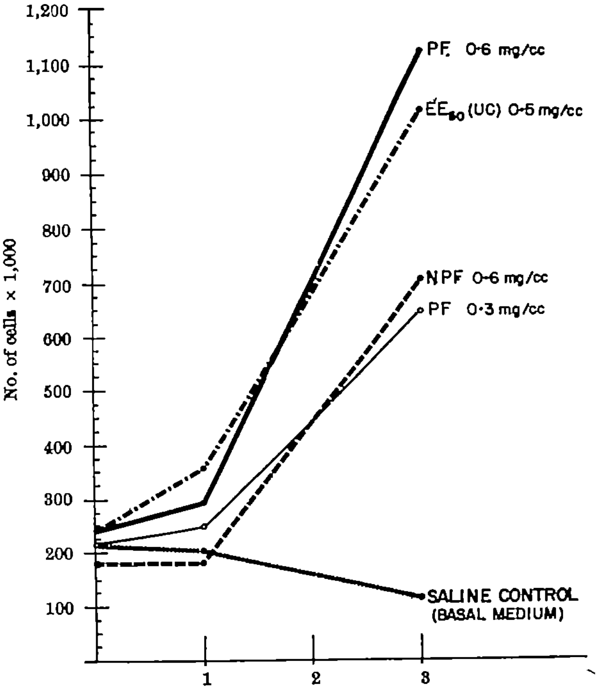

Fig. 1. Typical response of chick myoblast cells in first-generation glass substrate cultures
PF, protein moiety; *NPF*, nucleo-protein fraction; $EE_{50}(UC)$, 13-day chick embryo extract (EE_{50})

---

* Present address: San Francisco General Hospital.

At 24 hr. after inoculation and on succeeding alternate days, the cultures are given a 50 per cent medium change and gassed as above. Contents of three flasks are pooled and 4–8 aliquots are counted in a hæmocytometer. Three representative flasks per series are saved to be pooled for each cell count and their supernatants discarded. Each flask is rinsed with 1 ml. of Puck's saline A[6], which is also discarded. Using a capillary pipette, the cells in each flask are gently dispersed in 1 ml. of 0·1–1·0 per cent trypsin.

A typical experiment (Fig. 1) shows that: (1) the basal medium controls exhibit a third-day drop (or a static population, seen in other series); (2) all supplemented series increase rapidly during the first three days, with as much as a five-fold increase; (3) the nucleo-protein fraction is not as stimulating as the protein moiety on a dry-weight basis; (4) the protein moiety is almost as stimulating as $EE_{50}UC$ on a dry-weight basis; (5) the cell population response is proportional to the dose of material tested, within a certain range of concentration. For $EE_{50}UC$ a maximum response is obtained at the 4 per cent level.

It is noted that embryo extract (EE_{50}) prepared by low-speed centrifugation is very weakly and irregularly stimulating. After ultracentrifuging, the clear mid-fraction ($EE_{50}UC$) is uniformly very stimulating. Evidently the cell particulates or the lipids, which are both removed, interfere with the cell-growth response in this system.

In all cases the cells remain small and display a uniform non-granular spindled appearance typical of chick skeletal muscle fibroblasts in glass monolayer cultures. Extracellular fibre formation is usually noted in supplemented series with high populations.

It should be noted that this method uses tissues directly from the animal in contradistinction to the usual type of culture using established cell lines. The primary type of culture used in this experiment eliminates intervening mutational and adaptational effects arising during preconditioning of cultures, and makes interpretation of results in culture more applicable to events in the original host tissue in the animal. These effects may explain why the earlier experiments with the second generation cultures were inconclusive for embryonic fractions, for example, adapted cells may have lost their capacity to respond to the protein moiety.

These results indicate that there is a definite mitotic stimulation by the protein moiety and it is proportional to the dose of material. It is interesting to note that on a dry-weight basis, the ultracentrifuged EE_{50} is almost as active as its daughter product, the protein moiety. This may be due to progressive inactivation without denaturative precipitation during the long isolation procedures of the protein moiety. This could result in a large percentage of biologically inactive material in the final product which is still soluble and chemically indistinguishable from the active product.

With regard to growth mechanisms involved in the action of embryonic protein moiety, it is now possible to state that an increase in cell size does not seem to be involved in the growth response to the protein moiety, but an increase in cell number (mitotic stimulation) and extracellular deposition, that is, fibre formation, are directly involved. Cell migration may be involved, but more experiments are necessary to determine this.

Future experiments on the determination of the specific chemical groups involved in the biological activity of the protein moiety are planned. These may throw further light on the mechanism of inactivation during processing as well as the chemical basis of growth stimulation.

CARBOHYDRATE–PEPTIDE LINKAGES IN GLYCOPROTEINS AND METHODS FOR THEIR ELUCIDATION

By DR. A. GOTTSCHALK, W. H. MURPHY and E. R. B. GRAHAM

Department of Microbiology, John Curtin School of Medical Research,
Australian National University, Canberra

CARBOHYDRATE–PROTEIN complexes with chitin, hyaluronic acid, chondroitin-sulphates and similar polysaccharides as sugar moieties have been known for a long time. In these complexes the carbohydrate is characterized by a small repeating unit and a high degree of polymerization. A more recent development is the realization that a great number of proteins, classified as 'glycoproteins', have attached to them a carbohydrate with a relatively low degree of polymerization and so far with no indication of a short unit repeating itself. Ten years ago the concept was advanced[1] that glycoproteins are best visualized as conjugated proteins consisting of a polypeptide chain (core) to which relatively small polysaccharides are attached as prosthetic groups. The carbohydrate groups of the various glycoproteins differ widely in molecular weight, being, for example, 512 in ovine submaxillary gland glycoprotein and about 3,500 in human γ-globulin. They consist invariably of two or more different sugar residues; most of them contain hexosamine, and many possess a terminal sialic acid unit. The term 'heterosaccharide' may conveniently describe this wide range of carbohydrate structures since it does not prejudice the size. The number of heterosaccharide residues per glycoprotein molecule may be as low as one, as in ovalbumin (mol. wt. 45,000) and human γ-globulin (mol. wt. 160,000) or as high as 800 in ovine submaxillary glycoprotein (mol. wt. 1×10^6).

Concerning the carbohydrate–peptide linkage in glycoproteins, the available evidence indicates that a covalent bond joins the heterosaccharide to the polypeptide chain. For a complete understanding of this linkage the following information is required: (1) the composition of the heterosaccharide; (2) the nature of the amino-acid residue acting as 'acceptor' for the heterosaccharide; (3) the functional groups of the heterosaccharide and amino-acid residues respectively involved in the linkage. The first approach to the characterization of such linkages was the preparation of short glycopeptides by enzymatic fragmentation of glycoproteins. Thus, Rosevear and Smith[2] isolated from the papain digest of γ-globulin three glycopeptides by a procedure involving ion exchange resin, ethanol precipitation and starch column electrophoresis. The glycopeptides differing in length had the common sequence Asp. Tyr. Glu. Asp. (carbohydrate), the carbohydrate containing 3 galactose, 5 mannose, 2 fucose, 8 glucosamine and 1 sialic acid residues. After exhaustive treatment of the glycopeptides with aminopeptidase and carboxypeptidase a fraction was obtained which on hydrolysis with 6 *N* hydrochloric acid yielded only aspartic acid and glucosamine, thus establishing aspartic acid as the acceptor. Johansen, Marshall and Neuberger[3] digested crystalline ovalbumin with various proteolytic enzymes in succession and submitted the digest to column chromatography and column electrophoresis. The glycopeptide Asp(carbohydrate).(Leu, Ser, Thr).Val was thus obtained. The carbohydrate consisted of 5 mannose and 3 *N*-acetylglucosamine residues Nuenke and Cunningham[4] reported very similar results with regard to the composition of a glycopeptide isolated by them from ovalbumin by similar procedures; however, even the best preparations could be fractionated further by countercurrent distribution. The sequence analysis by these authors was nearly coincident with that given by Johansen *et al.* Both groups succeeded in removing from the non-reducing glycopeptide by carboxypeptidase all amino-acids but aspartic acid, to which the carbohydrate remained attached. This achievement proved linkage of the carbohydrate to aspartic acid. The authors also concurred in the observations that the amino-group of aspartic acid was non-substituted and that on mild acid treatment 1 mole ammonia/mole glycopeptide was liberated. Hydroxylamine failed to separate the carbohydrate from the peptide. From these data an aspartylglycosylamine structure (that is, an *N*-glycoside involving the amide group of asparagine), analogous to glycinamide ribotide (*N*-glycyl-5′-phosphoribosylamine)[5], was tentatively proposed.

Over the past years, our laboratory has made a detailed study of the composition and structure of ovine submaxillary gland glycoprotein (OSM). In this glycoprotein a carbohydrate–peptide linkage different from that present in ovalbumin was discovered. Application of chemical reagents acting preferentially on this linkage rendered it possible to define with precision the nature and position of the functional groups of the sugar and amino-acid residues involved in the linkage, without the laborious preparation, purification and sequence analysis of glycopeptides.

OSM is a macromolecule of about 1 × 10⁶ particle weight. In aqueous solution the particle most probably has a random coil configuration[6]. The substance is composed of about 41 per cent carbohydrate and 59 per cent protein. The carbohydrate consists nearly exclusively of equimolar amounts of *N*-acetylneuraminic acid and *N*-acetylgalactosamine. These components are present as the disaccharide α-D-*N*-acetylneuraminyl (2 → 6) *N*-acetylgalactosamine[7]; about 800 of such prosthetic groups are distributed along the polypeptide chain[8]. 85 per cent of the terminal *N*-acetylneuraminic acid residues can be split off by *Vibrio cholerae* neuraminidase, an enzyme acting specifically on the ketosidic linkage joining a terminal sialic acid unit to an adjacent galactose or galactosamine residue[9].

For the elucidation of the type(s) of linkage joining the prosthetic groups to the polypeptide chain three independent approaches were made:

(1) OSM (4 mgm./ml.) was heated in excess 0·2 *N* sodium hydroxide at 100°. After 5 min. only 8 per cent of the total prosthetic groups were found to be still bound to the polypeptide chain. The separation of the released prosthetic groups, identified chromatographically, was effected on 'Sephadex *G* 25' columns. Assuming pseudo-monomolecular reaction mechanism, $k = 4{\cdot}9 \times 10^{-1}$ min.$^{-1}$, that is, in 0·2 *N* sodium hydroxide at 100°, 50 per cent of the disaccharide residues were released in 1 min. 25 sec.

(2) OSM (0·7 mgm./ml.) was dissolved in excess *M* hydroxylamine at *p*H 12·2 and 37° and the *p*H kept constant as measured by type *B* glass-electrode (Titrator Type *TTT* 1*b*; Radiometer Inc., Copenhagen). The first-order rate constant of decrease of protein-bound prosthetic groups was $k = 2{\cdot}3 \times 10^{-3}$ min.$^{-1}$. The action of alkali (*p*H 12·2) on its own, determined in a control experiment without hydroxylamine, gave a first-order rate constant $k_{\mathrm{OH}^-} = 0{\cdot}6 \times 10^{-3}$ min.$^{-1}$. Since it is known that the presence of a negative charge in the vicinity of a hydroxylamine-susceptible bond decreases the rate of the hydroxylamine reaction[10], in another set of experiments 97 per cent of the *N*-acetylneuraminic acid residues of OSM were split off prior to the hydroxylamine treatment. Under these conditions the respective values for k and k_{OH^-} were found to be 7×10^{-3} min.$^{-1}$ and $1{\cdot}8 \times 10^{-5}$ min.$^{-1}$. In each case the release of the prosthetic groups by hydroxylamine was accompanied by the formation of hydroxamic acids, as shown by the absorption spectrum of their ferric complexes.

(3) OSM (1·7 mgm./ml.) was refluxed in excess 0·3 *M* $\mathrm{LiBH_4}$ in tetrahydrofuran for 10 hr. At the end of the reaction the boron-intermediate complex formed was decomposed according to equation (1):

$$2\,R{\cdot}\mathrm{CO{\cdot}O}{\cdot}R' + \mathrm{LiBH_4} \rightarrow \mathrm{Li^+}\,[(R{\cdot}\mathrm{CH_2O})_2\mathrm{B}(\mathrm{O}{\cdot}R')_2]^- \xrightarrow[3\,\mathrm{CH_3OH}]{\mathrm{HCl}} 2\,R{\cdot}\mathrm{CH_2OH} + 2\,R'\mathrm{OH} + \mathrm{LiCl} + \mathrm{B(OCH_3)_3} \qquad (1)$$

Analysis of the reaction products showed that 88 per cent of the dicarboxylic acids, corresponding to 80 per cent of the prosthetic groups, were reduced (amides and free carboxyl groups are not acted on under the same conditions). The prosthetic groups released by this treatment had their reducing groups intact[11]. In the case of bovine submaxillary gland glycoprotein (BSM), which closely resembles OSM in composition and structure, 83 per cent of the total dicarboxylic acids, corresponding to 81 per cent of the prosthetic groups (α-D-sialyl (2 → 6) *N*-acetylgalactosamine[12]), were reduced by $\mathrm{LiBH_4}$. The reduced dicarboxylic acids were identified as α-amino-γ-hydroxy-*n*-butyric acid (homoserine) and α-amino-δ-hydroxy-*n*-valeric acid. Again the released disaccharides were reducing[13].

There can be little doubt that in our OSM preparation either all or nearly all prosthetic groups are identical in composition and structure. Whether the 0·85 per cent non-amino sugars (galactose, mannose and fucose) are an intrinsic component of the molecule or a contaminant[7], is difficult to decide. However, recent investigations by Tsuiki *et al.*[14] would suggest that in BSM, in addition to the aforementioned disaccharides, an oligosaccharide composed of glucosamine, galactose and fucose is a minor component of the molecule rather than a contaminant. Again, whereas in OSM the sialic acid is nearly exclusively N-acetylneuraminic acid, in BSM a mixture of various N- and O-acylated neuraminic acids is present[15].

The susceptibility of most of the disaccharide–peptide linkages in OSM to mild alkali, hydroxylamine and lithium borohydride seems to prove this linkage to be of the ester type. The recovery of the disaccharides, liberated from the boron-intermediate complex, with their reducing groups intact, would indicate that this group is engaged in the ester linkage (see equation (1)). This is also borne out by the observation that OSM and BSM do not react with Benedict's reagent or o-dinitrobenzene in weak alkali, when heated shortly. The linkage is, therefore, of the glycosidic–ester type. The configuration of the anomeric carbon atom engaged in this linkage is unknown.

Sensitivity to very mild alkaline conditions seems to be characteristic for glycosidic-ester linkages. Recently, Zenk[16] reported that 1-(indolyl-3-acetyl)-β-D-glucose, isolated from the leaves of *Colchicum neapolitanum* Ten., was saponified at room temperature by both N potassium hydroxide and ammonia. Another ester linkage between carbohydrate and peptide, susceptible to mild alkali (N barium hydroxide, 100°, 1 hr.), was found in barley albumin. From the trypsin digest of a formic acid hydrolysate of this glycoprotein the reducing and ninhydrin-positive compound 4-L-alanyl-D-xylopyranose was isolated[17]. On the other hand, it is known that an N-glycosidic linkage to the amide-group of asparagine reacts very slowly with 0·2 N sodium hydroxide at 100° ($k = 5{\cdot}5 \times 10^{-3}$ min.$^{-1}$)[18].

In contrast to the general building plan of glycoproteins of animal origin, one basal component of the rigid structure of the cell wall of Gram-positive bacteria is a polymer backbone of alternating residues of N-acetylglucosamine and N-acetylmuramic acid to which small peptides are attached. Here, the linkage between carbohydrate and peptide seems to be invariably an amide link between the carboxyl group of muramic acid and the amino group of the terminal L-alanyl unit[19]. In the crystalline glycoprotein taka-amylase an O-glycosidic linkage to serine seems to be established. Tsugita and Akabori[20] prepared from this glycoprotein, by treatment with *Streptomyces* protease, a glycopeptide which had as N-terminal a serine residue and which on shortening with carboxypeptidase yielded a serine–carbohydrate complex.

For the investigation of glycosidic-ester linkages between carbohydrate and protein the procedures described in this article offer a simple and rational approach. It is to be hoped that future research will add to the available tools for linkage determination, specific enzymes such as the *Streptomyces* amidase[19] which cleaves in bacterial glycopeptides the amide link between muramic acid and L-alanine.

Throughout the animate world Nature adheres strictly to the glycosidic type of linkage when joining sugar to sugar, and to the amide type of juncture when adding amino-acid to amino-acid. Yet, in the attachment of carbohydrate to peptide almost any of the functional groups of the latter may be involved, resulting in a variety of modes of linkage.

One of us (A. G.) is recipient of a personal grant from the National Health and Medical Research Council of Australia. This investigation was supported in part by a grant (RG-8713) from the National Institutes of Health, U.S. Public Health Service.

DIFFUSION STUDIES OF BOVINE SERUM ALBUMIN WITH JAMIN INTERFERENCE OPTICS AND MICRO-DIFFUSION CELL

By AMALA CHATTERJEE

Saha Institute of Nuclear Physics, Calcutta

ALTHOUGH there has been a number of reports on the diffusion studies of bovine serum albumin using different physico-chemical conditions, most of them were carried out with the help of Rayleigh or Gouy interference optics. A general account of these works has been given by Gosting[1] and more recently by Thomson and Svensson[2]. The present article gives the results of diffusion investigations on bovine serum albumin, carried out with the Jamin interference technique and a micro-diffusion cell provided in the Antweiler[3] micro-electrophoresis diffusion equipment.

With this method, different points along the height of a Tiselius type of micro-diffusion cell can be scanned in steps of 0·1 mm. The refractive increment Δn or the corresponding concentration difference Δc compared to a reference channel is obtained directly as a function of X. This leads to a curve given by the well-known diffusion equation:

$$C_x = \frac{C_0}{2}\left[1 - \frac{2}{\sqrt{\pi}}\int_0^{x/\sqrt{4Dt}} \exp(-x^2/4Dt)\,\mathrm{d}(x/\sqrt{4Dt})\right] \quad (1)$$

where C_x is the concentration at a distance x from the place where the boundary is formed at an instant $t = 0$. Equation (1) may be written as:

$$\frac{C_x}{C_0} = \frac{1}{2}\int_{x/\sqrt{4Dt}}^{\infty} \frac{2}{\sqrt{\pi}} \exp(-x^2/4Dt)\, d(x/\sqrt{4Dt}) \quad (2)$$

Since the values of the probability integral $\frac{2}{\sqrt{\pi}}\int_{hx}^{\infty} \exp(-h^2x^2)\, d(hx)$ are tabulated in standard texts for different hx, one can easily prepare a table relating $x/\sqrt{4Dt}$ with any measured value of C_x/C_0. This relation may be represented by:

$$D = \frac{x^2}{t} \cdot g(C_x/C_0) \quad (3)$$

With the help of such a previously prepared table the diffusion coefficient D may be obtained from the measured values of C_x/C_0, x and t.

Often it is more practical to have the diffusion not between the concentrations C_0 and 0 but between two protein solutions of concentrations C_0 and C_v. In this case equation (3) becomes:

$$D = \frac{x^2}{t} \cdot g\left(\frac{C_x - C_v}{C_0 - C_v}\right) \quad (4)$$

With the help of the foregoing method the diffusion coefficient of crystalline bovine plasma albumin, fraction V, obtained from L. Light and Co., Ltd., Colnbrook, England, has been measured. For this purpose the protein was dissolved in a buffer (0·18 *M* sodium chloride + 0·02 *M* sodium acetate + 0·02 *M* acetic acid) of *p*H 4·55 and ionic strength 0·2. At a time t after layering of the two solutions the whole cell, covering a length of 4 cm., was scanned with light in steps of 0·2 mm. From the dial reading the fraction C_x/C_0 or $\frac{C_x - C_v}{C_0 - C_v}$ could be obtained directly and plotted against x. A preliminary diffusion experiment carried out with 0·5 per cent solution of bovine serum albumin in distilled water, diffusing against distilled water, revealed a marked asymmetry in the final curve given by equation (1).

Afterwards, all the experiments were performed by allowing the protein solution in the above buffer to diffuse against the same protein solution of lower concentration, the difference in concentration being always the same and equal to 2×10^{-3} gm./c.c. Fig. 1 shows a set of curves obtained in this way at different times within 2–5 hr. after the layering of the solutions. From each curve one gets for different values of x a set of D values. The mean of these values of D is taken as the diffusion coefficient for that time-interval. In order to take into account the time-interval involved during the layering process, the values of diffusion coefficient D obtained for different times were plotted against $1/t$ and extrapolated to $t = 0$. This gave the diffusion coefficient D_T at the mean concentration $\bar{C} = (C_0 + C_v)/2$.

The experiments were carried out at temperature T close to 25° C. and the observed diffusion coefficients D_T were referred to 25° C. by the relation $D_{25} = 298.\frac{D_T\eta_T}{\eta_{25}T}$, where η_{25} and η_T are the viscosity coefficients of the solvent at 25° C. and T respectively.

Diffusion coefficients were measured at several mean protein concentrations. Concentrations were measured generally by the dry-weight method and checked by the ultra-violet extinction value[4] ($E^{1\%}_{1\,\text{cm.}} = 6\cdot67$ at 279 mμ). When $1/D_{25}$ was plotted against $\bar{C}$, a straight line was found to fit best the experimental points (Fig. 2). The following relation between $1/D^0_{25}$ and C was deduced from the experimental curve, $1/D^0_{25} = 4 \times 10^5\, C + 1\cdot62 \times 10^6$. This is consistent with the theoretical observation of Fujita[5] and Philip[6] that $D = (mc + a)^{-1}$ was one of the solutions of the equation $\frac{\partial c}{\partial t} = \frac{\partial}{\partial x}\left[D(c)\frac{\partial c}{\partial x}\right]$, subject to the conditions $c = 0$, $x > 0$, $t = 0$ and $c = 1$, $x = 0$, $t > 0$. The extrapolated value of D at $c = 0$ was $D^0_{25} = 6\cdot173 \times 10^{-7}$ cm.²/sec.

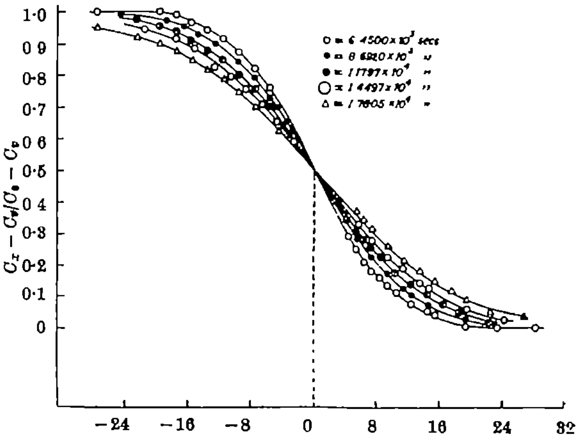

Fig. 1. Solute concentration distribution in the diffusion cell at different times in the process of diffusion

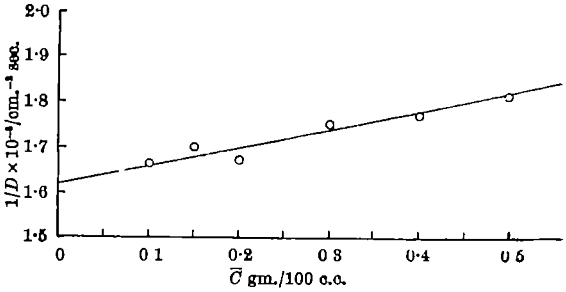

Fig. 2. Concentration dependence of the diffusion coefficients of bovine serum albumin

The measurements reported here refer to a concentration difference $\Delta C = 2 \times 10^{-3}$ gm./c.c. between the protein solutions. The influence of different values of ΔC on the nature of concentration dependence of D and also on the final value of D^0_{25} are being investigated and will be reported later.

I thank the Ministry of Scientific Research and Cultural Affairs, Government of India, for the award of a research fellowship, Prof. N. N. Das Gupta for his guidance and encouragement during this investigation, and Dr. S. N. Chatterjee, School of Tropical Medicine, Calcutta, for valuable discussions.

Institut für Mikrobiologie, Johann Wolfgang Goethe-Universität,
Frankfurt am Main

AFTER adsorption of a temperate phage by a sensitive bacterium the cell can develop either a lytic or a lysogenic infection. Which reactions occur seem to depend on a 'race' between two reaction chains[1-3]. One chain leading to lysogenization seems to depend on the synthesis of a specific cytoplasmic substance, called the repressor, which is able to overcome the alternative reaction chain leading to lysis. (Since our knowledge of the chemical nature of the repressor and the steps involved in its synthesis is very meagre, we confine our definition of the repressor to a substance the synthesis of which causes the limiting factor in establishing the repression of lytic phage development.) The alternative reaction chain leading to lysis of the complex involves the synthesis of specific proteins necessary for development of vegetative phage. According to a hypothesis proposed earlier[2] the reaction chain reaching the 'winning post' 'decides' for lysis versus lysogenization of the cell.

The chance in favour of lysogenization can be increased experimentally in two different ways: (*a*) Infection of a cell with more than one temperate phage[4-7], leading to the so-called 'multiplicity effect'. (*b*) Selective inhibition of the competing reaction chain, leading to lysis by a block of the protein synthesis, for example, with chloramphenicol (CHL)[1,2,8-10]. In both cases the synthesis of the repressor seems to be favoured. The following experiments were undertaken to obtain some information about the kinetics of repressor formation and its relation to protein synthesis.

(*A*) *Kinetics of repressor formation in the presence of chloramphenicol.* With regard to the kinetics of the 'multiplicity effect', it has been shown that the chance of 'survival' for lytic infected (L) and uninfected cells (U) decreases with multiplicity of infection m (mean number of phages per bacterium), or, inversely expressed, the yield of lysogenic infections (G) within a population of bacteria increases in one-hit kinetics with multiplicity m:

$$-\frac{\mathrm{d}(L+U)}{\mathrm{d}m} = k_{\text{lyg}} \times m\,; \quad \text{integrated}$$

$$L + U = \exp(-k_{\text{lyg}} \times m)$$

Since:

$$G + L + U = 1 \text{ respectively } L + U = 1 - G,$$

we get:

$$1 - G = \exp(-k_{\text{lyg}} \times m) \qquad (1)$$

where k_{lyg} denotes the probability for lysogenization for each infecting phage which depends on genetic factors and physiological conditions.

Equation (1) shows that lysogenization is 'dominant' over lysis. Therefore the lysogenic infections increase with 'multiplicity of lysogenization' $m \times k_{\text{lyg}}$.

It seems reasonable to conclude from equation (1) that every infecting phage is able to synthesize a certain amount of repressor under the physiological conditions given. With increasing multiplicity this amount may increase proportionally. Analogous to equation (1) the probability of an infected cell yielding a lytic response (L) will decrease with increasing concentration r of the repressor:

$$-\frac{\mathrm{d}L}{\mathrm{d}r} = c \times r; \quad \text{integrated}$$

$$L = \exp(-c \times r) \text{ resp.}$$

$$1 - G = \exp(-c \times r) \qquad (2)$$

Since we regard in this formulation only infected cells the relative amount of lysogenic infections (G) equals the frequency of lysogenization; c denotes a constant describing the probability of action of the synthesized repressor.

If the expression of the multiplicity of infection in terms of repressor concentration is correct (equation 2), then it can be expected that it is unimportant by what mechanism the repressor concentration is changed. As already stated, lysogenization with respect to repressor formation is favoured by a block in the protein synthesis. Since it is observed that the frequency of lysogenization increases with increasing time of CHL treatment, one is led to conclude that during the blockage of protein synthesis the repressor accumulates inside the cell. The increase of the frequency of lysogenization with the duration of CHL treatment should then reflect the time-course of repressor synthesis. If the rate of synthesis is independent of time we should obtain, if applying equation 2, a 'one-hit' increase of the lysogenizations with the duration of CHL treatment. Any other kind of kinetics of increase would mean that either equation 2 is incorrect or the rate of repressor synthesis is not independent of time, or both proposals are incorrect. Fig. 1*a* shows that the experimental data fit well enough the expectation for a rate constant in time. In each of the four experiments of Fig. 1*a* the absolute number of infections (lysis + lysogenization) remained constant during all periods of treatment with CHL; therefore the observed change in frequency of lysogenization is not caused by selective killing or curing from lytic or

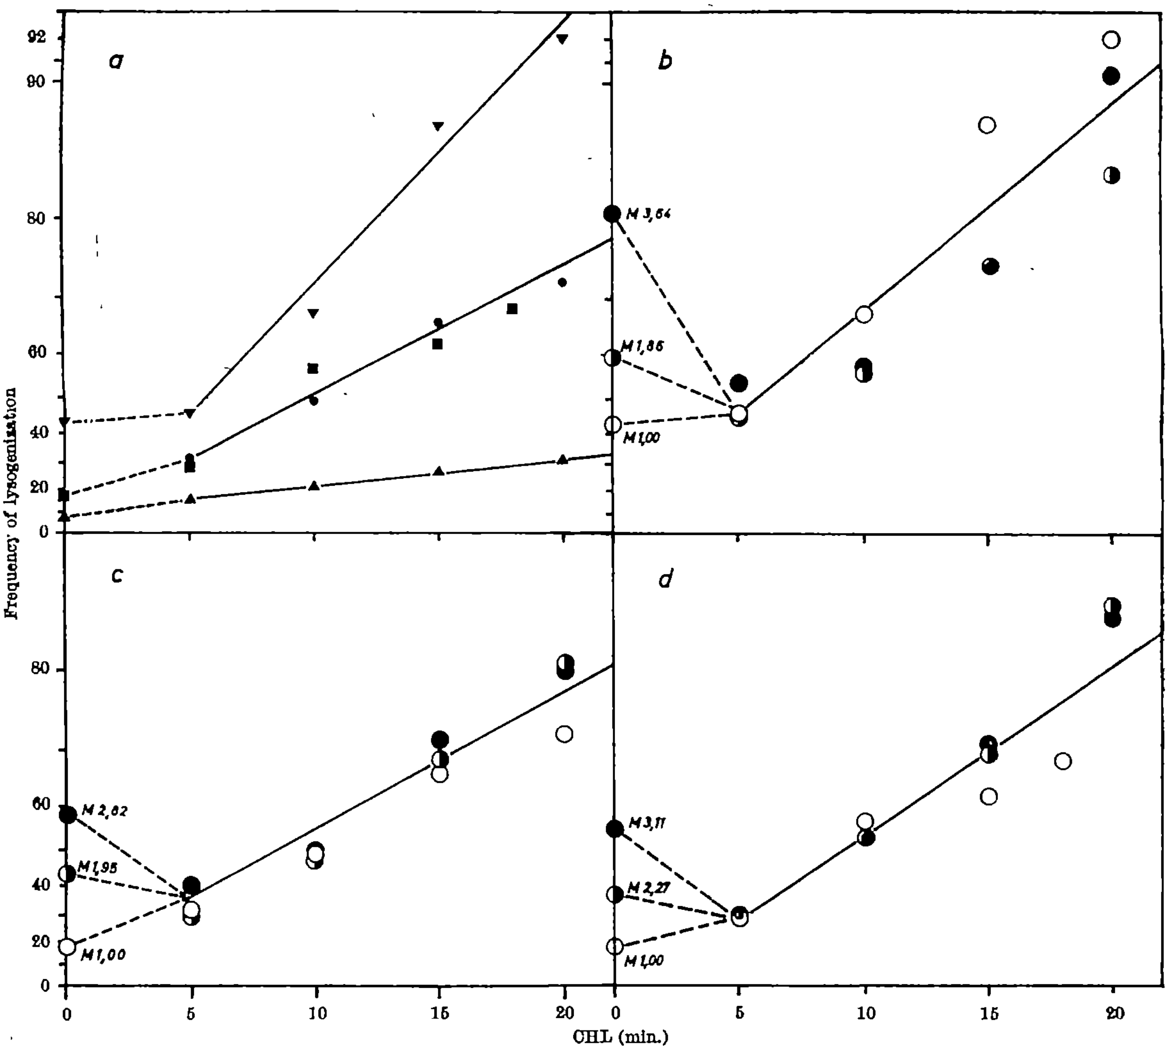

Fig. 1. *a*, Stationary cells of *Salmonella typhimurium try*8⁻ have been infected in phosphate buffer at 37° C. with $P22\ H_1$ in multiplicities ranging from 1/20 to 1/100; after 10 min. adsorption period (99 per cent adsorption) they were diluted 1/10 into anti-*P22*-serum in nutrient broth ($t = 0$). At time $t = 5$ min. the complexes have been transferred in nutrient broth + 12·5 μgm. CHL. The treatment lasting 5, 10, 15 or 20 min. has been terminated by dilution 1/50 in nutrient broth. At time $t = 25$ all samples with the different duration of treatment were plated after appropriate dilution with 'Tgal⁻' indicator in soft agar on nutrient agar plates with galactose (ref. 2). All treatments have been carried out at 37° C. Four different experiments

b–d, Same principle and same procedure as described for Fig. 1*a* with the exception that three parallel samples with different multiplicities of infection (*m*) were tested. In the figures the multiplicity of the complexes (*M*) is indicated at the corresponding points on the ordinate ($M = m/1 - e^{-m}$). Fig. 1*b*. $m = 0\ 046$, $M = 1{\cdot}00$ (○); $m = 1{\cdot}40$, $M = 1\ 86$ (◑); $m = 3\ 51$, $M = 3{\cdot}64$ (●). Fig. 1*c*. $m = 0\ 047$, $M = 1\ 00$ (○); $m = 1{\cdot}52$, $M = 1{\cdot}95$ (◑); $m = 2\ 64$, $M = 2{\cdot}82$ (●). Fig. 1*d*. $m = 0\ 017$, $M = 1\ 00$ (○); $m = 1{\cdot}94$, $M = 2{\cdot}27$ (◑); $m = 2{\cdot}95$, $M = 3{\cdot}11$ (●). The frequencies of lysogenization at $M = 1\ 00$ are the same experimental points as ▼, • and ■ in Fig. 1*a*

lysogenic infections. Hence we may formulate as follows:

$$1 - G = \exp(-t_{\mathrm{CHL}} \times k_{\mathrm{CHL}}) \text{ resp.}$$
$$\ln(1 - G) = -t_{\mathrm{CHL}} \times k_{\mathrm{CHL}} \qquad (3)$$

where k_{CHL} denotes the probability of lysogenization for an infecting phage under the physiological conditions of CHL treatment extrapolated back to time zero, and t_{CHL} the duration of treatment.

This result suggests that: (1) the repressor concentration inside the cell determines the probability of lysogenization according to equation 2; (2) that repressor formation indeed proceeds in a linear manner during the presence of CHL. It is likely that both proposals apply to conditions without treatment with CHL in the same way.

Since the synthesis of primary gene products proceeds in the same linear manner[11] we reach the conclusion that the repressor of lytic phage development behaves like a primary gene product. This idea is in full accordance with the concept developed by Jacob and Monod[3].

(*B*) *Influence of chloramphenicol on the multiplicity effect*. The repressor formation seems to consist of several steps each dependent on special biochemical reactions as the following experiments will show. Since the increase of lysogenic responses with multiplicity (see equation (1)) and the increase of frequency of lysogenization during treatment with CHL (see equation (2)) of the complex follow the same kinetics, and since both can be explained on the basis of different repressor concentrations, one is led to speculate that both the number of phages per infected cell (that is, multiplicity of the complexes M; $M = m/1 - e^{-m}$) plus the treatment of the complex with CHL should yield a higher frequency of lysogenization than without treatment with CHL. Surprisingly, this is not the case; rather the frequency of lysogenization in multiple-infected complexes decreases to the level of single infected ones after 5-min. treatment with CHL (Fig. 1*b*–*d*). (An influence of selective killing or curing of lytic or lysogenic infections at different multiplicities is excluded experimentally by the same reason as in the experiment illustrated by Fig. 1*a*.) If the treatment is increased further up to 20 min., the frequency of lysogenization increases in single and multiple-infected cells approximately with the same kinetics. This result can be taken as indicating that the blockage of protein synthesis prevents an important step in the establishment of the multiplicity effect by permitting formally only one of the infecting phages to synthesize repressor. The protein synthesis necessary for the expression of the multiplicity effect occurs within the 5th–10th min. after the start of the intracellular phage development, as can be shown experimentally. Accordingly, treatment with CHL after that time-interval (for example, starting at $t = 10$ or $t = 15$ min. after start of intracellular phage development) permits again the expression of the multiplicity effect, although slightly reduced.

Within the chain of reactions leading to repressor formation we now can distinguish two steps. The first one depends on the synthesis of some kind of protein which must be initiated by each infecting phage in order to contribute to the multiplicity effect of lysogenization. This contribution itself is a part of the second step, the synthesis of the repressor, which seems to be more or less independent of protein synthesis. A noteworthy feature of the first step is, that even in the presence of CHL formally one phage can initiate it, but all other infecting phage particles seem to be excluded from it. In other words, CHL treatment limits the 'capacity' of the cell for performance of the first step to one phage only.

UREA EXCRETION IN RUMINANTS

By H. G. LIVINGSTON, W. J. A. PAYNE and M. T. FRIEND

East African Agriculture and Forestry Research Organization,
Kikuyu, Kenya

VARIOUS authors[1,3–7] have published conflicting reports on the level of urea excretion in the urine of ruminants. Read[1], investigating the urine nitrogen excretion of a pregnant female camel (*Camelus bactrianus*) fed on sorghum leaves, sweet potato and salt, reported that there was only a trace of urea in the urine. As it has been generally accepted that urea is the most important of the nitrogenous waste products in mammalian urine[2], this finding excited the interest of other investigators. Petri[3] and Smith and Silvette[4] reported that they could not duplicate Read's results using either pregnant or non-pregnant camels (*Camelus bactrianus* and *Camelus dromedarius*). They state that the urine of the camels they investigated contained a normal amount of urea nitrogen, amounting to approximately 60 per cent of the total. Smith and Silvette[4] also reported that the urine of the llama (*Auchenia huanacos*) and the alpaca (*Auchenia vicunna*) contained normal amounts of urea. Meyer, Weir and Smith[5], studying sheep, observed low total urine nitrogen values when the animals were deprived of water and feed for limited periods.

The controversy was re-opened by Schmidt-Nielsen *et al.*[6], who examined the water metabolism of the camel (*Camelus dromedarius*) in Algeria. They reported that the urea excretion of the growing camel became extremely low under conditions of low intake of nitrogen and deprivation of water, and they maintained that their results suggested that there was no reason to doubt those of Read[1].

Schmidt-Nielsen and Osaki[7] have also shown that the excretion of urea nitrogen by sheep maintained on a very low crude protein content diet and *ad lib.* water is also low.

Current work in this laboratory, planned to investigate the nitrogen metabolism of *Bos taurus* and *Bos*

Table 1. ACTUAL AMOUNT UREA NITROGEN IN THE URINE AND PERCENTAGE UREA NITROGEN IN THE TOTAL URINE NITROGEN OF *Bos taurus* AND *Bos indicus* IDENTICAL TWIN SETS DURING FIVE 10-DAY EXPERIMENTAL PERIODS

Twin set	Species	Animal	Experimental periods	Approx. C.P. of ration	Urea-N per day gm.	Urea-N as per cent total urine-N

			V	12	39·6±1·84	68·7±2·23

In periods IV and V, twins A_2 and Z_1 were deprived of water for 96-hr. intervals.

indicus cattle under conditions of low intake of nitrogen and deprivation of water (stimulating nutrient stress conditions in the semi-arid areas of East Africa), has produced results which might help to explain these conflicting reports.

Two sets of identical steer twins, one *Bos taurus* (Ayrshire) and the other *Bos indicus* (Boran), were fed a ration containing approximately 12 per cent crude protein for a long standardization period, the final ten days being period I of this experiment. The crude protein content of the ration fed to one twin in each set was then progressively lowered, first to approximately 8 per cent (period II), then to approximately 4 per cent (period III). During these periods all the animals received water *ad lib.* The twins receiving the 4 per cent crude protein ration were then deprived of water but not of feed, only being allowed to drink for a very restricted period (20 min.) at 96-hr. intervals (periods IV and V). Period IV was essentially a change-over period when water deprivation was first introduced, while by period V it was assumed that the animals were accustomed to deprivation. During the five 10-day experimental periods 24-hr. collections of urine were made and this was analysed for total nitrogen, ammonia nitrogen and urine nitrogen. Determinations of intake of total nitrogen and total fæcal nitrogen were made at the same time. The percentages of urea nitrogen in the total urine nitrogen of the four experimental animals for five 10-day experimental periods are given in Table 1, together with data on actual urea nitrogen excretion.

It will be seen that a progressive reduction in the crude protein content of the ration immediately effects the actual amount of urea nitrogen excreted, and that deprivation of water leads to a further reduction. The percentage of urea nitrogen to total urine nitrogen does not, however, radically alter until the animals are deprived of water (periods IV and V). Within twin-set differences are statistically far more significant in periods IV and V than in periods I, II and III.

A comparison of the results published by Read[1], Petri[3], Smith and Silvette[4] and Schmidt-Nielsen *et al.*[6] with those obtained to date in this laboratory suggests that the experimental results of all these authors fit into a consistent pattern. Read[1] and Schmidt-Nielsen *et al.*[6], who claim that the urea content of camel urine falls below the normal standards were experimenting with ruminants receiving a low crude protein content diet and deprived of water to a greater or less extent; while Petri[3] and Smith and Silvette[4], who claim that the urea content of camel and other ruminant's urine is normal, were utilizing animals receiving a ration with an adequate crude protein content and water *ad lib.* The results published by Meyer, Weir and Smith[5] and Schmidt-Nielsen and Osaki[7] are also in agreement with the observations made in this laboratory.

It would appear from our preliminary results that variation in the excretion of urea nitrogen of cattle could be a function of both the crude protein content of the diet and deprivation of water, whereas variation in the percentage of urea nitrogen in the total urine nitrogen may be more a function of deprivation of water than the crude protein content of the diet.

A POSSIBLE MODE OF ACTION OF SOME ANTI-FUNGAL AND ANTI-BACTERIAL CHELATING AGENTS

By M. B. LOWE and J. N. PHILLIPS

Division of Plant Industry, Commonwealth Scientific and Industrial Research Organization, Canberra

RECENTLY it has been reported[1] that the rate of incorporation of metal ions into protoporphyrin dimethyl ester solubilized in aqueous detergent solutions can be influenced both by the charged nature of the detergent and by the presence of chelating agent, 8-hydroxyquinoline (oxine). The maximum rate was attained in anionic detergent solutions in the presence of equimolar concentrations of the metal ion and oxine. Further work has now indicated that a number of other chelating agents also catalyse this reaction, the most active ones belonging to a group of biologically active chelating agents which are believed to have a common mode of action.

The reaction between the 1 : 1 metal chelate complex (MKe^+) and the porphyrin (PH_2) in an aqueous detergent solution can be described by the bimolecular reaction:

$$MKe^+ + PH_2 \rightleftharpoons MP + H_2Ke^+$$

Table 1 summarizes the second-order rate constants (k) for the incorporation of copper into mesoporphyrin dimethyl ester in 2·5 per cent aqueous sodium dodecyl sulphate solution (SDS) at pH 7·0 and 20° C. in the presence of equimolar concentrations of cupric ions and various chelating agents. The experimental conditions were chosen so that the initial cupric ion concentration was approximately ten-fold the porphyrin concentration. The results were corrected for the formation of the inactive 1 : 2 copper chelate species during the course of the reaction.

Table 1. SECOND-ORDER RATE CONSTANTS (k) AT 20° C. FOR FORMATION OF PORPHYRIN-COPPER COMPLEX AT pH 7·0 IN 2 5 PER CENT SDS

Initial concentrations present: copper sulphate 5×10^{-4} M, chelating agent 5×10^{-4} M and mesoporphyrin dimethyl ester 6×10^{-5} M

Chelating agent	$k \times 10^{-3}$ (l./mole-min.)
Sodium diethyldithiocarbamate	8,300
Potassium ethylxanthate	1,100
2-Hydroxypyridine-*N*-oxide	1,000
8-Hydroxyquinoline	750
Kojic acid	550
Salicylaldehyde	110
Control (no chelating agent)	20
Salicylic acid	10
Glycine	10
Terramycin	10
Nitrilotriacetic acid	10
o-Phenanthroline	5
2-2′Dipyridyl	5
Histidine	5
Ethylenediamine tetraacetic acid	2

It will be noted that only certain of the chelating agents shown in Table 1 are catalytically active (some indeed are inhibitory). Moreover, the most active compounds, including sodium diethyldithiocarbamate, 2-hydroxypyridine-*N*-oxide, 8-hydroxyquinoline and kojic acid, although structurally unrelated to each other, belong to a class of anti-fungal and anti-bacterial substances which are believed to have a common mode of action[2,6].

A high level of activity has been shown to occur only in the presence of certain metal ions. Copper is the most universally active in this respect being co-toxic with the chelators against a variety of fungi and bacteria.

Dosage response studies indicate that the 1 : 1 metal chelate species is the primary active form.

On the basis of the results reported here and the earlier biological observations[2,6] it seems reasonable to suggest that the mode of action of these compounds might be associated with the incorporation of copper into a porphyrin precursor of some essential hæm-type pigment. In support of this hypothesis we may note that:

(1) The correlation between biological activity and catalytic activity occurs in a group of substances which are structurally unrelated and have little in common apart from their ability to chelate metals, a property shared by a vast number of other substances biologically and catalytically inactive in the sense described here.

(2) The 1 : 1 metal chelate complex is the active species both in the biological and catalytic systems.

(3) The cupric ion is the ion most readily incorporated into a porphyrin nucleus from an aqueous solution[3,4].

(4) The wide spectrum and high level of biological activity observed would be consistent with an interference in some essential hæm synthesis.

This work is being followed up both at the biological and chemical level.

OXYGENATION OF LEGHÆMOGLOBIN IN SOYBEAN ROOT-NODULES IN RELATION TO THE EXTERNAL OXYGEN TENSION

By DR. F. J. BERGERSEN

Division of Plant Industry, Commonwealth Scientific and Industrial Research Organization, Canberra

LEGHÆMOGLOBIN, the characteristic red pigment of legume root nodules, seems to be involved in some component reaction of the fixation of atmospheric nitrogen which these organs accomplish[1]. The role of this hæmoprotein has variously been postulated to be an oxidation-reduction catalyst, an oxygen carrier, a binder of nitrogen and an electron carrier[2-5]. The state of this pigment in functioning nodules has not been easy to determine, and it has been thought to be oxygenated or partially oxygenated. Appleby[6] has prepared purified leghæmoglobin as separate components and has determined their oxygen equilibria. He found that the components were half oxygenated at partial pressures of oxygen from 0·04 to 0·06 mm. mercury. He also reported that young nodules frozen in liquid nitrogen contained a mixture of ferro-leghæmoglobin and oxyleghæmoglobin, but refers to the difficulty of spectroscopic examination of intact nodules.

In the work to be reported here, soybean root nodules of known age were obtained as previously described[7] and used immediately after being detached from the roots. Spectroscopic methods were based on those described by Hartree[8] using a Beck microspectroscope mounted on a Galileo model *VFC* microscope equipped with a built-in light source. A preliminary investigation was made of the optical properties of intact and sliced nodules. It was found that only a small proportion of light entering an intact nodule from any angle passed through the central tissue: most of it 'tracked' around the cortex. The spectrum of this emerging light was therefore characterized by very faint absorption bands of leghæmoglobin masked with what may be regarded as stray light. In contrast, when light entered a cut surface of the central tissue, the emerging light showed intense absorption bands of oxyleghæmoglobin which were rapidly replaced by the less-intense band of ferroleghæmoglobin when the cut surface was pressed against a microscope slide[6,9,10]. No amount of masking or focusing of the incident light improved the absorption spectra of light emerging from intact nodules.

A glass chamber was therefore constructed from pieces of microscope slide cemented together (Fig. 1*a*) and equipped with large hypodermic needles for entry and exit of gas. The chamber was closed at the top by another piece of microscope slide which was pressed down by the microscope objective. Nodule pieces were cut which were 0·25 mm. thicker than the depth of the chamber by means of the guide illustrated in Fig. 1*c*. The cut surface was quickly pressed down on to a drop of 0·5 per cent agar in *p*H 7·0 phosphate buffer on the lower surface of the gassing chamber; the top was placed in position and pressed gently closed by lowering the microscope objective. The cut surface of the nodule was thus sealed against the lower surface of the chamber and held in position with gentle compression, while the rest of the intact surface was exposed to the atmosphere in the chamber.

The microscope optics were adjusted as in Fig. 1*a* so that the incident light was focused on the cut surface of the central tissue and the emerging light was focused on the entrance slit of the spectroscope by adjustment of the extension tube of the microscope without the eyepiece. In this way stray light was eliminated.

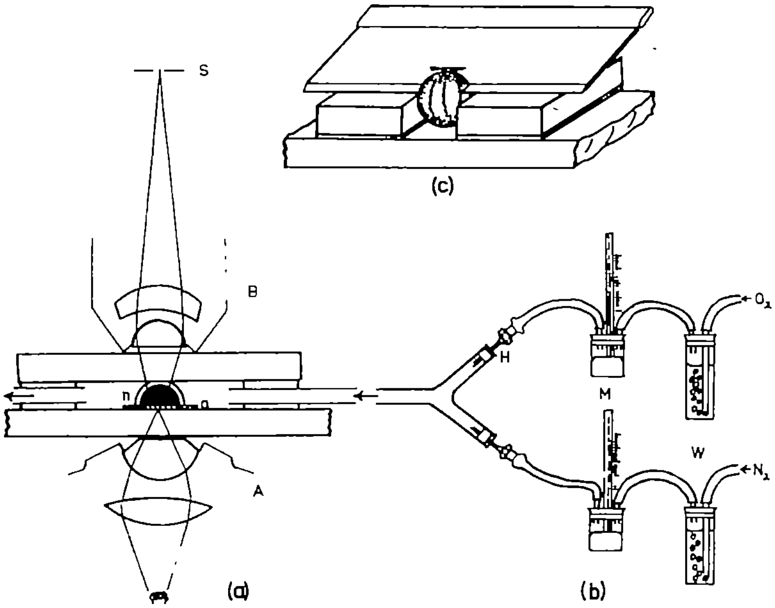

Fig. 1. (*a*), The optical system and gassing chamber. *A*, microscope condenser, *N.A.* 1·4; *B*, ×25 microscope objective; *S*, spectroscope entrance slit; *n*, nodule piece; *a*, 0·5 per cent agar drop. (*b*), The gassing line. *H*, hypodermic needles internal diam. 0·25 mm.; *M*, mercury manometers; *W*, warm water humidifiers. (*c*), The slicing guide constructed of microscope slide glass of the same thickness as that of the gassing chamber. Extra depth was obtained by the addition of pieces of 0 25 mm. thick microscope coverslip

Gas mixtures of various oxygen tensions were passed through the gassing chamber by means of the apparatus illustrated in Fig. 1*b*. The construction was such that a manometer reading of 300 mm. mercury gave a flow-rate of 500 c.c./min. By varying the relative pressures of oxygen and nitrogen with a combined pressure of 300 mm. mercury various partial pressures of oxygen were maintained in the chamber, measurement and calculation having shown that for both gases flow-rate was proportional to pressure. All experiments were done at 23° C. using good-quality commercial gases of about 98 per cent purity.

Initial experiments showed four readily recognizable types of absorption spectra. These are illustrated in Fig. 2 and were corroborated by independent observers. With actively nitrogen-fixing nodules aged 20–35 days in air the spectra showed a sharp band at 550 mμ, the bacteroid cytochrome *c* (ref. 11) and the broad rather diffuse band of ferro-leghæmoglobin extending from 550 to 570 mμ with the maximum absorption between 550 and 560 mμ. Except in cases where the seal between the cut surface and the glass was afterwards found to be faulty due to drying out of the tissue, no changes in this type of spectrum were observed until the partial pressure of oxygen in the chamber exceeded 50 per cent. Higher oxygen tensions than this caused progressively increased oxygenation of the pigment as shown in Fig. 2, reaching a maximum at 80–100 per cent when the prominent bands of oxyleghæmoglobin at 540–547 and 570–574 mμ (ref 12) were unmistakable. Older nodules showed oxygenation at lower oxygen tensions; for example, 39-day-old nodules began to show changes in the absorption spectra at 20–30 per cent oxygen. In no case was the 625 mμ band of ferrileghæmoglobin observed at any oxygen tension.

The progressive oxygenation of the leghæmoglobin of soybean nodules was next estimated at various oxygen tensions with the aid of a wedge trough in the light path of the comparison beam of the spectroscope.

In the first experiments fresh nodule extract was used as the source of hæmoglobin, but because of its instability, human hæmoglobin was substituted in later work. However, the same results were obtained irrespective of the source of the comparison pigment The procedure was as follows: 15 ml. phosphate buffer (*p*H 7·0, *M*/15) were placed in each compartment of the wedge trough. A nodule was prepared and placed in the gassing chamber and 100 per cent oxygen passed through until the hæmoglobin in the nodule was fully oxygenated. Oxyhæmoglobin was then added to one compartment of the wedge trough with a graduated pipette until the comparison spectrum matched the nodule spectrum with the trough in the position in which the comparison light passed through the maximum width of the oxyhæmoglobin compartment. The oxygen was turned off and nitrogen passed through the chamber and an equal volume of hæmoglobin solution was added to the buffer in the other side of the wedge trough together with enough sodium dithionite to maintain the pigment in the reduced state for the duration of the measurements. The matching of the oxy-forms of the pigment in nodule and wedge trough was more reliable than matching of the reduced forms. However, when spectra were matched as oxy-forms they also matched well when reduced. Gas mixtures of various oxygen tensions were then passed through the gassing chamber for 1·5 min. to allow equilibration, after which the nodule and comparison spectra were matched by sliding the wedge trough across the path of the comparison beam.

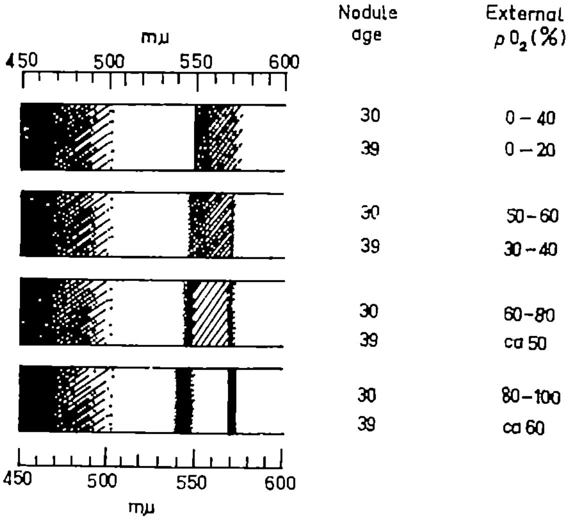

Fig. 2. Diagrammatic representation of the four types of absorption spectra identified by independent observers at various oxygen tensions (pO_2)

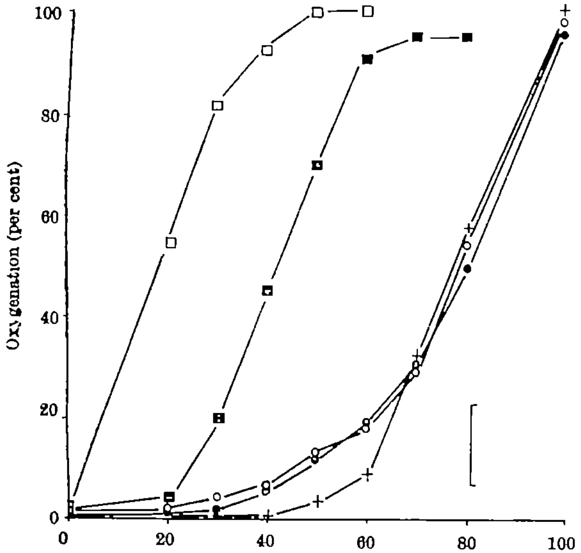

Fig. 3. The progressive oxygenation of nodule leghæmoglobin with increasing oxygen tension (pO_2) for nodules of various ages. The maximum standard deviation obtained for any of the points is shown at lower right. Nodule age (days): +, 28; ●, 34; ○, 35; □, 35 (green centre); ■, 39

That this brief equilibration time was sufficient is shown by the following results for a typical nodule: After slicing, the fresh nodule piece in the chamber in nitrogen was fully reduced in 15·5 sec.; on changing the gas to oxygen the nodule was fully oxygenated in 18·0 sec.; after measurements lasting 15 min. the fully oxygenated leghæmoglobin was reduced after 43 sec. in nitrogen and on changing to oxygen the oxyleghæmoglobin bands appeared after 10 sec. and were fully developed in 44 sec. The wedge trough positions were converted to percentage oxygenation of the pigment from the ratios of the lengths of the comparison light path through oxy- and ferro-hæmoglobin solutions.

The results of experiments with nodules of various ages are shown in Fig. 3, in which each point is the mean of determinations with 3 or 4 nodules: an exception is the curve for the 35-day-old green centred nodule, only one of which was found. The magnitude of the maximum standard deviation of the data for any point is also shown. The reliability of the methods used is shown by the close agreement of the data for 34- and 35-day-old nodules obtained on successive days. Nodules which were actively fixing nitrogen showed little if any oxygenation of hæmoglobin until the oxygen tension in the chamber exceeded 40–50 per cent. At higher oxygen tensions oxygenation increased rapidly to the maximum values. The low percentage oxyleghæmoglobin values obtained at low oxygen tensions are not very reliable because of the difficulty in detecting by eye the small changes in absorption spectra which occur. It is not possible to say that the pigment was entirely reduced at 20 per cent oxygen, but it was certainly less than 5 per cent oxygenated and because of the shape of the curves was probably less than 1 per cent oxygenated. The results also show that as the nodules aged or degenerated (the green centred nodule) so did the oxygenation of the pigment commence at lower oxygen tensions.

The nitrogen-fixing central tissue of soybean root nodules consists of large host cells, each of which contains large numbers of bacteroids (the nodular form of the nodule bacteria) which are enclosed in groups of 4–6, together with the hæmoglobin, in double-layered membrane envelopes[5]. The results presented support the conclusions drawn from respiratory and nitrogen fixation studies[13] that there is an oxygen barrier in the nodules which does not permit the passage of oxygen into the envelopes until a certain oxygen tension has been exceeded. The curves of Fig. 3 also bear a striking resemblance to those obtained when the Michaelis constant for nitrogen fixation is plotted against external oxygen tension[13]. The oxygenation curves for leghæmoglobin in pure solution obtained by Appleby[6] indicate that the oxygen tension within intact nodules in air is much lower than that derived from other work[14] and probably lies below 0·005 mm. mercury or less than 0·0007 per cent. It should also be emphasized that these results could only be obtained with nodules with homogeneously aged central tissue cells such as occur in soybean nodules; nodules with growing points such as those of clover, peas, etc., present a confused spectrum due to the gradation in age of the central tissue cells.

I thank Dr. C. A. Appleby for help in observation and discussion and other colleagues of the Division of Plant Industry for independent observation of spectra.

INFLUENCE OF MACROCLIMATIC CONDITIONS ON THE DEVELOPMENT OF BLAST AND HELMINTHOSPORIOSE OF RICE

By P. M. NAHA

Central Rice Research Institute, Cuttack, Orissa, India

IN spite of limitations of meteorological records to explain the intimate association of host and parasite[1], such observations have been found to be valuable in forecasting disease and in epidemiological research[2]. While microclimate (environment close to the plant) controls the process of initial establishment of a pathogen[3], macroclimate helps in disease correlation and spread.

Forecasting of disease in rice, particularly with reference to blast (*Piricularia oryzae* Cav.), has been

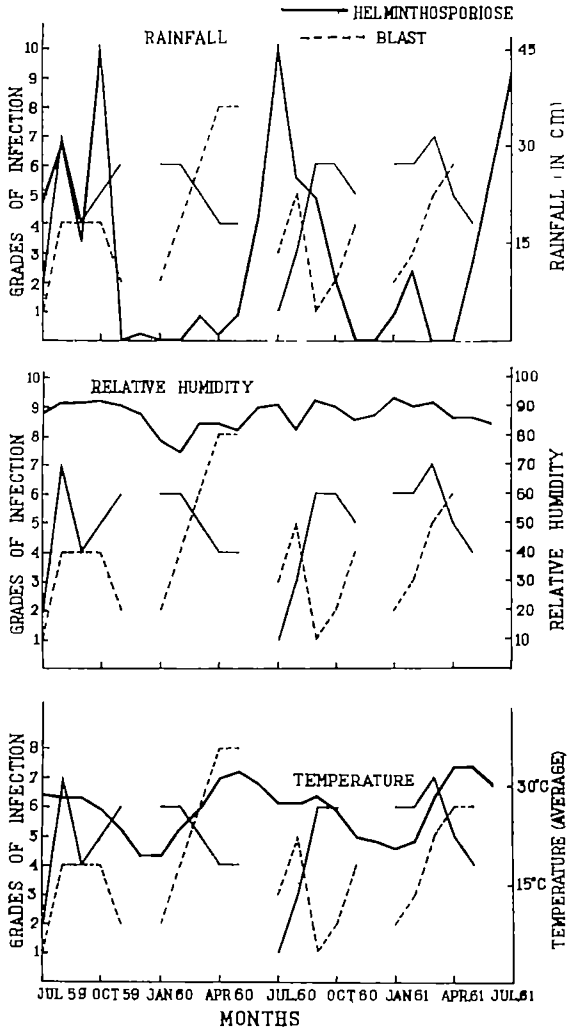

Fig. 1. Graphs showing relationships of the incidence of blast and helminthosporiose to meteorological conditions of rainfall, relative humidity and temperature

investigated to a certain extent in Argentina[4] and Japan[5,6]. Hashioka[7] stated that the prevalence to blast in temperate areas is dependent on the temperature suitable for growth of the pathogen, in sub-temperate areas on the age of the plant (which affects their resistance) and in the tropics on the relation of temperature to the resistance of the host. Published records show that little work has been done in India in this connexion[8].

During a survey of incidence of blast (*P. oryzae* Cav.) and helminthosporiose (*Helminthosporium oryzae* Breda de Haan) of rice due to natural infection in Cuttack and Puri Districts of Orissa State, I made an attempt to correlate them with the meteorological conditions of rainfall, relative humidity and temperature. Incidence of diseases was studied statistically by the method of multi-stage stratified random sampling technique (formulated by the Indian Council for Agricultural Research). Ten grades of infections of both blast and helminthosporiose were made, depending on the number of undeveloped and developed spots of infections (including neck and node blast), which were followed as standard infection score-charts. In an area of more than 8,249 square miles altogether about 20 improved and more than 100 unimproved local varieties of rice plants were cultivated. Soil conditions varied from alluvial to laterite, sandy to loamy and clayey; *p*H ranging between 5·2 and 6·8.

Helminthosporiose. The development of helminthosporiose on rice plants showed a direct relationship with the rainfall during the four rice-growing seasons examined. The relationship seemed to be more with the amount of moisture present in the soil than that on the plant surface or atmospheric humidity, since the incidence of disease showed an increase only in the months following rainfall and not during the months of actual rainfall. It might be mentioned here that the two peaks in the rainfall curve (Fig. 1) caused widespread floods over an extensive area, submerging the standing crop for a short time. But even under this submerged condition (October 1959 and July 1960) incidence of disease did not rise rapidly. It showed a slow and gradual increase, reaching its severest form during the months of November 1959 and September 1960, when there was practically little or no rainfall. Thus, it appeared that the expression of helminthosporiose on rice plants seemed to bear a correlation to soil moisture and plant uptake. The same was true for the cultivation season of January–June, when soil dried up and moisture percentage decreased. There was relatively a steady fall in the incidence of helminthosporiose; but a sudden increase in rainfall in February 1961 caused an immediate increase in disease incidence in March 1961.

Since the average temperature of minimum and maximum never fell below 20° C. or went above 34° C., limiting conditions of temperature in the development of helminthosporiose could not be determined. Between 20° and 34° C. atmospheric temperature did not seem to have any relationship with the incidence of the disease.

Blast. Of the three principal meteorological conditions studied, temperature appeared to show the closest parallelism to the development of blast on paddy in all the seasons. Between the average temperatures of 20°–34° C. the relationship was more or less directly proportional. The optimum temperature for highest incidence of blast was recorded within 28°–30° C. Above 30° C. the development of the disease was checked, and below 24° C. it showed a marked fall. Thus, during August–October 1959 incidence of blast remained constant, when the average temperature ranged between 26°–28° C.; thereafter a fall in the temperature was followed immediately by a fall in the prevalence of the infection. Again, with the rise of temperature from January 1960 onwards, there was direct increase of blast incidence. The season January–June 1961 was remarkably consistent with the above observation.

But the preceding season (July–December 1960) posed a problem in this respect in that, when temperature was most suitable (24°–28° C.) for development of blast, there was a sharp fall followed again by an increase in the incidence of the disease. It may be noticed that, during the period, the relative humidity was as high as 80–90 per cent, which was optimum for the development of blast[9]. The explanation for this retardation might lie in the excessive rainfall during the period. Earlier literature[10] supported that susceptibility to blast varied in inverse ratio to the amount of water contained in the soil. Similar observations were made by me during the survey of rice fields subjected to floods. In one particular field, 45-day-old seedlings carried blast infection symptoms up to Gr. 5 before the area was flooded for 3–4 days. After the flood water receded, there was practically no sign of the disease in that area during that season. This observation might offer a possible explanation of the above problem arising out of a sudden retardation in blast incidence during August–September 1960 and may in itself carry a latent solution in the control of blast.

In general, for the development of blast, temperature seemed to be more important than humidity[11]. During the present survey study humidity was always very high (above 80 per cent); so a condition of relative humidity becoming limiting never arose.

I thank Dr. R. H. Richharia, director of this Institute, for assistance.

EFFECT OF GIBBERELLIN ON A NON-FLOWERING GENOTYPE OF RED CLOVER

By J. L. STODDART

Welsh Plant Breeding Station, Aberystwyth

DURING the multiplication of pedigree stocks of Aberystwyth *S*.123 extra late-flowering red clover (*Trifolium pratense* L.) it has been noted that a low frequency of non-flowering segregates appears. These plants tiller vigorously, but do not form stem internodes or initiate inflorescences even after prolonged periods under continuous light.

Previous work on the responses of red clover to gibberellic acid[1,2] suggested that failure to produce stems might be due to inadequate synthesis of endogenous gibberellin, and to test this hypothesis a series of estimations of 'gibberellin-like' activity were made on extracts of normal and non-flowering genotypes.

Extraction of 500 gm. fresh weight samples with 95 per cent ethanol was carried out at 0° C. over a period of 12 hr., and, after decanting, the alcohol was removed in a rotary evaporator, leaving an amber-coloured aqueous residue. After further purification procedures the extracts were line-loaded on to strips of Whatman 3*MM* paper and chromatographed in 80 per cent isopropanol. The developed strips were each cut into segments and assayed for 'gibberellin-like' activity using a red clover seedling test similar in general method and sensitivity to the lettuce hypocotyl assay of Frankland and Wareing[3].

In Fig. 1 typical activity histograms derived from early- and late-flowering red clover varieties at the third extended internode stage are compared with results from non-flowering material grown for two months under continuous light. While the general pattern of activity is similar in all three cases, large quantitative differences clearly exist. The pronounced 'gibberellin-like' activity present in the extracts of the early-flowering variety at R_F 0·7–0·8 can be correlated with the fact that floral initiation occurs when 2–3 extended internodes are externally visible, this process being delayed until about the sixth internode stage in extra late-flowering types[4]. Similarly, a parallel can be drawn between the R_F 0·4 activity and the rate of stem extension, which is more rapid in early- than in late-flowering varieties, and is non-existent in non-flowering types. The corre-

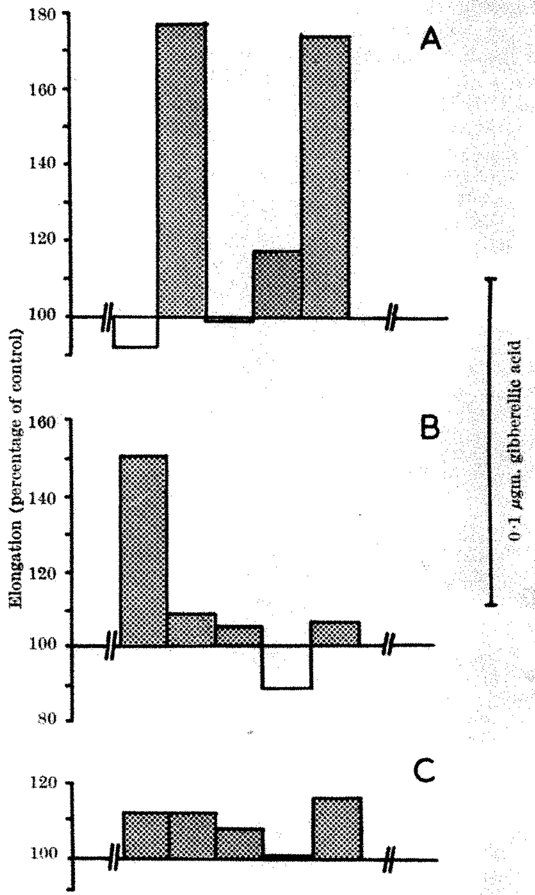

Fig. 1. Activity histograms of red clover extracts after chromatography in 80 per cent isopropanol. Red clover seedling bioassay. *A*, Dorset Marl, early-flowering; *B*, Aberystwyth *S*.123, extra late-flowering; *C*, non-flowering genotype

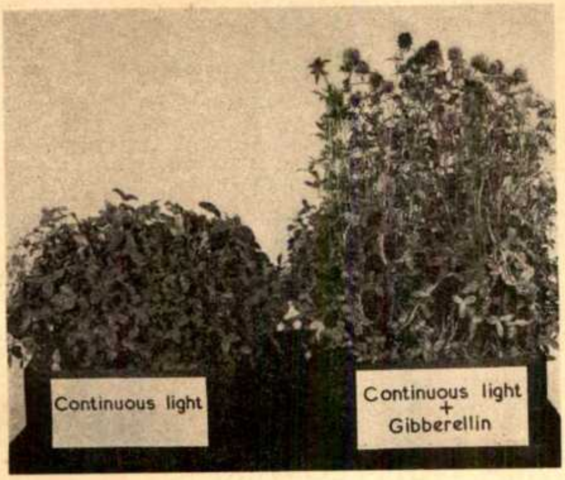

Fig. 2. Non-flowering genotype with and without gibberellin treatment after two months growth under continuous light

spondence in chromatographic mobility between the R_F 0·4 activity and authentic gibberellin A_3 suggests they may be identical or interchangeable, and, therefore, that treatment of non-flowering types with gibberellic acid might be expected to bring about internode extension.

Clonal material of several non-flowering genotypes was placed under inductive day-length conditions and half the propagants were given a foliar spraying of 1 mgm. of gibberellic acid in 0·1 per cent ethanol weekly for five weeks, making a total dosage of 5 mgm./plant. The remainder were sprayed with 0·1 per cent ethanol only on each treatment date. As may be seen in Fig. 2, the gibberellin promoted considerable internode extension and also profuse flowering, a response which is typical of all the genotypes tested. The induction period under continuous light for the treated material was of the order of 28 days, compared with the 12 days required by normal, related plants of *S*.123 red clover. In terms of yield and quality of seed the gibberellin-induced plants compared favourably with the parent variety.

Repeated treatment with gibberellic acid will not bring about floral initiation in normal plants of *S*.123 under non-inductive day-length conditions, but considerable internode extension is promoted, a response which can also result from exposure to low-intensity directional light under high-temperature (70° F.) conditions. This suggests that a two-factor system is operative, the first part, regulating stem, petiole and leaf expansion, consisting principally of a temperature-controlled process producing endogenous gibberellin similar to, or identical with, gibberellin A_3. Under inductive day-length conditions the secondary process is initiated whereby this gibberellin, or subsequent products, are modified in form substances capable of altering the course of differentiation at the shoot apex towards the reproductive state. It may be postulated that the R_F 0·7–0·8 'gibberellin' already described is directly concerned with apical differentiation and that the day-length controlled reaction consists of a chemical transformation from one form of gibberellin to another with a different activity pattern.

On this basis it is possible to interpret the non-flowering condition as a reduced ability to synthesize endogenous gibberellin A_3, a deficiency which would limit response to inductive treatments. Failure of normal plants to flower under unfavourable day-length conditions in the presence of gibberellic acid would then be due to the absence of the secondary day-length mediated system.

LIFE-FORMS IN CARBONACEOUS CHONDRITES

IN the figures published by Claus and Nagy[1] there are several organized elements. I do not recognize that called type 5 by those authors, but would like to direct attention to certain similarities between two different photographs entitled type 2 organisms and certain anemophilous pollen grains.

In Fig. 2 of their original article Claus and Nagy portray an object which has, clearly visible, pores. Although the plane in which these pores lie is not accurately discernible, they resemble the pore arrangement in pollen grains of, for example, *Corylus*. Pollen of this genus is approximately 22–31μ in diameter, psilate, aspidate, and usually having three pores on the equator. In polar view the grains are more or less triangular, in equatorial view sub-oblate[2]. It should be noted that several other genera occur in temperate latitudes alone which have similar pollen grains, for example, *Betula* and *Myrica*.

With regard to the other photograph of a type 2 organism, Claus and Nagy do not say whether this is the same structure as that shown in Fig. 2. However, similar considerations to those outlined suggest that this is not the case. The rather ill-defined object in the photograph resembles the oblate-spheroidal to sub-oblate form of the pollen of *Alnus*, a suggestion which is supported by the presence of what might be interpreted as pores at the three visible corners of the object. In fact, the size indicated on the photograph suggests that the specimen, although illustrated obliquely, is rather too small for the European species of *Alnus*[2].

Claus *et al.* further mention other structures which, although similar, had external appendages. I am not clear from their texts[1,3] how many they had of these, but note that they state that these varied in size from 8μ to 30μ in diameter. Although the small objects represented in the photographs of their recent publication[3] do not fit any angiosperm pollen grain or fungal spore met by me in my limited experience, I would like to point out that there are many pollen grains of approximately 30μ in diameter which have spines or appendages of some sort, for example, the Campanulaceae, which are echinate, and *Crepis paludosa*, which is ridged.

Pollen grains occur in vast numbers in the atmosphere[2,4,5] and accumulate in quantities in organic deposits. Claus and Nagy suggest that since these organic structures and others were present the meteorite could not have undergone a temperature in excess of 200° C. May I suggest that before accepting this conclusion we should consider:

(1) Were the subsequent investigations which are reported in ref. 3 carried out at the same time of the year as the earlier ones? Pollen of *Corylus* and *Alnus* is only produced for a limited period and that from a nearby tree can attain high values as a biological contaminant of laboratories during this period.

(2) At what temperature would the meteorite have solidified had it, in fact, exceeded the suggested maximal temperature of 200° C. and been molten during entry of the Earth's atmosphere? Pollen grains are very resistant to oxidation and indeed the normal palynological procedures involve oxidizing off the other plant material to leave only pollen grains, fungal spores and such structures as the thecæ of the Desmothoracan *Clathrulina*.

It would be preferable to disprove the simplest explanation that these structures are of terrestrial origin before moving to more elaborate hypotheses. It is, incidentally, of considerable interest that what might be explained as a pollen tube can be seen leading away from one organism (Fig. 2 of ref. 1).

Identity of Organized Elements from Meteorites

THE publication[1] of further illustrations of organized elements from the Orgueil and Ivuna meteorites raises the question of whether the possibility of their terrestrial origin has been adequately explored. The illustrations, although prepared under extremely difficult conditions, prompt the following tentative suggestions towards identification. The elements illustrated by Nagy, Claus and Hennessy in their Fig. 1*a* and *b* could well be the spore of a cryptogam, possibly a basidiospore. The object depicted in Fig. 5 (of Nagy *et al.*) in size, shape, rough wall and equatorial crest strongly resembles an ascospore of one of the larger members of the *Aspergillus glaucus* group. The object in Fig. 4*b* (Nagy *et al.*) resembles in size, shape, possible septation and surface characters a spore that occurs frequently in the air spora of southern England, though we have not yet been able to identify it or trace it to its source. It is presumably a spore of one of the Fungi Imperfecti, and a specimen from air has been illustrated recently[2]. The element illustrated in Fig. 3 (Nagy *et al.*) has some resemblance to a pollen grain of nettle (*Urtica*) except that it is only about two-thirds the usual diameter.

To refer to illustrations in the earlier article[3], it seems that Figs. 2 and 3 could well be a fungus spore. The remarkable object depicted in Fig. 4, except for the halo, which may be an extraneous deposit, has some resemblance in size and three thickened areas to a germinating pollen grain.

Any one person can be familiar with only a fraction of the morphological diversity of plant spores, and a large series of drawings and photographs of these organized objects from meteorites should be published so that as wide a range of specialists as possible can attempt identifications.

Further Life-forms in the Orgueil Meteorite

I OBTAINED some test material derived from the Orgueil meteorite—at my request—from G. Claus and B. Nagy. I crushed the meteorite sample in a sterile porcelain mortar to powder and, putting it under sterile circumstances partly into glycerol, partly into 'Caedax', I examined it under a microscope. During my examinations I found in the meteorite powder six different filamentous formations which, relying on their qualities known so far, remind one of the algae.

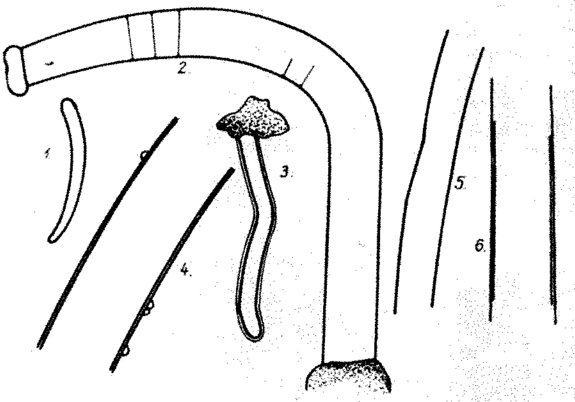

Fig. 1

Characteristics of the filaments are as follow: breadth, 3μ; length, 40μ; somewhat curved. One end of the filament is rounded off, the other slightly acuminate (Fig. 1, 1). Part of the filament is 4μ wide and 55μ long. It is covered with a follicle, the apex is rounded off (Fig. 1, 2). Part of the filament is 12μ wide and 170μ long. The filament is slightly tapering towards the apex. The apical cell is like a head (Fig. 1, 3). Part of a 23-μ wide filament is shown in Fig. 1, 4. On the double wall here and there small warts can be seen. Part of a 10-μ wide filament is illustrated in Fig. 1, 5. In part of a 16-μ wide filament, here and there the double cell wall can be easily seen (Fig. 1, 6).

Part of the filaments described here may possibly be indigenous to the meteorite.

ASTROPHYSICS

Polarization of the Light from the Magellanic Clouds

The importance of studies of the polarization of starlight in galactic research has been recognized for some time, and interpretation of the results in terms of paramagnetic interstellar grains preferentially orientated in the galactic plane by a general galactic magnetic field appears well supported. The possibility of observing polarization of light from other galaxies has been investigated[1–3]. Two extragalactic systems which seem to have escaped attention in this respect are the Magellanic Clouds.

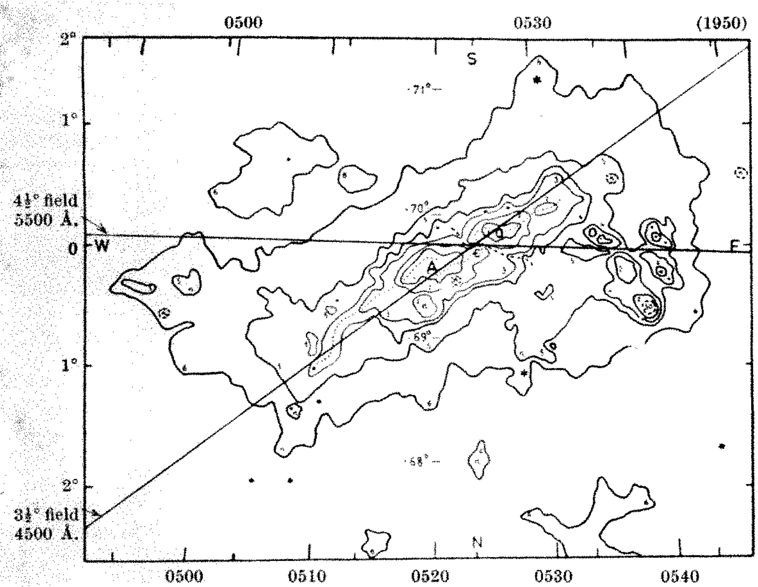

Fig. 1. Plane of polarization of the Large Magellanic Cloud for two field sizes drawn on the isophote map in blue light as determined by de Vaucouleurs (*Astron. J.*, **62**, 71; 1957)

In June–July 1961, during an expedition to a high-altitude observing site at Chacaltaya in the Bolivian Andes (16° 19′ S., 68° 10′ W.; 17,100 ft.) with the principal aim of making a detailed photometric study of the Zodiacal Light, the polarizations of the Large and Small Magellanic Clouds (LMC and SMC) were measured. Because of the very transparent skies experienced at Chacaltaya the extinction corrections in the photometry of extended objects such as the Zodiacal Light or the Magellanic Clouds could be reliably made. The instrument used was a photoelectric polarimeter with an electronically operated variable retardation plate as analyser and a piece of polaroid as detector. The instrumental and observational details will be described fully in a later publication. The observational results are summarized in Table 1.

Table 1

	Field (deg.)	Position angle (deg.)	Degree of polarization (per cent)	Effective wave-length (Å.)	No. of observations
SMC	4½	177	24 ± 5	5500	16
LMC	3½	126	25 ± 5	4500	46
LMC	4½	88	33 ± 7	5500	13

The position angle gives the orientation of the plane of polarization, here defined as the plane of vibration of the electric vector, measured east of north. The errors in the degree of polarization are due mostly to the variation in the intensity of the background light of the sky from night to night; this was because the night sky photometer records, from which the background correction was determined, were obtained on different nights from those on which the polarization measurements were made. This night-to-night variation amounted to ± 15 per cent. The difference of 38° between the position angle as determined in blue light for the LMC with a 3½° field and the position angle in yellow light with a 4½° field is not entirely understood but may possibly be due to the following cause. The telescope was set using the circles and then adjusted by the slow motion to the Cloud centre using the rather sharp maximum on the meter recording intensity. This means that the field centre may have been different in the two cases because the yellow and blue isophotes will not coincide for the same field size; also the 4½° field may introduce additional structural features which may further separate the centres of the two fields and also directly influence the orientation of the polarization plane. Fig. 1 shows an isophote map of the LMC for blue light with the planes of polarization for the two field sizes drawn in. Each observation consists of one determination of the degree of polarization at a given position angle. While there seems to be no obvious correspondence between any optical feature and the plane of polarization in the case of the Small Cloud, for the Large Cloud the polarization plane for the 3½° field lies very close to the bright bar, shown as a dotted line in Fig. 1. The values found for polarization of the light from other galaxies[1–3] lie between 4 and 12 per cent for 11 galaxies of either spiral or elliptical type; two other galaxies, *NGC* 3077 and *NGC* 4449, both of irregular type, were found by Vashakidze[3] to have polarizations equal to 15 and 21 per cent, respectively. The latter is a Magellanic type irregular galaxy. Any interpretation of these results in terms of structural features, differing ratios of gas to dust and of magnetic fields is clearly premature; but it is likely that a detailed polarimetric study of bright nearby systems, particularly the Magellanic Clouds, will enable such an interpretation to be made.

I thank Prof. D. E. Blackwell, who planned the expedition to Bolivia and so made this work possible, the Royal Society, who financed the expedition, Mr. D. W. Beggs, who designed the electronic equipment, and the Department of Scientific and Industrial Research for a maintenance grant.

PHYSICS

Burst-Type Signal from Small-Field Aurora

Photoelectric observations of luminosity fluctuations in small-field aurora have already been reported[1]. This communication illustrates some cases of burst-type signal recorded in two channels at Saskatoon (52·1° N., 106·6° W.). As briefly outlined in the earlier report, signals from two fields each 0·55° in size and separated from each other by 3° were recorded using a two-channel Sanborn recorder.

Fig. 1 *a*, *b* and *c* shows the signals from different auroral forms. The signal-burst has a pulse-like structure. These pulses may be sharp as well as broad. There could be one or several pulses in a burst. The pulse-length has a range of 0·5–5 sec. and the pulse recurrence time varies from 0·5 to 10 sec. The duration of the signal is 60–80 sec. The auroral form as visually observed in each of the three cases was of intensity II–III according to the international brightness coefficient scale or corresponding to 10–100 kilo rayleighs.

Fig. 2 *a* and *b* shows the signal from an unusual pulsating form. The intensity of this form as observed visually was only I–II or 1–10 kilo rayleighs. The signal looks like a combination of several bursts having pulse-like structure with relatively longer smooth oscillations. These low-amplitude short pulses last 0·1–0·3 sec. with recurrence time in the range 0·1–0·5 sec. The relatively longer oscillation periods vary between 4 and 5 sec. and less sometimes. This type is a less frequently recorded signal. When recorded it is seen to last for several minutes.

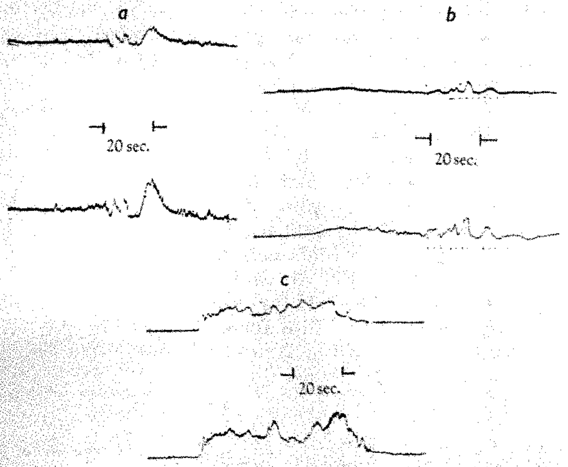

Fig. 1. *a*, Signal from a flaming aurora; *b*, signal from a corona; *c*, signal from a rayed band

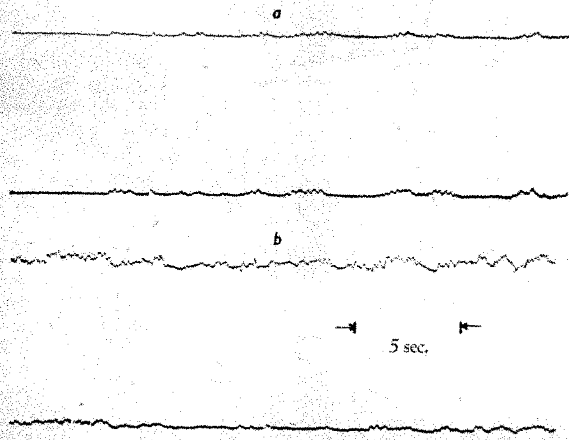

Fig. 2. *a* and *b*, Signal from a pulsating aurora

The similarity in the signal-pattern in the two channels is striking. Quiescent forms of aurora are not seen to give this type of signal in the two channels. In the cases of active forms illustrated in Fig. 1, possibly but not certainly, the effect of simultaneous intensity coruscations and motion might be involved. Perhaps, the excitation processes have also something to do particularly in the type of signal as in Fig. 2.

I thank Dean B. W. Currie and Dr. G. G. Shepherd for their help in this work.

Heating in Capillary Flow

The temperature profile in an essentially Newtonian liquid in laminar flow in a capillary has been measured experimentally. Previously the phenomenon of capillary heating (that is, heat produced by the internal friction of liquids in flow in a capillary) had been the subject of extensive theoretical treatment[1,2]; but with little experimental verification. These experiments show that the system is essentially adiabatic, in contradiction to widespread belief that the 'isothermal wall' condition existed.

Measurements were made on a mineral oil thickened with 3 per cent polyisobutylene, with a viscosity of 1 poise. The degree of non-Newtonian behaviour at the shear-rates used is insignificant. Stainless steel, conically tipped capillaries were used and the thermocouple was made of very fine (0·003 in.) iron and constantan wire. The thermocouple was mounted on a microscope feed and could be moved across the diameter of the stream in increments of 0·0002 in. The temperature measured was, of course, some integrated temperature over an increment of the

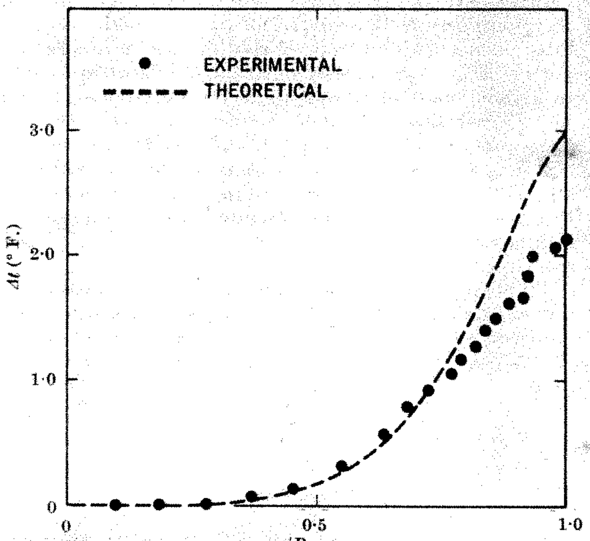

Fig. 1

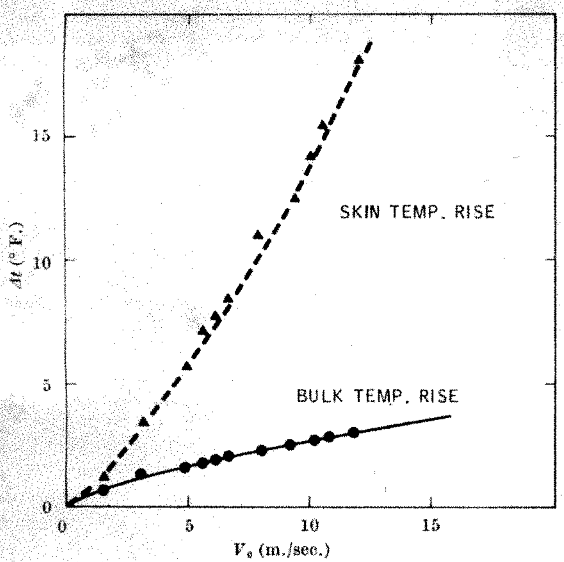

Fig. 2

stream equal in width to the thermocouple's diameter. The diameter of the stream was approximately 1 mm., and the measurements in the stream were made within 0·004 in. of the outlet of the capillary. Temperature measurements were also made of the conical tip of the capillary itself in order to verify the measured 'skin' temperature. The two temperatures were approximately equal over the entire range of experiments.

A typical profile is shown as measured in Fig. 1. Contrary to popular belief, the point of maximum temperature rise is seen to be at the wall rather than in the centre of the stream, proving the existence of the adiabatic condition. The dotted line is the prediction, under the same experimental conditions, from Brinkman's[1] equations for the adiabatic case. As would be expected, since the system is truly in steady state and not quite adiabatic, the heat transferred manifests itself at the wall in a measured temperature lower than that which would exist for the completely adiabatic case. Notwithstanding the simplifying assumptions of Brinkman's calculation and the experimental deviation from true adiabatic conditions, the comparison is seen to be quite good. Fig. 2 illustrates the variation of rise in skin temperature with velocity. A velocity of 12 m./sec. (corresponding to a shear rate of about 10^5 sec.$^{-1}$) gives rise to an 18° F. increase in temperature at the wall. On the same plot can be seen the stream's bulk temperature rise. At 10 m./sec. the increase in skin temperature is about 7 times the increase in bulk temperature. Preliminary results also show the temperature profile to depend on capillary length as predicted from theory.

These observations are not only of significance in high shear capillary viscometry, but also are, on the basis of initial tests, critical in the evaluation of viscous and elastic components in free-flying jet work and in polymer extrusion investigations.

Electrical Resistance of Oxide Films formed on the Roll of a Corona Discharge Roll-Type Separator

During the course of an investigation into the underlying principles of a corona-discharge roll-type separator (Fig. 1), very inconsistent results were obtained, which were eventually traced to the erratic formation of oxide film on the brass roll.

In order to examine these oxide films more conveniently, a polished brass plate, about 6 in. × 12 in., was set in an upright position in front of, and touching, the roll so that the corona discharge was beamed on to the plate from a distance equivalent to that of the nearest point of the drum (3¾ cm.). The corona discharge was then passed for 3 hr. under normal conditions (30 kV. at 200 μamp). A clearly visible oxide film was formed, which had striations at right angles to the corona wire due to non-uniform emission from the wire (Fig. 2). The experiment was repeated using plates made of stainless steel, chromium-plated brass, and duralumin.

Some trouble was experienced in making contact with the oxide film so as to measure the electrical resistance through the thickness of the film by the conventional d.c. Wheatstone bridge method. 'Free' electrodes using mercury droplets or small gold-plated spheres on a loose copper 'spring' were tried; results from the former were very erratic, while it proved impossible to put sufficient pressure on the latter without breaking through the delicate film of oxide. Various types of conducting paint were then tried; it was eventually found that slightly diluted colloidal graphite applied with a hypodermic syringe (without a needle) gave a 2–3-mm. diameter electrode which was stable and strong, had no appreciable intrinsic contact resistance and did not tear the oxide film on drying. Contact was made by allowing a soft pencil lead to rest on the graphite dot.

Apart from its physical hardness, three properties of the oxide film which can be inferred from the resistivity curves (Fig. 3) and which determine the suitability of a metal for roll construction are: (*a*) The sensitivity of film formation to ion current. The curves shown in Fig. 3 are smoothed plots drawn

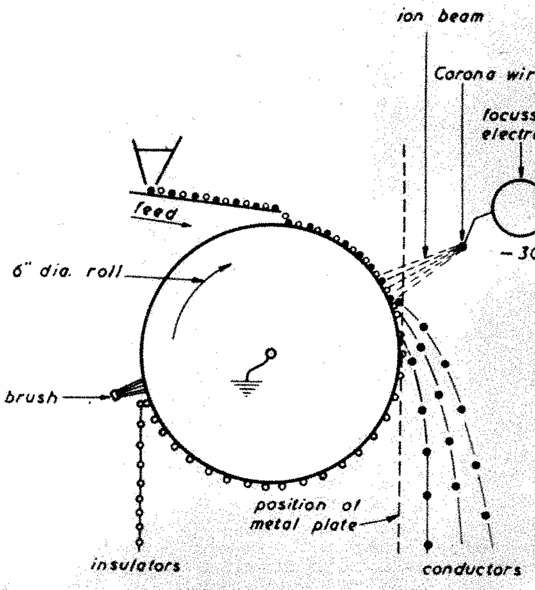

Fig. 1. Corona discharge roll-type separator

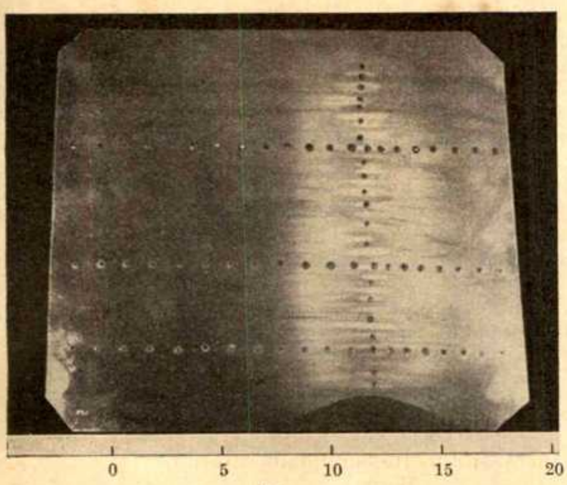

Fig. 2. Oxide film on brass plate

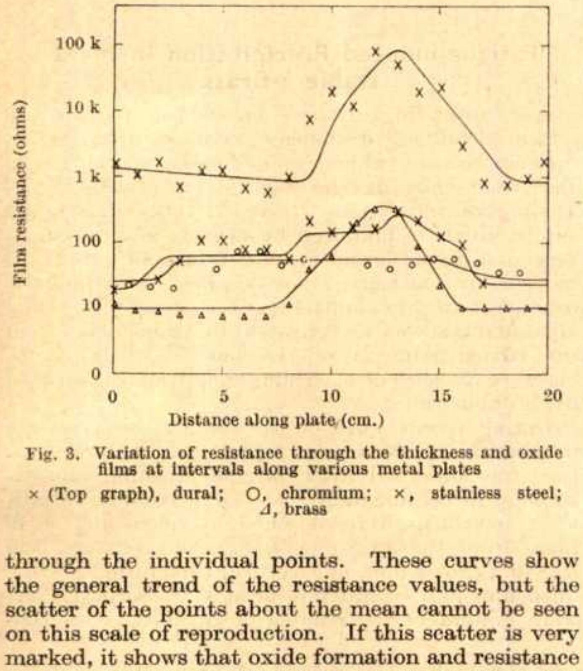

Fig. 3. Variation of resistance through the thickness and oxide films at intervals along various metal plates

× (Top graph), dural; O, chromium; ×, stainless steel; Δ, brass

through the individual points. These curves show the general trend of the resistance values, but the scatter of the points about the mean cannot be seen on this scale of reproduction. If this scatter is very marked, it shows that oxide formation and resistance are very sensitive to the local intensity of the corona discharge and this leads to erratic results in mineral separation. Similarly, the sharper the main peak of the curve, the more sensitive is the oxide film to ion current. (*b*) The absolute value of the resistivity of the oxide film exclusive of the main peak. This should preferably be low. (*c*) The overall range of resistivity values. The lower this range, the more suitable is the metal for roll construction.

Table 1. OXIDE FILM PROPERTIES

Metal	Mechanical* hardness	Sensitivity to corona	Range of resistance (π)
Brass	Soft (unsuitable)	Very sensitive (unsuitable)	10–300 (fair)
Chromium	Hard (suitable)	Insensitive (suitable)	20–60 (suitable)
Duralumin	Hard (suitable)	Not very sensitive (suitable)	500–80 k (unsuitable)
Stainless steel	Hard (suitable)	Not very sensitive (suitable)	20–300 (fair)

* This is apparent abrasive resistance.

Table 1 shows the results of the experiment for the four metals used, and the degree of suitability of each metal for use as roll material.

METALLURGY

Fatigue Failure in Copper Single Crystals at Low and High Amplitudes of Torsion

IN the discussions of fatigue failure under cyclic stresses a distinction should be made, as has been pointed out by Wood[1], between cycling at low-strain amplitudes and cycling at high-strain amplitudes. By low-strain amplitudes are meant amplitudes in the flat part of the *S–N* curve where the specimens are relatively long lived. High-strain amplitudes are those on the steep part of the *S–N* curve corresponding to relatively short lives. In Fig. 1 is sketched an *S–N* curve wth the *H* (hardening) and *F* (fatigue) regions indicated according to Wood. In the course of work being carried out on the modes of fatigue failure of oriented single crystal copper rods cycled in alternating torsion some rather striking examples of the distinction between high- and low-amplitude fatigue were observed.

The single crystals were grown in two orientations by Bridgman's technique from 99·999 per cent pure copper in graphite moulds. As grown, the crystals were about 4 in. long and 3/8 in. in diameter. Prior to cycling in the torsional fatigue machine a gauge-length of 1¼ in. long and 1/4 in. in diameter was electrolytically machined into the central portion of the as-grown crystals. The crystals shown in Fig. 2*a* and 2*b* have a cube edge or $<100>$ direction along the longitudinal axis, while the crystals shown in Fig. 3*a* and 3*b* have a cube diagonal or $<111>$ direction along the longitudinal axis.

The crystal shown in Fig. 2*a* was cycled in torsion at an amplitude of ± 0·0019 surface shear strain for 5×10^6 cycles. It appears that in this case the crystal failed by growth of fissures on the octahedral planes until the remaining portion of the cross-section of the crystal was no longer able to support the

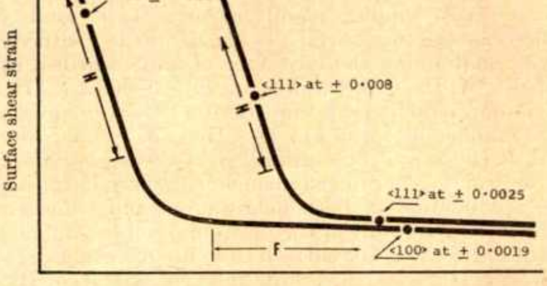

Fig. 1. *S–N* curve showing the *H* and *F* regions. The relative locations of the crystals described in the text are as indicated. Preliminary experiments lead to the establishment of distinct *S–N* curves for crystals of different orientation as shown in the figure

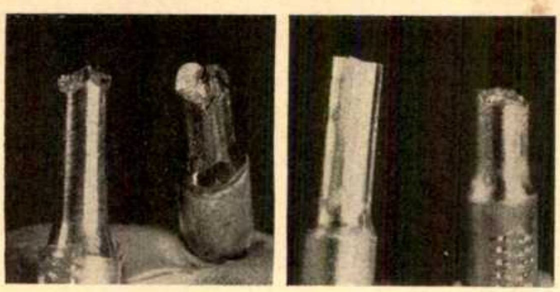
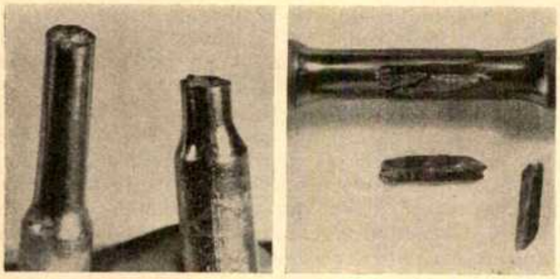


(*a*) (*b*)

Fig. 2. *a*, < 100 > axis crystal cycled at low amplitude (*F* region) to failure. Fracture surface follows {111} planes. *b*, < 100 > axis crystal cycled at a higher amplitude (*H* region) to failure. Fracture surface is irregular



(*a*) (*b*)

Fig. 3. *a*, < 111 > axis crystal cycled at low amplitude (*F* region) to failure. Fracture surface composed of segments of {111} planes. *b*, < 111 > axis crystal cycled at a higher amplitude (*H* region) to failure. Chips with sides approximating {211} planes are loosened during the cycling

applied stresses. In this case there is no evidence of the formation and propagation of irregular microcracks in the usual sense. The crystal in Fig. 2*b* was cycled at an amplitude of ± 0·012 for 6×10^3 cycles. In this case no fissures were formed of the kind described by Wood; but, rather, a series of ridges and grooves formed in 90° sectors around the circumference of the crystal. Failure occurred following the formation and propagation of cracks in the grooves.

The mode of failure of the < 111 > axially oriented crystal is shown in Figs. 3*a* and 3*b*. The crystal shown in Fig. 3*a* has been cycled at a surface shear strain amplitude of ± 0·0025 for 4×10^6 cycles. Fissures have penetrated to some distance along the octahedral plane perpendicular to the crystal axis. Due to the fact that at certain positions around the circumference of the crystal the resolved shear stress on the cross slip plane is equal to that on the primary plane, cross slipping readily occurs. This results in the final fracture surface being segmented although still maintaining the character of an octahedral slip plane. At the higher amplitude of ± 0·008 a < 111 > axially oriented crystal failed after 3×10^5 cycles in the manner shown in Fig. 3*b*. Here, as in the case of the < 100 > axis crystal cycled at the higher amplitude, there is no development of fissures but rather the production of both longitudinal and transverse cracks which result in the ejection of chips similar to that in Fig. 3*b*. The sides of this chip have an interior angle of 120° which, taking into consideration their orientation on the crystal, means that they may be bounded by planes of the form {211}. Here, as in the case of the < 100 > axis crystal, the appearance of the crystal on failure is entirely different for low and high amplitudes; but, nevertheless, the mode of failure is still governed by the crystallographical symmetry of the crystal. It would appear, from these observations, that any theory of fatigue damage based on dislocation interactions will have to be for a specified amplitude; that is, the cyclic movement of dislocations at small amplitudes leads to an entirely different mode of crystalline damage than the dislocation movement at higher amplitudes. This difference may possibly be correlated with the observed sequence in work hardening, that is, the easy glide, linear hardening, and parabolic regions of the work hardening curve.

A more detailed account of the crystallography of the torsional fatigue failure of the oriented single crystals is being submitted for publication elsewhere.

Fatigue-induced Precipitation in Metastable β-Brass

A NUMBER of instances have been recorded in which metallurgical changes have occurred due to fatigue stressing which would not have occurred in the same time at the same temperature in the absence of the fatigue stress[1–4]. The changes are similar to those produced by heating and appear to be caused by either an increased diffusion-rate or an increase in nucleation sites. Two most obvious examples are the apparent over-ageing of certain aluminium alloys investigated by Hanstock[1,2] and the virtual removal of the long incubation time observed in normal aged aluminium alloys reported by Stubbington[4].

During recent work on the fatigue behaviour of metastable β-brass similar fatigue-induced precipitation was observed after fatigue stressing and on subsequent heating at 200° C. All metastable β-cantilever specimens were obtained by quenching 60/40 brass from the all β-region. Specimens were held at 840° C. for 2 min. in a vertical tube furnace before quenching into saturated brine at 4° C. Surface layers were ground off to remove de-zincified layers con-

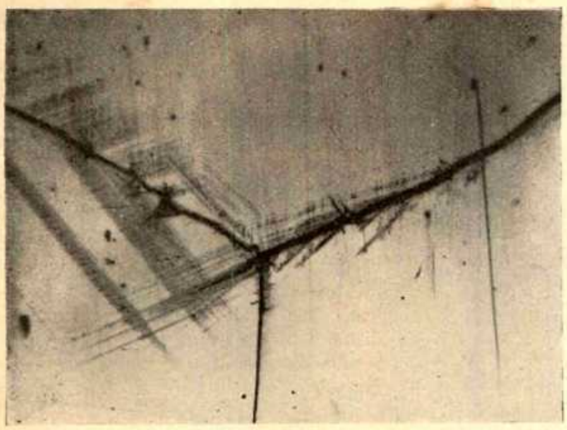

Fig. 2. Surface of fatigued metastable β-brass specimen. Fatigue-induced precipitation adjacent to grain boundaries. (Unetched. × c. 420)

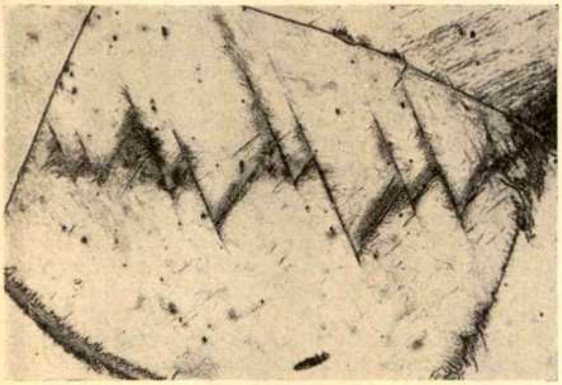

Fig. 3. Surface of fatigued metastable β-brass specimen after tempering for $1\frac{1}{2}$ hr. at 200° C. Preferential precipitation at a fatigue crack. (Etched in alc. $FeCl_3$. × c. 248)

taining phases other than metastable β. The resulting specimens were carefully mechanically polished and finally electro-polished before fatiguing in reverse plane bending at a frequency of 8,400 c./min. Certain specimens were tempered after fatiguing for $1\frac{1}{2}$ hr., at 200° C.

Fatigue-induced precipitates were observed to form either in slip markings or adjacent to grain boundaries (Figs. 1 and 2). A glancing-angle X-ray photograph indicated that these precipitates were face-centred cubic in type and that their cell dimensions were approximately 3·65 Å. (at 21° C.). Fatigued material showing no precipitation, after tempering showed preferential precipitation of α-solid solution in areas where damage had been greatest and in general an increased amount of precipitation (Fig. 3).

The fatigue-induced precipitation observed is considered to be α-solid solution. The precipitation is attributed to an acceleration of diffusion due to vacancies and interstitials produced in concentrations above their equilibrium values by the motion of dislocations under fatigue stresses. The precipitation observed after tempering fatigued material is thought to be due to the large number of nuclei present in fatigued material. Thomas and Whelan[5] have shown that dislocation loops formed by the collapse of vacancy disks can act as precipitation nuclei and recent observations have shown many such dislocation loops in fatigued material.

CRYSTALLOGRAPHY

Non-Crystalline Excrescences from Heated Silica

THREE different forms of filamentary silica have been discussed recently. Jaccodine and Kline[1] reported the growth of whiskers on the devitrified surface of vitreous silica which had been heated in a nitrogen stream for 24 hr. at 1,425° C. Abrahams and Stockbridge[2] showed that these growths were proper whiskers (Nabarro and Jackson[3]) of high-cristobalite with [111] as whisker axis. They also examined whiskers found on hydrothermally grown crystals of α-quartz[4], and showed that these were α-quartz crystals elongated along [0001]. Haller[5] grew fibres of silica, non-crystalline and optically isotropic, on heated platinum surfaces (temperature about 1,100° C.) exposed to a mixture of silicon tetrafluoride and water vapour in a nitrogen stream.

We wish to report the formation of excrescences of silica in circumstances different from the foregoing. These have been found in blisters formed on the outer surfaces of 'Vitreosil' furnace-tubes held, in air, at temperatures of 1,100–1,200° C. for periods of up to 8 weeks. The material of the tubes was originally vitreous silica; but this partially devitrified after some weeks at temperature. Blisters formed during this period and the tubes eventually fractured. On breaking open the blisters it was found that these contained excrescences of silica. Although there were opaque crystalline regions within the blisters, the excrescences all originated from regions that were still vitreous. They were optically isotropic, and X-ray diffraction patterns (copper $K\alpha$ radiation) showed only the diffuse rings characteristic of non-crystalline

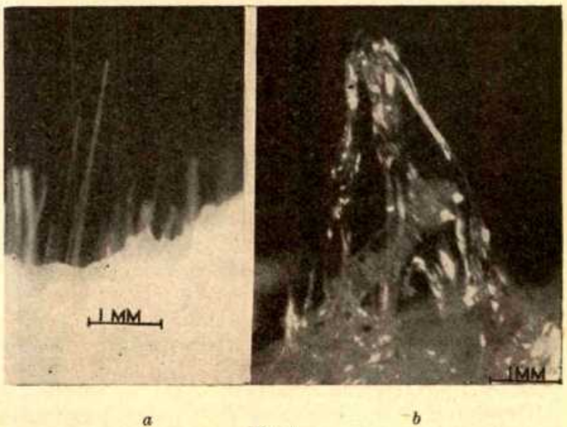

Fig. 1

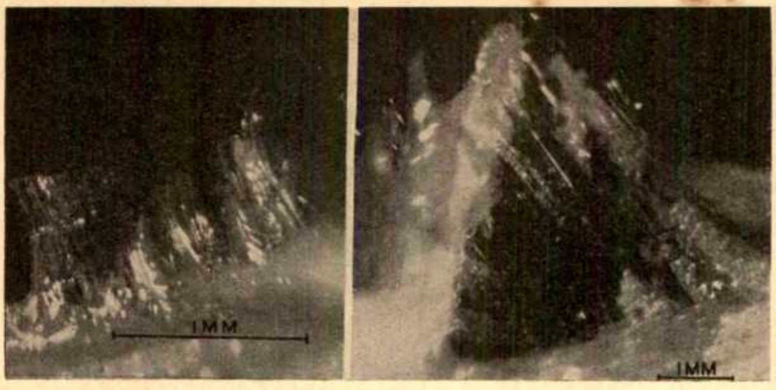

a *b*

Fig. 2

material, with no sign of preferred orientation. Some excrescences were filamentary in form (Fig. 1*a*), while others showed more complex arrangements of threads (Fig. 1*b*). Another characteristic shape was that of long, narrow ridges (Fig. 2*a*).

In many cases the excrescences stretched across the narrower regions of a blister (Fig. 2*b*). This observation suggests that the excrescences described here were formed by vitreous silica, which after softening to a plastic condition was stretched between roof and floor of the slowly extending blister. Filaments formed in this way would break if the extension became too large, and a number of examples were in fact seen of 'stalactite–stalagmite' pairs in complementary positions on top and bottom inner surfaces of blisters. No growths were seen on the outer surfaces of the blisters.

The devitrified regions of the tube were shown by X-ray diffraction to be low-cristobalite. Spotty powder patterns (crystallite size about 0·05 mm.) were obtained. No excrescences were seen to emerge from these crystalline regions and it is probable that the temperature was too low for the growth of proper whiskers.

Thermal Formation of Etch Pits after Polymorphic Transformation

LINES of etch pits form at phase, twin, and subgrain boundaries on the surface of crystals of thallous nitrate maintained at temperatures greater than 70° C.

The room temperature orthorhombic form, in which the cations are in a primitive pseudo-tetragonal array[1], is in equilibrium at 76° C. with a related pseudo-cubic trigonal structure[2]. In one mechanism of the change orthorhombic to trigonal the orientation relationship $(010)_o//(011)_{pc}$ and $<101>_o//<1\bar{1}1>_{pc}$ is maintained[3], the interface being parallel to $(010)_o$. As there is also a shape deformation, the change shares the main features of martensitic transformations[4]. The pseudocubic form is in equilibrium at 143° C. with a closely related cubic phase. Good crystals about 0·3 mm. long with an impurity content of approximately 500 p.p.m. were grown from aqueous solution. To investigate etching in untransformed crystals slip and twinning were introduced by applying pressure. Undeformed specimens were used for experiments involving transformation.

When the deformed crystals were held at 70° C. pits appeared along twin boundaries but not along the slip boundaries. In the orthorhombic to trigonal transformation, pits formed at stationary interfaces, becoming clearly visible under the microscope after 5 hr. at 85°–90° C. After this period the number and position remained constant. The spacing of pits was uniform within each row, but differed at separate interfaces within the same crystal by a factor of up to 2. The spacings in different crystals ranged from 0·6μ to 2·4μ. No pits were observed along striations left on the trigonal form parallel to the interface.

Crystals annealed in the trigonal phase for 10 hr. at 110° C., then kept in the cubic form at 150° C. for one to two days, showed either almost randomly placed pits, or an irregular network. In the former case there were always close to 10^7 pits per cm.^{2}. In the latter case a typical value for the spacing of pits was 1μ, and the rows clearly outlined subgrains of mean area 50μ^2. The presence of subgrains is consistent with our X-ray observations that this transformation creates some strain and annealing produces polygonization[5].

Although proof is as yet lacking, the appearance and arrangement of the pits make it highly probable that these correspond to dislocations, though not necessarily to all the dislocations present. Thermal etching of dislocations has been observed on a few metals[6] and on aluminium oxide crystals[7]. Dislocations at the phase interface could be associated with the arrays by means of which the moving interface in a martensitic transformation has been described[4,8].

This work suggests that: (1) preferential thermal etching of dislocations occurs on this ionic material; (2) dislocations expected to be present in the coherent interface between two solid phases have been revealed by etch pits; (3) subgrains are present after some polymorphic transformations, and in this example their mean area was 50μ^2.

GEOCHEMISTRY

Separation Techniques in Sedimentary Geochemistry illustrated by Studies of Boron

THE geochemical distribution of elements in sedimentary rocks is genetically complex because they may be concentrated in the detrital fraction or resistates; the clay fraction; the chemically precipitated fraction; and the organically precipitated fraction. It follows that advances in sedimentary geochemistry depend on increased knowledge of the distribution of elements in these four constituents. Hence, analysis of the bulk rock, which is generally the standard practice in igneous geochemistry, may not be a successful method when applied to problems in sedimentary geochemistry.

An investigation of boron in British sedimentary rocks illustrates some of the problems and techniques involved in the separation of different constituents of a sedimentary rock. Boron is concentrated in clays and in the resistates mainly in tourmaline. A method to differentiate between boron in the clay and in the resistate fractions is described here and may prove applicable to other problems of sedimentary geochemistry. Detailed results and conclusions concerning the geochemistry of boron will be reported fully elsewhere.

Harder[1] followed by Frederickson and Reynolds[2] showed that much of the insoluble boron in sediments is concentrated in the clay mineral illite. In these early studies clays were isolated from the resistates by size fractionation and were assumed to be tourmaline free. During the present investigation it was found that size fractions less than 0·5μ could be isolated by sedimentation in beakers of one litre capacity. However, consistent success with this simple method was only achieved when the experimental conditions were rigidly controlled.

Carbonate rich rocks were disaggregated by solution in 2 normal hydrochloric acid. Low carbonate rocks were ground to B.S.S. 100 mesh size and treated with hydrochloric acid. After reaction with acid ceased, the samples were washed at least ten times by repeated decantation with distilled water and dispersed in 1/25 normal sodium carbonate solution. Different size fractions were isolated by sedimentation in beakers of one litre capacity, followed by decantation at the time-intervals shown in Table 1.

Table 1. EMPIRICAL RELATIONSHIP BETWEEN GRAIN SIZE AND SETTLING TIME FOR A 10-CM. COLUMN AT 70° F.

Grain size (μ)	Settling time Days	Hr.	Min.	Sec.
60·0	–	–	–	30
30·0	–	–	1	40
10·0	–	–	18	0
5·0	–	1	13	0
2·0	–	7	47	0
1·0	1	7	7	0
0·5	5	4	30	0

The coarse fractions were recovered by filtration and the finest fractions were concentrated in a centrifuge. If a suitable centrifuge is not available, a few drops of concentrated hydrochloric acid are added to the fine fractions. The acid causes flocculation and aids recovery of the finest fractions.

The amount of illite in any size fraction could be computed from potassium analyses according to the following formula, because X-ray diffraction studies showed that other potassium-bearing minerals were absent.

$$\text{Per cent pure illite} = \frac{\%K_2O}{8{\cdot}5} \times 100$$

The amount of illite calculated by the above method is much less than the amount observed from X-ray diffraction studies. However, illite in sediments is degraded compared with muscovite mica and the potassium content provides a measure of the number of muscovite-type layers in the illite. Since Harder[3] has shown that boron is incorporated in the muscovite structure it is better to compare boron concentration with potassium content rather than with illite content estimated from X-ray studies.

Potassium was estimated in solution by a standard flame photometric procedure. The solution was prepared by digesting 100 mgm. of sample with 15 ml. of hydrofluoric acid and 3 ml. of sulphuric acid in a small polythene beaker. The acid was fumed off over a steam bath for 24 hr. and the remaining salts were washed into a small glass beaker. The contents of the glass beaker were reduced by evaporation to about 3 ml. and strongly heated. Nitric acid was cautiously added dropwise to oxidize carbonaceous matter. After this treatment, warming with distilled water brought all salts into solution.

The above technique involves slightly more handling than the standard procedure in which platinum crucibles are used. However, the number of samples that can be prepared at any one time is not restricted by availability of expensive apparatus. If samples are analysed in batches of 25 the speed of the method compares favourably with X-ray fluorescence used by Frederickson and Reynolds[2].

The boron content of the different size fractions was determined spectrographically. Boron 2497·7 was used as the analysis line and a beryllium triplet at 2494·6 was used as an internal standard line. The true boron content of pure illite (adjusted boron content) was calculated according to the following formula:

$$\text{Adjusted boron} = \frac{8{\cdot}5}{\%K_2O} \times \text{observed boron}$$

The observed and adjusted boron contents of illite in size fractions of the insoluble residue from the Main Limestone, Yoredale Series, Hawes, Yorkshire (Nat. Grid Ref. 34/835944), is shown in Fig. 1. Although observed boron decreases in the coarser fractions due

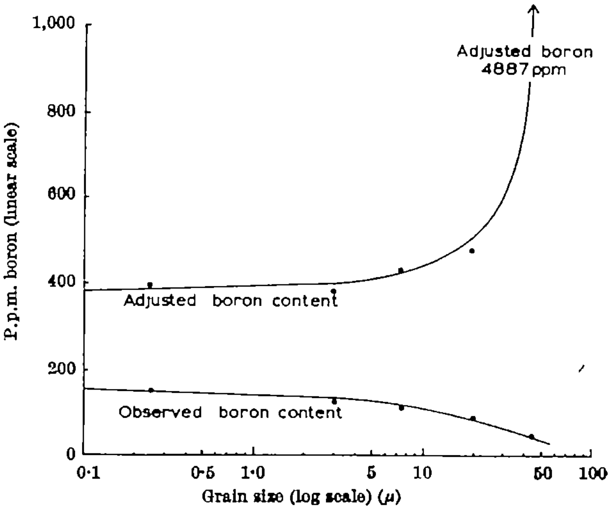

Fig. 1

to decrease in the amount of illite, adjusted boron increases. This is believed to indicate that some of the boron in the coarser size fractions is contributed by tourmaline. In particular, the boron content of pure illite decreases to a constant value in size fractions less than 5µ, indicating that the effect of tourmaline in these very fine fractions is negligible. Six other samples which were investigated showed a similar relationship between grain size and boron.

Frederickson and Reynolds[2] proposed that the boron content of pure illite was closely related to the salinity of the water in which the illite was originally deposited. The boron content of pure illite has been determined for seventeen rocks the inferred depositional environment of which varies from fresh or brackish water to evaporitic. The adjusted boron content of pure illite from normal marine rocks in the Yoredale series ranged between 400 and 650 p.p.m. In dolomites from the top of the Lower Magnesian Limestone of Yorkshire the adjusted boron content of pure illite ranged between 691 and 768 p.p.m., and in halite of unknown age from a borehole in Tanganyika, Africa, the adjusted boron content was 961 p.p.m. These results agree with the published results of Frederickson and Reynolds[3].

The adjusted boron contents of illite from two supposedly freshwater limestones from the Upper Jurassic Purbeck Beds of the south of England were 509 p.p.m. and 554 p.p.m. Marine illite from the same formation was found to have an adjusted boron content of 520 p.p.m. These values do not agree with the very low concentration of boron recorded by Frederickson and Reynolds[2] in illite from freshwater environments.

RADIATION CHEMISTRY

Phase Effects in the Radiation Chemistry of Organic Compounds which may arise from Long-Range Energy Transfer

WE have recently investigated the γ-ray-induced destruction of the solute (S = either I_2, $FeCl_3$ or DPPH) in dilute liquid and solid solutions in the organic solvents listed here. For all liquid solutions at 30° C. $G(-S)$ is independent of solute concentration and dose and shows the expected dependence on solvent structure (Table 1). In contrast to this simple situation the corresponding solid solutions show the following two distinct types of radiation response:

(1) Crystalline solutions in diethyl ether or dioxan and glassy solutions in phenetole or 2-methyl tetrahydrofuran have $G(-FeCl_3)$ values which are independent of dose, temperature and solute concentration and are smaller than the values for the corresponding liquid solutions.

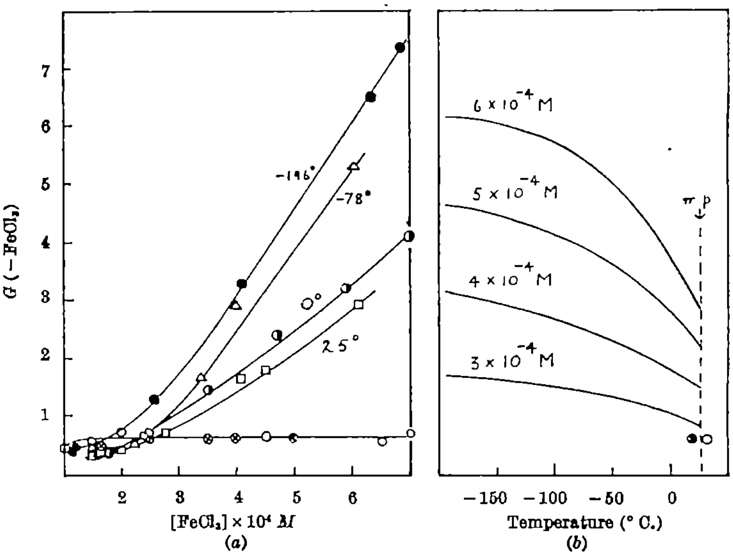

Fig. 1. $G(-FeCl_3)$ for solutions of $FeCl_3$ in diphenyl ether. (*a*) Effect of changing solute concentration. Liquid at 30° (○), supercooled liquid at 25° (⊗), crystalline solid at 25° (□), 0° (◐), −78° (△) and −196° (●). (*b*) Effect of temperature at different solute concentrations

(2) $G(-S)$ for crystalline solutions of $FeCl_3$ in the first four solvents in Table 1 and of iodine in diphenyl ether or phenetole[2] is markedly dependent on concentration, increases with diminishing temperature of irradiation and may be very much larger than the value in the liquid phase. This behaviour is illustrated in Fig. 1.

Low-temperature spectrophotometric studies of 2-methyltetrahydrofuran glass shows that a reaction actually occurs in the solid phase[3]. Although the same technique is inapplicable to the crystalline systems, a number of other experiments indicated that there is no segregation of the solute and that type (2) behaviour is determined by reaction occurring in the solid solution during irradiation. That type (2) behaviour is controlled by the state of aggregation rather than by any effect of temperature *per se* is shown by the observations that supercooled solutions in diphenyl ether show behaviour characteristic of the liquid at a higher temperature rather than the solid at the same temperature (Fig. 1), and that glassy phenetole solutions conform to type (1), whereas crystalline phenetole solutions at the same temperature conform to type (2). Since the solute is itself immobile, the action of the radiation must be to produce some entity in the solvent which is able to migrate to, and cause chemical change in, the solute. The marked dependence of $G(-S)$ on $[S]$ in type (2) systems indicates that the mean migration distance

Table 1

Solute / Solvent	$FeCl_3$	I_2	DPPH
Benzene	0·86 ± 0·12[1]	0 41 ± 0 04[1]	0 69 ± 0·03[1]
Diphenyl ether	0·66 ± 0·05	0·38$_5$ ± 0 04[2]	0·40 ± 0·01
Diphenyl methane	0·90 ± 0·05		
Phenetole	0·85 ± 0 05		
p-Dioxan	3·5 ± 0 25		
2-Methyl-tetrahydrofuran	4 0 ± 0·2		
Diethyl ether	12·5 ± 1		

must be limited and since $G(-S)$ is still increasing with $[S]$ at the highest value of $[S]$ which can be used (10^{-3} M) this distance cannot exceed 75 Å. The migrating entity could be either energy, ionization or an electron. We consider ionization transfer to be unlikely because $\mathscr{I}_{FeCl_3}$ is greater than the ionization potential of the aromatic molecules comprising the solvent in type (2) systems. Electron transfer can be excluded because the large G_{e^-} values which it would be necessary to postulate to account for the highest $G(-S)$ values (>12 for the benzene–$FeCl_3$ system) are irreconcilable with probable W values and ionization potentials of the solvent, and are much larger than those recently measured by Hamill *et al.*[3]. Moreover, if naphthalene were a more efficient electron trap than $FeCl_3$, its presence should cause $G(-FeCl_3)$ to be smaller. In fact, although it does cause $G(-FeCl_3)$ in 2-methyl tetrahydrofuran to become zero, it has no effect on $G(-FeCl_3)$ in phenetole. We are therefore left with energy transfer as the only possible mechanism, and this hypothesis has many merits. If the process is one of transfer by inductive resonance, as described by Forster[4], a necessary condition is overlap of the absorption spectrum of the solute with the emission spectrum of an excited state of the solvent. This condition is satisfied by all those systems which give type (2) behaviour and by none which give type (1) when $FeCl_3$ or I_2 is the solute. Furthermore, the absorption spectrum of naphthalene overlaps more completely than that of $FeCl_3$ with the emission spectrum of phenetole, and the inhibiting effect of naphthalene in this medium and its lack of effect in 2-methyl tetrahydrofuran are thus readily explicable. It is also known that irradiation of solutions of $FeCl_3$ or I_2 by light of wave-length within the range 2500–3500 Å. causes photo-dissociation of these solutes so that chemical change in the solute is a likely consequence of energy transfer. The resonance transfer mechanism also predicts a dependence of $G(-S)$ on $[S]$ which is broadly in agreement with that observed. The efficiency of this transfer increases with the coupling energy, which is probably large in the type (2) systems studied and is therefore likely to increase with increasing density, that is, decreasing temperature, and it might also be expected that a high degree of structural regularity such as exists in benzene crystals would favour energy transport.

It is interesting to speculate whether persistence of structural regularities in liquids could be sufficiently large to enable a degree of donor-acceptor coupling which would permit energy migration. The radiation chemistry of dilute solutions of $FeCl_3$ in benzene[1] does provide evidence of the participation of excited benzene molecules, and unusual quenching effects in the radiation-induced fluorescence of terphenyl in benzene[5] support the notion that aggregates of 10–20 benzene molecules do exist.

We thank the Rockefeller Foundation for the gift of the cobalt source and the Department of Scientific and Industrial Research for a research studentship awarded to one of us (J. J. C.).

CHEMISTRY

Intrinsic Viscosity of Gelatin

THE intrinsic viscosity ($[\eta]$) is commonly used to characterize high polymers; but its determination is often complicated by adsorption of the high-polymer solute to the apparatus[1]. It has been widely assumed and has recently been categorically stated[2] that adsorption effects can be neglected in the determination of the intrinsic viscosity of gelatin. The examination of more than a score of gelatin samples in this laboratory indicates that under normal working conditions this is not so. Considerable errors attend the use of sintered glass filters in the preparation of samples through removal of significant amounts of gelatin by adsorption. The extent of this error depends on the size and porosity of the filter disk. For example, when 50 ml. of a 0·1 per cent solution of alkali-bone gelatin ($[\eta] = 65$ ml./gm.) in molar potassium chloride at pH 7 was filtered through a 2-cm. diameter disk, the adsorptions determined by chemical analysis of the filtrate[3] were 4, 7 and 13 per cent, for disks of porosity 1, 2 and 3 respectively. It is possible that the influence of this adsorption on the viscosity is greater than indicated by these figures since high-molecular-weight species of polymers are usually more readily adsorbed. When membrane filters (Membranfilter Gesellschaft No. 1) were used for filtering the solution, the adsorption was not detected analytically and may be presumed to be less than 1 per cent.

Adsorption also occurs to the capillary of the viscometer. A similar 0·1 per cent solution of gelatin was placed in an Ostwald viscometer (British Standard, size A) at 40° C. and the time of flow was determined. The solution was then removed and the viscometer was rinsed with saline solvent and filled with solvent. The time of flow of solvent was observed to be about 0·5 per cent higher than with a cleaned (50 per cent v/v nitric acid) viscometer. This small change in flow-time (1·0s) will, however, account for an 8 per cent error in viscosity number. The thickness of the adsorbed layer has been calculated from the increase in flow-time to be of the order of several hundred Ångstrom units. The thicknesses of 25–50 Å. determined by Pouradier and Roman[4] for the layers of gelatin adsorbed to silver bromide are not necessarily inconsistent with the above, since these authors derived the thickness from the weight of gelatin per unit area of surface and do not refer to the thickness of the layer in contact with solution. Both adsorption errors become increasingly important as the concentration is reduced, particularly below about 0·3 gm. gelatin/100 ml. Since the two errors are in opposition the shape of the viscosity number/concentration curves will vary with the exact experimental conditions. We have on two or three occasions obtained, we believe, quite fortuitously, linear relationships over the gelatin-concentration range 0·1–0·6 gm./100 ml. If membrane filters are used the viscosity number always increases as the concentration falls below about 0·25 gm./ml. This effect is most marked for high molecular weight fractions.

These two errors can be reduced but not eliminated by making intrinsic viscosity determinations in molar potassium thiocyanate at pH 7 (Fig. 1). The amount of gelatin adsorbed is somewhat less and the viscosity is about 10 per cent higher than in molar potassium chloride. Both facts tend to reduce the percentage error. With this solvent and membrane filters,

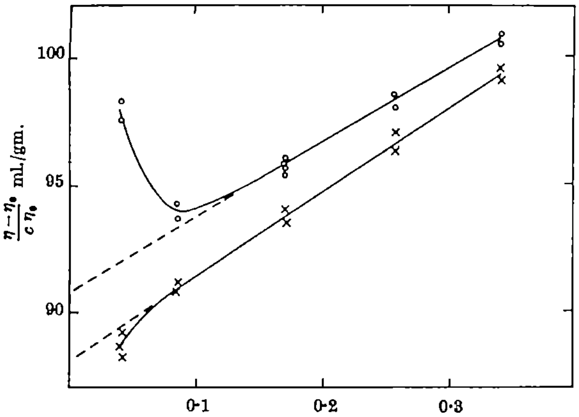

Fig. 1. Reduced viscosity ($\eta-\eta_0/c\eta_0$) as a function of the nominal concentration for solutions of an alkali-process gelatin fraction in molar potassium thiocyanate. ○, Filtered through a membrane filter; ×, filtered through a No. 2 sintered glass filter. The filters used were 2 cm. diameter in each case and 20 ml. of solution was allowed to pass before taking samples for test. The fall in gelatin concentration indicated by analysis amounted to 1 per cent for the membrane filtration at all concentrations, within experimental error, but varied for sintered glass filtration from 8 per cent at 0·1 gm. gelatin/dl. to 4 per cent at 0·3 gm./dl.

viscosity numbers determined at concentrations above 0·2 gm./100 ml. bear a linear relationship to concentration which can be extrapolated to zero concentration to obtain the intrinsic viscosity. This applies even to fractions of alkali-processed gelatins having an intrinsic viscosity of 170 ml./gm.

In the foregoing experiments all glassware (viscometers and filters) after use with gelatin were cleaned by soaking in 50 per cent v/v nitric acid and washing with water before using again.

Activation Energy and Fractional Order

CONSIDER the case of a unimolecular gas reaction catalysed by a surface obeying the Langmuir adsorption isotherm, with true velocity constant k, adsorption coefficient b, heat of adsorption λ, surface coverage θ, pressure p. It is possible to derive a very simple relation between apparent activation energy E_a, true activation energy E_t, and θ, which should prove of considerable utility. The rate r is:

$$r = k\theta = kbp/(1 + bp)$$

where

$$b = b_0 e^{\lambda/RT}$$

hence:

$$E_a = RT^2 \frac{d \ln r}{dT} = E_t - \lambda + (1 + bp)^{-1} \lambda bp$$
$$= E_t - \lambda\,(1 + bp)^{-1}$$

substituting $\theta/1 - \theta = bp$

$$E_a = E - \lambda\,(1 - \theta) \qquad (1)$$

For the extreme cases of $\theta \rightarrow 0$ and $\theta \rightarrow 1$ this reduces to Hinshelwood's well-known result[1].

The result may be related to Sandler's relation[2]. The Freundlich and Langmuir isotherms often coincide over a limited pressure range, and where this is so we may equate $d\ln\theta/dp$ derived for the two isotherms. This leads to the relation[3]:

$$n = 1 - \theta$$

where n is the exponent of the pressure in the Freundlich isotherm. Substituting in equation (1), we obtain Sandler's relation:

$$E_a = E_t - \lambda . n. \qquad (2)$$

Reactions of Sodium with Active Oxygen

IN a recent investigation of the chemiluminescent flame formed when sodium diffuses into hydrogen coming from a discharge, Polanyi and Sadowski[1] found that the sodium was being consumed at a rate which was 10^4–10^5 times faster than could be accounted for on the basis of ternary reactions. Since electronically excited hydrogen could be excluded as a reagent, they accounted for the sodium consumption in terms of the binary reaction:

$$\mathrm{Na} + \mathrm{H_2}\dagger\,(v \geqslant 6) \rightarrow \mathrm{NaH} + \mathrm{H} \qquad (1)$$

where $\mathrm{H_2}\dagger(v \geqslant 6)$ refers to molecular hydrogen in at least the sixth vibrational level of the ground electronic state. In the present work, the depletion of sodium in an atmosphere of active oxygen produced in a Wood's tube discharge was measured by means of the Polanyi sodium diffusion-flame technique[2]. The apparatus has been previously described[1]. Argon was used as a carrier gas for the sodium vapour.

The product, kp, was calculated from the Polanyi diffusion-flame equation[2]:

$$kp = \frac{\delta[\ln(x_0 r_0/xr)]^2}{(r_0 - r)^2} \qquad (2)$$

where k is the rate constant associated with the sodium-consuming reaction, p is the concentration of the atmospheric reagent, δ is the diffusion coefficient of sodium in the reaction mixture, r_0 is the nozzle radius, x_0 is the partial pressure of sodium at a distance r_0 from the nozzle, x is the partial pressure of sodium at the visible periphery of the flame, and r is the distance from the nozzle to the flame periphery.

In a typical experiment, the Wood's tube current was adjusted until a flame of radius 1·7 cm. was obtained. In this experiment, the total reaction vessel pressure was 0·4 mm. consisting of 0·3 mm. oxygen and 0·1 mm. argon; the reaction vessel temperature was 300° C., x_0 was approximately $1{\cdot}7 \times 10^{-3}$ mm., r_0 was 0·057 cm., x was 7×10^{-6} mm., r was 1·7 cm. and δ was $2{\cdot}01 \times 10^3$ cm.^{2} sec.$^{-1}$. Although δ for sodium in oxygen is not known, a good approximation is δ in nitrogen. Therefore, the value listed was obtained by correcting Heller's[3] determination of δ in nitrogen to the present experimental conditions.

The product, kp, was found to be $3{\cdot}0 \times 10^3$ sec.$^{-1}$. If we consider the reaction:

$$\mathrm{Na} + \text{active oxygen} + M \xrightarrow{k_3} \text{products} + M \quad (3)$$

and suppose that the partial pressure of active oxygen is 0·4 mm., that is, is equal to the total pressure of the reaction vessel, then k_3 would have to be at least 3×10^{19} c.c.^{2} moles^{-2} sec.$^{-1}$ to account for the consumption of sodium. This is between 10^2 and 10^3 times larger than any termolecular rate constant reported. Termolecular association reactions between sodium and oxygen atoms would require rate constants at least an order of magnitude higher, since it is doubtful that the level of oxygen atoms exceeded 10^{-2} mm. It seems therefore that a termolecular reaction cannot account for the observed sodium consumption.

In support of this conclusion is the fact that whereas contained flames could easily be obtained when the oxygen was activated in an electrical discharge, a contained flame could not be obtained in normal oxygen. Bawn and Evans[4] were able to obtain contained flames only at total reaction vessel pressures which were from ten to sixty times as great as those used in the present investigation. The reaction prevailing in their system was:

$$\mathrm{Na} + \mathrm{O_2} + M \xrightarrow{k_4} \mathrm{NaO_2} + M \quad (4)$$

The most likely sodium-consuming reaction in the present system appears to be the bimolecular process:

$$\mathrm{Na} + \mathrm{O_2}^* \xrightarrow{k_5} \mathrm{NaO} + \mathrm{O} \quad (5)$$

where, in order to render reaction (5) thermoneutral, $\mathrm{O_2}^*$ would have to be molecular oxygen in at least the 9th vibrational level of the ground electronic state, at least the 5th vibrational level of the $^1\Delta_g$ state, or at least the 2nd vibrational level of the $^1\Sigma_g^+$ state. Both these latter states are metastable with respect to the transition to the ground state ($^3\Sigma_g^-$), since a magnetic dipole transition is required. The radiative lifetime for the $^1\Sigma_g^+ - {}^3\Sigma_g^-$ transition has been estimated to be 7 sec.[5]. Foner and Hudson[6] and Herron and Schiff[7] have detected good yields of $\mathrm{O_2}^*(^1\Delta_g)$ in oxygen which had been passed through an electrodeless discharge.

For k_5 between 10^{12} and 10^{14} c.c. mole^{-1} sec.$^{-1}$, the pressure of $\mathrm{O_2}^*$ would have to lie between 1×10^{-1} and 1×10^{-3} mm., a not unreasonable range in view of the findings of Foner and Hudson[6], and of Herron and Schiff[7]. The relative importance of the postulated oxygen species in reaction (5) could not be determined in the present investigation.

I thank Dr. J. C. Polanyi, of the Department of Chemistry in the University of Toronto, for his assistance. Fundamental NH$_2$ Stretching Frequencies in Amines and Amides

In molecules with functional groups of the type $-AB_2$, two stretching vibrations corresponding to the symmetric (ν_s) and asymmetric (ν_{as}) modes of vibration of the B atoms are observed. Bellamy and Williams[1] have demonstrated that so long as the two A–B bonds are equivalent, and mass and coupling effects are negligible, polar effects acting on the group induce proportional changes in ν_s and ν_{as}. For sixty-two primary amines covering a wide range of molecular type in solution and in the pure liquid state, they found:

$$\nu_s = 345{\cdot}5 + 0{\cdot}875\,\nu_{as} \quad (1)$$

with a standard deviation of 4·8 cm.$^{-1}$. Where neighbouring groups destroyed the bond equivalence, as in hydrogen bond interactions with only one hydrogen atom of the amino-group, this relationship no longer held. Stewart[2] has shown that equation (1) can be predicted from the force field treatment of Linnett[3], assuming identical NH bond stretching force constants.

For a more restricted range of molecular type, *meta*- and *para*-substituted anilines in very dilute carbon tetrachloride solution, Krueger and Thompson[4] found:

$$\nu_s = 1{,}023 + 0{\cdot}682\,\nu_{as} \quad (2)$$

with an average deviation of less than 1 cm.$^{-1}$. The greater precision of equation (2) with respect to equation (1) can undoubtedly be ascribed to the fact that the correlation of Bellamy and Williams was based on experimental measurements under slightly different conditions from a number of laboratories. The possibility that the nitrogen atom is in different hybridization states in this very broad correlation may also be a contributing factor. A solvent effect on the ν_s/ν_{as} correlation in substituted anilines has also been noted[5].

For the corresponding first overtone bands in substituted anilines, Whetsel *et al.*[6] have reported:

$$\nu_s = 1{,}304{\cdot}6 + 0{\cdot}790\,\nu_{as} \quad (3)$$

with a standard deviation of 3·2 cm.$^{-1}$. For both the fundamental and overtone aniline frequencies, *ortho*-substitution (except *ortho*-alkyl) lowers ν_s with respect to ν_{as} by destroying the exact equivalence of the NH bonds. Recently, Puranik and Ramiah[7] have shown that the NH$_2$ stretching frequencies in primary amide monomers follow:

$$\nu_s = 1{\cdot}1214\,\nu_{as} - 542{\cdot}5 \quad (4)$$

with an average deviation of about 3 cm.$^{-1}$, except in hydrogen bonded systems such as those using dioxane as a solvent. Cannon[8] has previously presented evidence for extensive conjugation between the carbonyl group and the amino-group in amides, leading to planarity.

Fig. 1 shows the correlations corresponding to equations (1) and (4) respectively in relation to the data for the substituted anilines, where both the symmetric and asymmetric NH$_2$ frequencies rise with increasing electron-withdrawing power of the substituent groups[4]. The significantly lower slope of the aniline correlation (A) as opposed to the general amine correlation (B) and the amide correlation (C), and the displacement of line C to the right with respect to B, is interpreted in terms of a systematic decrease of the sp^3/sp^2 character of the amino-group in the aniline series as the electron-withdrawing

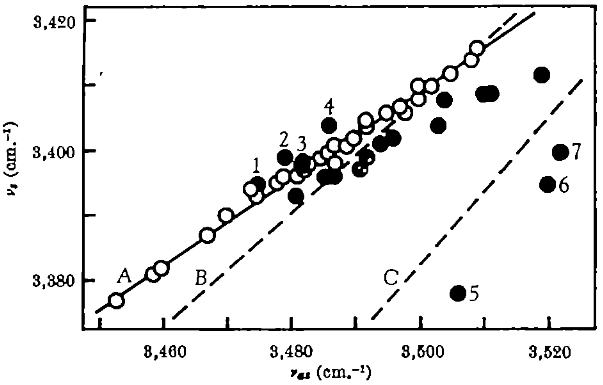

Fig. 1. Symmetric and asymmetric NH_2 frequency relationships. *A*, for substituted anilines; *B*, for primary amines generally, *C*, for primary amides. *Ortho*-substituted compounds of special interest: (1) 1-naphthylamine, (2) 2,4,6-trimethylaniline; (3) *o*-toluidine; (4) 2,6-dimethylaniline, (5) ethyl anthranilate; (6) 2,4-dinitroaniline; (7) *o*-nitroaniline

nature of the substituents increases. This concept is in harmony with more detailed calculations which show an HNH angle of 109·4° in *p*-phenylenediamine, and a smooth rise to 111·1° in aniline and 113·6° in *p*-nitroaniline. No recent NH_2 frequency measurements on simple primary alkyl amines (where the nitrogen atom bonding orbitals are certainly sp^3) in dilute carbon tetrachloride solution appear to be available.

Ortho-substitution in general leads to angle opening, or more extensive sp^2 contribution to the nitrogen-bonding orbitals. Where the substituents are 2-NO_2, 2,4-diNO_2, and 2-$COOCH_2CH_3$, HNH angles of 121·7°, 122·6° and 123·6° respectively were calculated from infra-red frequency measurements. Fig. 1 shows these three compounds displaced farther from the general amine correlation than are the amide values, in agreement with the above angles.

Little definite evidence concerning the geometry of the amino-group in aromatic amines has been presented so far, as Brand and Speakman[9] have recently pointed out. From Kerr constant measurements they suggest a non-planar structure. Wepster[10] has also reported supporting evidence for a pyramidal amino group in these compounds. My infra-red measurements confirm these deductions, and also show that strongly electron-donating substituents drive the amino-group fairly completely into a pyramidal ammonia-like structure, whereas strongly electron-withdrawing substituents tend to pull the amino hydrogen atoms towards the plane of the aromatic ring, thereby increasing the HNH angle. *Ortho*-substituents involved in strong intramolecular hydrogen bonding appear to lead to planar molecules in which the HNH angle may exceed 120°.

BIOCHEMISTRY

Infra-Red Spectra of Some Melanins

MELANINS are pigments of high molecular weight formed by enzymatic oxidation of phenols and usually occur as granules in which the melanin may be combined with protein[1]. The classical work of Raper[2] established the basic role of indolyl-5,6-quinone in the formation of melanin from 3,4-dihydroxyphenylalanine (dopa), and it is now accepted that melanin structures result from polymerization of enzymatically produced *o*-quinone substrates. The detailed structure of melanin is still unknown, and it has been the practice to identify melanins in living organisms by a number of non-specific tests[3], for example, insolubility in common solvents other than strong aqueous alkali (from solution in which the pigment is precipitated on acidification), solubility in ethylene chlorhydrin, reduction of ammoniacal silver nitrate, bleaching with hydrogen peroxide and reduction by sodium thiosulphate and re-oxidation with potassium ferricyanide.

During the course of an investigation of the melanin pigment in *Arenicola marina*, it was decided to compare the properties of this pigment with those from other invertebrate animals (*Holothuria niger*, *Sepia* ink-sac and a beetle) and with ox-eye choroid. As the tests outlined were found to be of little value, an investigation of the infra-red absorption spectra of carbon tetrachloride mulls of the pigments was carried out with the Perkin Elmer Infracord. The main difficulty is the isolation of the pigment in a pure form, particularly in removing any attached protein. Protein material was hydrolysed by digestion with trypsin at 37° for one week followed by hydrolysis with 6 *N* hydrochloric acid for some hours, and the black insoluble material remaining was filtered. Treatment of trypsin (and other proteins) with hydrochloric acid alone gives rise to a black insoluble substance, 'humin', but it was found that this product from trypsin was completely soluble in tetrahydrofuran; all samples of melanin after the treatment with acid were extracted with this solvent by boiling under reflux before the infra-red analyses were carried out. Since tetrahydrofuran is miscible with water, this treatment probably provides a water-free sample of pigment. The pigment was ground to a fine powder which was mixed with carbon tetrachloride and re-ground; the sample was then transferred to a sodium chloride plate, a few drops of carbon tetrachloride added and the second plate pressed on the mixture and the two plates rotated to achieve a uniform distribution of material. The infra-red spectrum was then recorded as soon as possible, since slow evaporation of the solvent occurs.

Typical spectra are shown in Fig. 1. Only beetle melanin had a marked solubility in *N* sodium hydroxide, and the spectrum recorded is that of the sample precipitated from the alkali solution by acidification. Ox-eye melanin was partially soluble in alkali and the spectra of the soluble and insoluble fractions are shown. Melanins from *Arenicola* and *Holothuria* had only a very slight solubility in alkali while *Sepia* melanin was completely insoluble. The most significant feature of these results is the implication of the similarity of the pairs of pigments, *Arenicola* and *Holothuria*, and alkali-soluble ox-eye and beetle and their dissimilarity from *Sepia*. Synthetic melanins, obtained from catechol and dopa by keeping their aqueous solutions (containing a little tyrosinase)

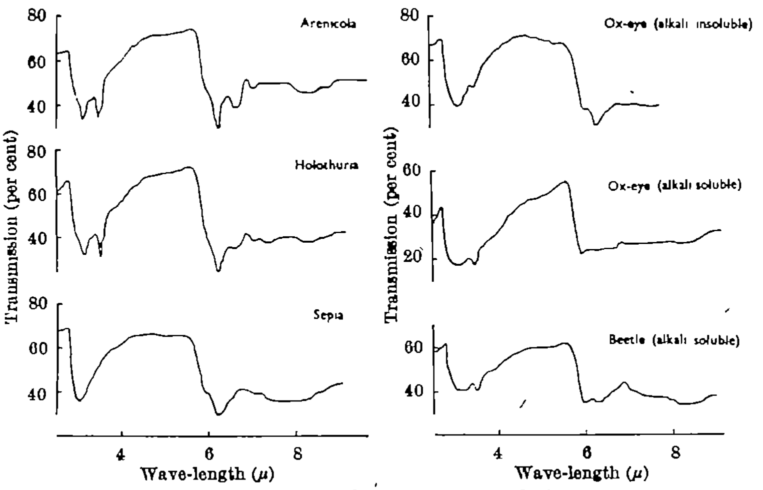

Fig. 1. The infra-red spectra of some melanins

exposed to air at 37° at pH 6·8 (phosphate buffer) and then boiling with 6 N hydrochloric acid and extracting the black residues with tetrahydrofuran, gave infra-red spectra closely similar to that of *Sepia*. In all spectra there are characteristic absorptions which can be attributed to NH (or OH) bonds (at c. 3μ) and conjugated carbonyl groups (at c. 6μ) in accord with the known basic units of melanin structure.

Confirmation of these differences in infra-red spectra was obtained through the generous co-operation of workers at the Max Planck Institute of Biochemistry in Munich during a recent visit. The samples were then prepared in potassium bromide disks and the spectra were found to be identical with those obtained with carbon tetrachloride mulls. The potassium bromide disk method is clearly capable of providing at least a semi-quantitative comparison of the characteristic absorptions recorded.

Ascorbic Acid, Oxygen, and the Disappearance of Adrenochrome and Noradrenochrome

Adrenochrome undergoes change in the presence of ascorbic acid[1,2]. Despite the fact that derivatives of this process have been demonstrated by chromatography[2], the reaction mechanism remains obscure. For example, the necessity for a great excess of ascorbic acid is not characteristic of its reducing action elsewhere[3]. The role of ascorbic acid in the destruction of adrenochrome may well have physiological significance, especially as an explanation for the presence of 400–500 mgm. of ascorbic acid in 100 gm. of fresh adrenal tissue[4]. The present investigation probes the mechanism of the interrelationship of ascorbic acid and adrenochrome or noradrenochrome *in vitro*.

Aqueous solutions containing 0·057 M reagent-grade ascorbic acid were prepared immediately before use. Solutions containing $3 \cdot 0 \times 10^{-3}$ moles of epinephrine or norepinephrine per litre of 0·01 M hydrochloric acid were kept in the refrigerator, and aliquots were removed for daily use. Serum was separated from specimens of freshly clotted human blood and then pooled. The buffer was 0·1 M sodium phosphate of pH 7·4.

Adrenochrome or noradrenochrome was formed immediately before each experiment by bubbling oxygen for 1 min. through 15 ml. of a solution containing the indicated amount of catecholamine, 0·3 gm. of manganese dioxide[5], and 0·02 M sodium phosphate. The manganese dioxide settled within 1 min. To 4·5 ml. of the supernatant solution was added the indicated amount of ascorbic acid. The residual absorbancy of the adrenochrome or noradrenochrome was measured after various periods of time at 480 mμ in a Beckman *DU* spectrophotometer with tungsten lamp. The absorbancy of ascorbic acid at this frequency was negligible. Subtraction of the reading of the appropriate blank yielded the net absorbancy of the experimental solution. Some of the adrenochrome or noradrenochrome was added to serum immediately prior to ascorbic acid.

In view of the large excess of ascorbic acid, possible mechanisms for the disappearance of the chrome compounds might include a first-order reaction or a rearrangement in an environment modified by the ascorbic acid. The results of a series of experiments with various concentrations of ascorbic acid and noradrenochrome are presented in Table 1. Concentrations of ascorbic acid below $1 \cdot 20 \times 10^{-3}$ M had no effect on adrenochrome or noradrenochrome. With ascorbic acid constant, the noradrenochrome disappeared relatively more rapidly as its concentration increased. Increase in ascorbic acid accelerated the disappearance also. Thus, the process was not a first-order reaction, since the relative rate of disappearance of noradrenochrome was not independent of its initial concentration, nor was variation in the excess of ascorbic acid without significant effect[6].

Table 1. DISAPPEARANCE OF VARIOUS AMOUNTS OF NORADRENOCHROME IN THE PRESENCE OF ASCORBIC ACID

Concentration of noradrenochrome ($\times 10^{-3}$ M)	Concentration of ascorbic acid ($\times 10^{-3}$ M)	Time for disappearance of 20 per cent of noradrenochrome (min.)	Time for disappearance of 40 per cent of noradrenochrome (min.)
0·24	2·40	12·1	25·0
0·59	2·40	7·4	18·0
1·18	2·40	5·0	13·5
0·24	7·20	5·2	10·0
0 59	7·20	2·2	3·8
1·18	7·20	1 3	2·3

In a further series of experiments, one of three identical solutions containing noradrenochrome was vigorously oxygenated, the second nitrogenated, while the third remained in free contact with air (Fig. 1). Immediately thereafter, ascorbic acid was added to each tube. The bubbling of oxygen essentially prevented the disappearance of the noradrenochrome until air had an opportunity to diffuse into the solution, while nitrogen accelerated the disappearance. Bubbling of nitrogen for prolonged periods of time was without effect in the absence of ascorbic acid. Thus, the disappearance of the noradrenochrome was strongly dependent on the oxygen in the

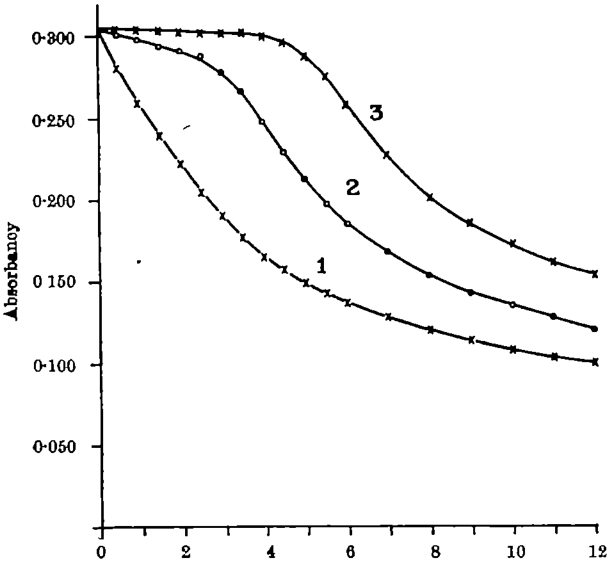

Fig. 1. Nitrogen was bubbled for 1 min. through 4·5 ml. of a noradrenochrome-containing aqueous solution (curve 1). Oxygen was simultaneously bubbled through a second similar volume (curve 3), while a third solution remained open to the air (curve 2). Immediately thereafter, at zero time, 0·4 ml. of 0·057 *M* ascorbic acid was added to each tube. The final solutions contained $0{\cdot}59 \times 10^{-4}$ *M* noradrenochrome and $4{\cdot}80 \times 10^{-3}$ *M* ascorbic acid. The absorbancies were read at 480 mμ after various periods of time

solution. Ascorbic acid ,appeared to modify the environment through reduction in the free oxygen.

Increase in the concentration of ascorbic acid by a factor of 3 caused adrenochrome and dopachrome to disappear in the same way as noradrenochrome. Replacement of 60 per cent of the water by serum did not change the results.

The formation of many stable compounds from adrenochrome indicates the existence of more than one reaction pathway. At least the first step—the disappearance of adrenochrome, noradrenochrome, or dopachrome—proceeds only in an environment modified by a large excess of ascorbic acid. The importance of the interrelationship of ascorbic acid and oxygen is that it provides a way for the disappearance of adrenochrome and noradrenochrome, which requires relative anoxia, to proceed in oxygen-containing physiological fluids such as serum. This investigation is compatible with the possibility that the maintenance of an optimum oxygen environment for physiological reactions in general may be an important role of ascorbic acid and similar substances.

Preparation of Profibrinolysin-free Fibrinogen and Thrombin from Human Plasma

AMBRUS[1] has described an *in vitro* assay for fibrinolytic enzymes and has correlated his results with the therapeutic effectiveness of the preparations tested. Both the fibrinogen and thrombin used in this assay must be free or nearly free of profibrinolysin in order to distinguish between fibrinolysin and profibrinolysin activator activity.

Several investigators[2-4] have reported procedures for the preparation of profibrinolysin-free fibrinogen, and others[5-8] have published methods for preparing profibrinolysin-free bovine thrombin. We wish to report our methods for the preparation of profibrinolysin-free clotting reagents from human plasma which result in greater yield of product.

Profibrinolysin-free human fibrinogen was prepared by blending the Fraction I paste of Cohn[9] derived from 1 litre of normal human plasma into 45 ml. of *p*H 6·4, 0·055 *M* sodium citrate: 0·2 *M* sodium chloride buffer at 5°. The resulting suspension was warmed and stirred at 25° for at least 30 min., and then recooled to 5°. An equal volume of 2 per cent aqueous ethanol was added to precipitate the cold-insoluble globulins. After centrifugation the opalescent supernatant was adjusted to *p*H 3·8 with 2 *M* hydrochloric acid to precipitate fibrinogen with a purity of more than 80 per cent. The precipitate, recovered by centrifugation, was dissolved in 135 ml. of *p*H 3·7, 0·05 *M* acetate buffer at 5°. While stirring without aeration, 10·8 ml. of 2·9 *M* sodium chloride was added to precipitate fibrinogen of better than 90 per cent purity. This fibrinogen was recovered by centrifugation and dissolved and precipitated again in the same manner to further reduce profibrinolysin contamination. After the reprecipitation, the fibrinogen was again dissolved in 135 ml. of the *p*H 3·7, 0·05 *M* acetate buffer at 5°. To this solution was added 6·1 ml. of 2·9 *M* sodium chloride, and precipitate No. 1 was recovered by centrifugation at 5°. To the cold supernatant was added 3·1 ml. of 2·9 *M* sodium chloride and precipitate No. 2 was recovered by centrifugation at 5°. Precipitates Nos. 1 and 2 were each suspended at 5° in 15 ml. of *p*H 7·2, 0·055 *M* sodium citrate buffer containing 4 per cent dextrose. The *p*H value of each suspension was carefully adjusted to 6·5 with *M* sodium hydroxide, after which time the mixtures were warmed to 20° before further adjusting to *p*H 7·2. This *p*H was maintained while the fibrinogen was dissolved. Generally all the precipitates dissolved after stirring for 60 min. at 20°. Occasionally a small amount of insoluble material remained and was removed by centrifugation at 20°. The resulting fibrinogen solutions were adjusted to a protein concentration of 4·5 per cent by the addition of further citrate–dextrose buffer. These solutions of precipitate Nos. 1 and 2 were dried from the frozen state, and designated 'profibrinolysin-free' fibrinogen No. 1 and No. 2, respectively. We have routinely recovered 1·0 gm. of No. 1 and 1·6 of profibrinolysin-free fibrinogen No. 2 from each litre of plasma processed. These dried powders contained about 60 per cent protein of which at least 94 per cent was coagulable by thrombin.

Profibrinolysin-free human thrombin was prepared from fraction III-2 fractionated from human plasma by the method of Oncley *et al.*[10]. The prothrombin of this fraction was converted to thrombin by the use of human placental thromboplastin[11]. Two gm. of crude thrombin powder (which was obtained from about 1 litre of human plasma) was suspended in 135 ml. of 5°, *p*H 7·3, 0·5 *M* phosphate buffer. Four gm. of powdered calcium orthophosphate (J. T. Baker Chemical Co.) was added, and the mixture stirred at 5° for 30 min. prior to centrifugation. To the supernatant was added 90 ml. of cold 50 per cent (w/v) ammonium sulphate to precipitate inactive protein and trace amounts of residual profibrinolysin. After centrifugation at 5° the clear supernatant was dialysed against *p*H 7·3, 1·5 × 10^{-4} *M* phosphate buffer until free of ammonium sulphate. The imperviate, containing profibrinolysin-free thrombin, was dried from the frozen state. A yield of about 0·33 gm. of powder containing at least 30 per cent of the starting thrombin activity was obtained.

For use in the Ambrus[1] assay the dry profibrinolysin-free fibrinogen was dissolved in *p*H 7·2, 0·05 *M* imidazole buffer containing 0·05 *M* sodium chloride to give a protein concentration of 0·6 per cent. The profibrinolysin-free thrombin was dissolved in *p*H 7·2, 0·05 *M* imidazole buffer to give 10 NIH thrombin units per ml. When tested for profibrinolysin contamination, by titration with streptokinase according to the procedure described by Ambrus, lysis times of over 5 hr. (less than 0·005 profibrinolysin units) were obtained with profibrinolysin-free fibrinogen No. 1—profibrinolysin-free thrombin clots, while lysis times of well over 10 hr. (less than 0·001 profibrinolysin units) were obtained with profibrinolysin-free thrombin clots. Since the addition of 1 RPMI unit of fibrinolysin to similarly prepared clots will result in a lysis time of 2 min., the profibrinolysin contamination in these reagents may be considered as of no consequence.

Structure of a Monophosphoinositide from Brain

SEVERAL workers[1-4] have reported the presence of monophosphoinositide (MPI) in phospholipid fractions originating in brain tissue. Only Dittmer and Dawson[3], however, claim to have isolated a pure sample of a phospholipid analysing as a simple MPI, and they did not elucidate its structure. Brockerhoff and Ballou[4] have suggested that the D-glycerol 1-(L-myoinositol 1-phosphate) residue is contained in brain MPI, but they did not isolate the parent lipid or its deacylation product in a pure state.

A chromatographically pure sample of MPI has been isolated from brain and its structure established using degradative methods similar to those already applied successfully to horse liver MPI[5].

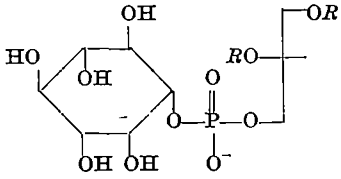
Following a modified Folch procedure[5,6], an ethanol-insoluble fraction of phospholipids was isolated in a yield of 1·35 per cent of wet bovine brain tissue. Chromatographic analysis of this brain fraction on formaldehyde-impregnated paper[7] showed that it consisted largely of phosphatidyl ethanolamine and phosphatidyl serine and that it also contained small amounts of MPI, phosphatidyl choline, and complex phosphoinositides.

We were unable to separate chromatographically pure MPI from nitrogen-containing phospholipids by chromatography on aluminium oxide or silicic acid columns. However, dinitrophenylation by means of fluorodinitrobenzene (FDNB) of the ethanol-insoluble phospholipids with a modification of a procedure due to Wheeldon and Collins[8] led to complete reaction of the nitrogen-containing phospholipids and a consequent increase in R_F values. The chromatographic properties of the MPI were unchanged and a separation of the latter from the yellow dinitrophenylated lipids was readily achieved. A pure sample of horse liver MPI, when treated under the same conditions, but omitting the FDNB, was essentially unaffected; a small proportion (< 10 per cent) was converted to a phosphatidic acid-like compound.

A sample (6·5 gm.) of the ethanol-insoluble fraction in dry benzene (100 ml.) was treated with FDNB (1·45 gm.) in the presence of triethylamine (2·5 ml.) at 30–40° C. for 2 hr. Evaporation of the reaction mixture to dryness gave a yellow residue which was dissolved in chloroform for application to a silicic acid–Hyflo Supercel column (2 : 1 w/w, 405 gm.; 4·2 cm. diameter). A stepwise eluting technique was used. Chloroform/methanol (6 : 1 v/v) first removed non-lipid material; further elution with chloroform/methanol (6 : 1 v/v) and then (4 : 1 v/v) brought dinitrophenylated phospholipids and small amounts of a substance chromatographically similar to phosphatidic acid off the column. Chromatographically pure MPI was then eluted by chloroform/methanol (3 : 2 v/v), giving the proportion of MPI in brain tissue as 0·03 per cent. This sample contained an unestimated amount of plasmalogen groups.

The chromatographically pure brain MPI (100 mgm.) was treated with hydroxylamine for 10 min., which led to complete deacylation. Working up as before[5] gave an aqueous phase containing glycerol myoinositol phosphate, with traces of glycerol 1- and 2-phosphate. After the separation of the glycerol myoinositol phosphate by preparative paper chromatography, the *cyclo*hexylammonium salt was formed in aqueous solution. It had an $[\alpha]^{20}_{589}$ in water of − 11 ± 2°. Its specific rotation and chromatographic properties showed that it was identical with the corresponding compound from horse liver MPI; the latter has been proved to be *cyclo*hexylammonium D-glycerol 1-(L-myoinositol 1-phosphate)[5].

The phosphate-myoinositol linkage position was confirmed by a degradation to myoinositol 1-phosphate. The *cyclo*hexylammonium salt (6 mgm.) of the glycerol myoinositol phosphate was treated with an excess of sodium metaperiodate for 15 min. at room temperature. Glycerol was then added to destroy the remaining periodate. After a further 15 min., phenylhydrazine formate at *p*H 6 was added to the solution. The reaction mixture was incubated at 40° for 5 hr. and then centrifuged. The clear supernatant was acidified with 'Dowex-50 (H+)' resin, neutralized with dilute ammonia, and investigated by paper chromatography. The product was myoinositol 1-phosphate; traces of inorganic phosphate were also observed. Acidic equilibration of the myoinositol 1-phosphate gave a chromatographically resolvable mixture of myoinositol 1-phosphate and myoinositol 2-phosphate. This establishes the structure of the deacylated product as I (*R* = H).



I

The locations of the fatty acid groups were determined from the raction of the MPI with acetic acid[8]. MPI (3 mgm.) was heated in 88 per cent acetic acid (0·2 ml.) at 100° for 20 min. The solvent was then evaporated off leaving a residue which was partitioned between chloroform and water. Myoinositol 1-phosphate and myoinositol 2-phosphate, but no glycerol phosphate, were detected in the aqueous phase. The chloroform solution contained diglyceride and monoglyceride and in addition small amounts of unreacted MPI and lysophosphatidyl inositol showing that the acyl groups are on the glycerol residue. The nature of the fatty acid residues has not been investigated.

From the above evidence it is concluded that the brain monophosphoinositide is 2,3-di-*O*-acyl-D-glycerol 1-(L-myoinositol 1-phosphate) (I; *R* = acyl residue), accompanied by a smaller amount of a corresponding plasmalogen.

Mechanism of Antitumour Action of 1-Amino-*Cycl*opentane Carboxylic Acid

The unnatural amino-acid 1-amino-*cyclo*pentane carboxylic acid (ACPC) has been reported to inhibit the growth of Novikoff rat hepatoma[1], Walker rat carcinoma 256 [2], sarcoma 180 and carcinoma 755 [3]. Berlinguet *et al.*[4] recently reported that this unnatural amino-acid does not undergo any metabolic change in normal rat, and so far nothing is known concerning the mechanism of its action.

Steinberg *et al.*[5] and many other workers[6,7] previously demonstrated that synthetically prepared amino-acid analogues like the amino-acids themselves could be incorporated into proteins and they can thus compete with the natural amino-acids for the latter's incorporation into proteins. That ACPC might act as an amino-acid antagonist was first mentioned by Ross[3]. Mickelson[8], using bacterial systems, failed to demonstrate any such effect of ACPC. In order to elucidate the mechanism by which this unnatural amino-acid exerts its antitumour effect, the following experiments were performed.

A 20 per cent rat liver homogenate was prepared in a Dounce homogenizer at 0° C. in a medium containing 0·35 *M* sucrose, 0·25 *M* potassium chloride, 0·035 *M* potassium bicarbonate and 0·004 *M* magnesium chloride, and centrifuged at 2,300*g* in the cold. 0·05 ml. of the supernatant fraction containing the microsomes and cell sap was incubated at 37° C. for 30 min. with ^{14}C-ACPC (1·5 × 10^5 counts/min.) or with ^{14}C-valine (0·5 × 10^5 counts/min.) in the presence of 3 μmoles of ACPC, 5 μmoles of Mg^{++}, 2 μmoles of ATP, 5 mgm. of creatine phosphate and 50 μgm. (protein) of purified creatine kinase. The reaction was terminated by adding 5 ml. of 5 per cent TCA. The TCA precipitable material was washed, plated and counted according to the procedures previously described by Devi *et al.*[9].

Table 1. Incorporation of ^{14}C-Valine into Proteins in the Absence and Presence of 1-Amino-*cyclo*pentane Carboxylic Acid

	c.p m /mgm. TCA-precipitable material			
Source of microsome-cell sap preparation	No. of Expts.	Range of values	Range of values in presence of ACPC	Percentage of inhibition
Liver of normal rat	5	142–160	84–96	40
Liver of tumour bearing rat (Walker)	4	130–146	86–98	32
Walker tumour	4	150–166	96–108	36

For *in vivo* experiments, five rats weighing 120–140 gm. each received an injection of 20 mgm. of ACPC 48 hr. prior to the administration of ^{14}C-valine (1·2 × 10^6 counts/min.); in another set of experiments ^{14}C-valine was injected after 3 hr. of the administration of ACPC. A similar number of rats received only ^{14}C-valine, which served as controls. The animals were killed 3 hr. after injection of carbon-14. 1 gm. of liver from each rat was homogenized in 5 ml. of 0·25 *M* sucrose and to 1 ml. of such homogenates 5 ml. of 5 per cent TCA added. The washings, plating and counting of the TCA-precipitable material were similar to those described before. Similar experiments were also performed with tumour (Walker)-bearing rats, where 1 gm. of the tumour tissue was homogenized, precipitated and the precipitate was washed, plated and assayed for its radioactivity.

The results can be summarized as follows. When the microsome-cell sap fraction was incubated with ^{14}C-valine and ACPC, the incorporation of carbon-14 into proteins was reduced to varying degrees depending upon the amount of ACPC present. The maximum inhibition noted was 41–47 per cent in the presence of 10 μmoles of ACPC. This effect of ACPC to inhibit the incorporation of ^{14}C-valine was also noted when microsome-cell sap preparation obtained from Walker tumour was used. When ^{14}C-ACPC was used instead of ^{14}C-valine no incorporation of carbon-14 into proteins could be demonstrated.

In *in vivo* experiments where ACPC (1·56 × 10^7 counts) was injected 48 hr. prior to the injection of ^{14}C-valine, the extent of the latter's incorporation into proteins was reduced by 32–40 per cent. Somewhat less (25–28 per cent) inhibition was noted when ACPC was administered only 3 hr. prior to the injection of ^{14}C-valine. When ^{14}C-ACPC alone was injected, a very small but definitely measurable amount of it was found to be incorporated into proteins.

Table 2. Inhibition of Incorporation of ^{14}C-Valine, *in vivo*, into Proteins by 1-Amino-*cyclo*pentane Carboxylic Acid

Source of homogenate	c.p.m./mgm. TCA-precipitable material Controls	ACPC administered 8 hr. prior to ^{14}-C injection	Percentage of inhibition	ACPC administered 48 hr. prior to ^{14}-C injection	Percentage of inhibition
Liver of normal rat	90	66	27	48	47
Liver of tumour bearing rat	82	58	29	44	46
Tumour	102	75	27	60	41

Each value is an average of four such determinations.

The incorporation of ^{14}C-uridine into RNA was not inhibited by ACPC whether the incorporation of ^{14}C-uridine was carried out *in vitro* or *in vivo*. The procedure for these experiments is similar to those of Devi and Sarkar[10]. ACPC did, however, prevent the incorporation of ^{14}C-valine into transfer RNA by 40–50 per cent in the experiment where ^{14}C-valine was incubated with high-speed supernatant fraction in the presence of ACPC, Mg^{++} and ATP.

It follows from the foregoing results that ACPC does inhibit the incorporation of ^{14}C-valine into proteins to an extent of 40–50 per cent.

The initial stages of protein synthesis, as we know them to-day, are the activation of amino-acids by specific amino-acid-activating enzymes, followed by their incorporation (attachment) into specific soluble RNA's. In the second stage, the amino-acids from *S*RNA-aa's complexes are transferred to template RNA's whereby some hitherto unknown mechanism, protein with proper amino-acid sequences, is formed and released[11]. The fact that ACPC does inhibit the incorporation of ^{14}C-valine by 40–50 per cent suggests that this unnatural amino-acid perhaps exerts its antitumour effect by suppressing protein synthesis although no significant amount of it has been found to be incorporated into proteins. This is not unexpected as several analogues have been recently shown to inhibit protein synthesis without being incorporated into proteins[12,13]. Our results also indicate that the most likely site of its action is at the initial stage of protein synthesis because in the presence of ACPC the incorporation (attachment) of ^{14}C-valine into *S*–RNA is reduced by 40–50 per cent.

Hormone Influence on the Thiol Content of *Hevea brasiliensis* Latex

Field experiments carried out in Malaya[1] have proved that the application of certain growth regulators, such as 2 : 4-dichlorophenoxyacetic acid (2 : 4-D), to mature *Hevea brasiliensis* trees will effect substantial increases in rubber yield. This communication shows that a further and possibly correlated effect of these growth regulators is to alter the ratio of reduced to oxidized low-molecular-weight thiol content of the latex.

It has previously been shown[2,3] that the redox potential of fresh latex is probably controlled by such sulphydryl components the nature and concentration of which have been determined[4]. The application of growth regulators influences markedly the general metabolism of pea seedling tissues and of bean[5] seedlings, with concomitant changes in sulphydryl redox[6].

Using the colorimetric method for thiol previously adopted, the —SH and —S : S— content of the acid-soluble portion of small (50 mgm.) samples of latex containing upwards of 1·6 μgm. —SH were determined, before and after reduction with zinc and hydrochloric acid, with a reproducibility within 3 per cent. It was found that when young seedlings of *Hevea brasiliensis* are maintained in tropical conditions of temperature and humidity, but under subdued and constant illumination, then the endogenous acid-soluble thiol content of the latex, the 'equilibrium' content, is reached at a value of 1·5–2·0 μequiv./gm. latex.

The percentage of thiol in the reduced condition, a reflexion of the redox potential, is rather variable. Application of hormone to the leaves or stem of such plants generally increases the reduced thiol content and lowers the oxidized content towards zero in the space of 48 hr. Table 1 shows the effect of gibberellic acid, applied in alcohol–water (50 : 50) solution to freshly tapped 1 year-old seedlings.

Table 1

	μ equiv. —SH/gm. latex (1-yr.-old seedlings)						
Reduced	1 9	1·7	1·7	1·6	2·5	2·5	3·7
Oxidized	2·5	2·7	2·9	2 7	0	0·6	0
Hours after application	− 20	− 10	− 5	+ 5	+ 45	+ 55	+ 60

The reduced thiol content, prior to treatment, in this case averaged 40 per cent, rising to 100 per cent thereafter. There was a tendency in a few other instances for this percentage to rise slightly during the pre-treatment period, possibly due to increased metabolic activity resulting from loss of latex on

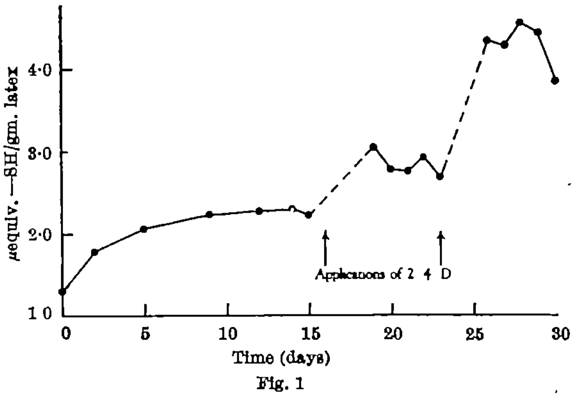

Fig. 1

tapping. This effect was noticeable on more prolonged tapping.

Fig. 1 illustrates the influence of 2 : 4-dichlorophenoxyacetic acid on 2-year-old potted seedlings. Here the pretreatment percentage of reduced material varied in the 60–80 range, at a final 'equilibrium' thiol level of about 2·3 μequiv./gm. Several applications of the hormone increased the percentage to 100 at a final thiol content of approximately 4·5 μequiv./gm. This was followed by a fall towards the equilibrium values.

Since the conversion of 'active isoprene' (isopentenyl pyrophosphate) to rubber may be dependent on the activity of an isomerase which is inhibited by sulphydryl inactivators[7], the possibility exists that the incorporation of this precursor into rubber is influenced by the redox potential and that the latices from growth regulator-treated plants will exhibit greater efficiency in this respect. Experiments are to be carried out to test this possibility.

Effect of Ascorbic Acid in Aniline Poisoning

ASCORBIC acid has been utilized extensively in large doses in the therapy of industrial methæmoglobinæmia, although Halsted[1] commented that at developments greater than 60 per cent methæmoglobinæmia, it is ineffective because of its lack of ability to bring on rapidly a reversion mechanism. But the rapidity of reversion is only the first problem. The second problem to be settled is whether, in chemical cyanosis, the effect of ascorbic acid may not be restricted only to bring about the reduction. It is known that ascorbic acid promotes the rate of hydroxylation of aniline to *p*-aminophenol[2], which is a potent agent in the production of Heinz bodies not only *in vivo* but also *in vitro*[3], and ascorbic acid is able to produce Heinz bodies *in vitro* without any toxic agents[4]. We have found that in rats poisoned with aniline the formation of Heinz bodies is promoted by treatment with ascorbic acid.

Twenty male white rats each weighing 270–320 gm. were used. All animals received intraperitoneal injections of 1 per cent aniline (0·08 ml. aniline/kgm.), and 250 gm. ascorbic acid (in 10 per cent buffered solution) was administered to 10 of them by the tail vein immediately before injecting aniline. The methæmoglobin concentration was determined as a percentage of total hæmoglobin by means of Evelyn and Malloy's method[5] modified by Magos[6] at 1, 3, 5, 7, 24 and 48 hr. after the treatment. Proportions of Heinz body red cells were determined at 48 hr. in wet preparations stained with methyl violet. Not only was the percentage of Heinz body red cells determined, but also the intensity of Heinz body formation by means of an index. 250 red blood cells were carefully examined and the intensity of Heinz body formation in a single cell was signed with index numbers as follows: no Heinz body, 0; one small Heinz body, 1; two small Heinz bodies or of one moderate size, 2; two moderate Heinz bodies or one conglomerate, 4. In the following equation n is the number of cells in the group.

$$\text{Heinz body index} = \frac{(1 \times n_1) + (2 \times n_2) + (4 \times n_4)}{n_0 + n_1 + n_2 + n_4}$$

On the basis of the results given in Table 1, it seems that, although ascorbic acid decreases the degree of maximal methæmoglobinæmia (the period of the methæmoglobinæmic phase remained unchanged), its effect on intensifying Heinz body formation is much more significant.

Table 1. MAXIMAL METHÆMOGLOBINÆMIA, HEINZ BODY RED CELLS (H.B.R.C.) AND HEINZ BODY INDEX (H.B.I.) IN ANILINE POISONING WITH OR WITHOUT ASCORBIC ACID TREATMENT

	Treatment				
	Aniline	Aniline ascorbic acid	S_D	t	P
Maximal methæmoglobinæmia	26·5 ± 4·27	22·7 ± 3·06	1·68	2·262	$0·05 > P > 0·02$
H.B.R.C.	46·5 ± 10·4	65·0 ± 11·4	4·88	3·818	$0·01 > P > 0·001$
H.B.I.	1·34 ± 0·54	2·23 ± 0·37	0·210	4·833	$0·001 > P$

These findings indicate that, apart from the lack of ability to bring about rapidly the methæmoglobin reduction, it is advisable to avoid the therapeutic use of ascorbic acid in chemical cyanosis because of its irreversible effect.

PHYSIOLOGY

Regular Impulse Activity of Single Units in the Cat Striate Cortex

IN the course of an investigation into the spontaneous and evoked activity of single cells in the visual cortex of unanæsthetized, unrestrained cats, a number of cells have been discovered, remarkable for their regularity and rate of discharge. Each of these cells, of which five have so far been observed, discharged a single spike whenever it fired, and each spike was followed by a long silent period lasting many seconds. As may be seen in Fig. 1, the inter-spike intervals for a given cell are, with few exceptions, distributed over a very narrow range. In calculating the mean value of the inter-spike intervals of cells 2, 3 and 4, certain intervals were omitted. In cell 2, for example, the interval which was omitted lasted 20·29 sec., that is, approximately twice the modal inter-spike interval (9·5–9·99 sec.) for this unit. Similar prolonged periods of silence occurred occasionally between action potentials from cells 3 and 4, but always these gaps were, to a close approximation, a multiple of the modal interval. It is possible that the missing spikes were lost in the base-line of the

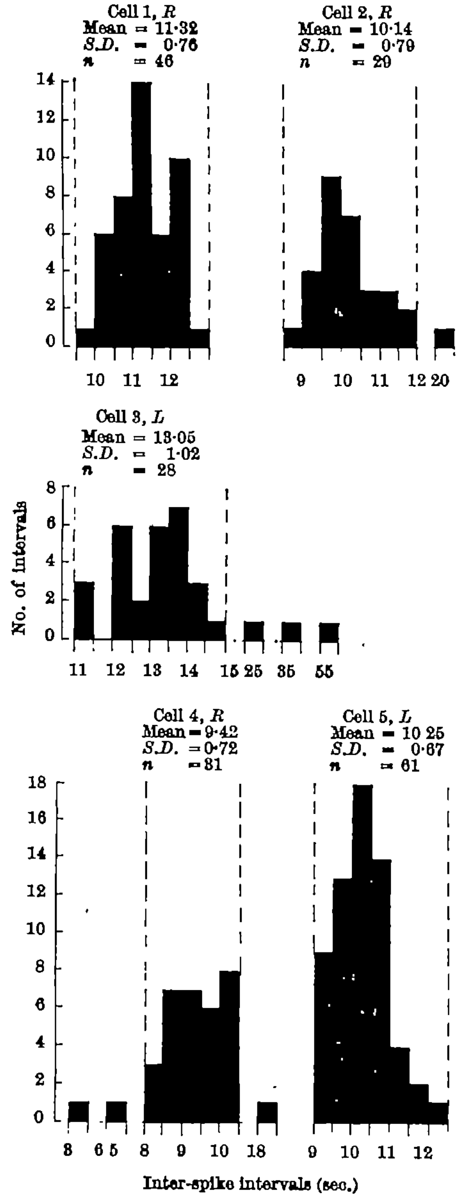

Fig. 1. Histograms of inter-spike intervals. The hemisphere in which each cell was found is indicated by *L* (left) and *R* (right). The mean (in sec.) and standard deviation (*S.D.*) for each cell refer to the intervals (*n* in number) enclosed by the broken lines

record; but there were instances where the failure to fire appeared genuine, for careful examination of those records where the signal/noise ratio was particularly good failed to reveal the missing spike. That this property of maintaining the overall rhythm is real is suggested from the behaviour of cell 4. The mean value of the regular inter-spike intervals of this cell was 9·42 sec.; but of the three intervals excluded in calculating this value, one was 18·39 sec. (approximately twice the expected interval), one was 6·60 sec. and one was 3·21 sec. These last two intervals occurred in succession so that the overall regularity of discharge was maintained.

The five cells were recorded at various depths below the pial surface of the striate cortex of both right and left hemispheres. They were all found in one cat from which it had been necessary, for reasons relevant to the original experiment, to take prolonged and continuous film records of cortical impulse activity. The existence of these cells was not suspected until the film records were analysed, and they would certainly not have been discovered without such extensive records, for there would then have been too few spikes to give a statistically useful number of intervals. Each unit was discovered while investigating the activity of another cell which discharged irregularly and with a much higher frequency, and the action potentials of which were larger than those of the regularly firing units. The microelectrode thus recorded simultaneously from two cells. The regularly firing cells were not seen on the oscilloscope at the time of filming, in part because they fired so rarely, but also because they were relatively small, with an amplitude in the region of 0·5 mV. Action potentials of this size could be generated by a small cell lying close to the tip of the microelectrode. However, since these small spikes appeared with other, larger, spikes from another cell, one cannot exclude the possibility that the smaller spikes were generated by a cell situated some distance from the microelectrode tip. In this position the cell would be less exposed to the risk of mechanical stimulation by the electrode than might otherwise be the case. Finally, the rate of discharge of the regularly firing cells was quite unaffected by diffuse retinal illumination or by weak electric shocks applied to the skin of the animal, although the other cells the spikes of which appeared on the same trace were all affected by one or both of these stimuli.

In considering the mechanism of activation of the regularly firing cells, two simple hypotheses present themselves. On one hand, the cells might be part of a very long chain of cells showing reverberating activity. However, with the exception of cells 2 and 5 (which came from right and left hemispheres respectively) the mean value of the intervals of each cell differed significantly ($P < 0·001$) from that of all the other cells. Since all these units came from the same animal, it is necessary to suppose that there are at least four such chains showing reverberating activity, each firing independently of the other. On the other hand, the pattern of discharge could be an expression of some chemical excitatory process occurring independently within each of the five cells. On the basis of the small range of variation of the inter-spike intervals of each unit, and the relatively wide range of variation of the means between units, the latter hypothesis seems the more economic and attractive.

Osmotic Changes caused by the Accumulation of Dulcitol in the Lenses of Rats fed with Galactose

CATARACTS produced experimentally in rats maintained on a diet high in galactose or xylose or by alloxan injection have similar clinical manifestations[1]. Since the development and appearance of these cataracts are similar, there is the suggestion that a common mechanism or factor may be involved. We wondered whether the accumulation of polyols first

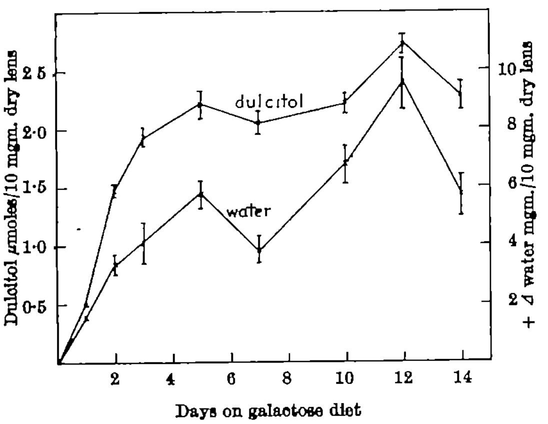

Fig. 1. Accumulation of water and dulcitol in the lenses of galactose-fed rats

observed by van Heyningen[2,3] might possibly be the initiating factor in these cataracts. It seemed possible that the accumulation of polyols, along with the keto sugars, in the lens fibres might be sufficient to create an osmotic disturbance. Because of the increase in the osmotically active substances, water would be drawn into the lens fibres. Since sugars, especially the sugar alcohols, do not readily diffuse through biological membranes, their concentrations might reach a level which would increase the volume of water sufficiently to cause the lens fibres to swell and perhaps to rupture their membranes.

To test this possibility we measured the accumulation of hexitol in the lenses of the galactose-fed rats. Sprague–Dawley strain of rats weighing about 100 gm. were put on a diet of 50 per cent galactose as described by Yudkin and Arnold[4]. Control rats were fed the same diet but with 50 per cent glucose. The analyses of various sugars in the lens were made on a protein-free filtrate after precipitation by barium hydroxide and zinc sulphate. Hexitol was determined by the procedure of West and Rapoport[5] as modified by Faulkner[6]. The other sugars were determined by conventional methods.

The galactose cataract appears to be a simpler disorder to examine than the alloxan diabetic cataract. First of all, the cataract develops earlier than in diabetes. Secondly, the level of blood sugar does not need to be as high as that in diabetes to produce a cataract. The most significant difference is that dulcitol, the sugar alcohol form of galactose, is the only derivative which accumulates in the lens. Enzymatic studies using lens extracts indicated that two enzymes are involved in the metabolism of polyols. In the presence of reduced triphosphopyridine nucleotide, galactose and glucose are converted to their alcohol form by aldose reductase. A second enzyme, polyol dehydrogenase, in the lens of the rat, man, rabbit, cat and calf catalyses the oxidation of sorbitol to fructose, but apparently does not attack dulcitol. Since dulcitol does not appear to penetrate the lens membranes readily, once formed it accumulates.

In Fig. 1 is shown the accumulation of dulcitol and water in the lenses of rats fed galactose for varying periods of time. In these experiments approximately 100 rats were used, half of them placed on the galactose diet and the other half on the control glucose diet. One lens from each animal was used to determine the dulcitol content while the other was used to obtain wet and dry weights. The lenses of the rats fed glucose for a period up to 15 days showed no appreciable increase in the hexitol content from that observed in the normal rat lens (0·04 µmole per lens). On the other hand, as shown in Fig. 1, there was a rapid increase in both dulcitol and water in the lenses of the galactose-fed rats. In most cases the increase in water and dulcitol appears to be proportional. The results are based on 10 mgm. of dry weight of lens, the approximate weight of the rat lenses used.

The accumulation of dulcitol in these lenses was considerable. The lenses of rats on the galactose diet for 3 or more days contained dulcitol, which accounted for 3–5 per cent of the dry weight of the lens. Since galactose-1-phosphate has been suspected of playing a part in the development of cataracts in galactosæmic patients and rats fed galactose[7,8], it was of interest to relate the amount of dulcitol found in these experiments to that amount of galactose-1-phosphate accumulating under similar circumstances. Korc[9] has reported that in rats fed galactose for 11 days there was less than 0·005 µmole of galactose-1-phosphate accumulated per lens. The results as shown in Fig. 1 revealed that 2·2 µmoles of dulcitol per lens were found after 10 days on the diet. Paper electrophoretic and chromatographic examinations by the procedures of van Heyningen[2] identified the sugar accumulating as dulcitol. No significant amount of sorbitol was detectable. After 3 days, the levels of dulcitol and water appeared relatively constant with the exception of the increase observed at 12 days. This plateau may be more apparent than real since one of the factors not controlled was the amount of galactose ingested. Usually after 5 days on the diet, the rats did not appear to consume as much food. The sudden increase observed at 12 days was caused most likely by the higher intake of food by this group of rats.

The first sign of opacities was observed ophthalmoscopically in the lenses of rats maintained for 5 days on the galactose diet. At this stage of cataract development, the lens had accumulated 2·2 µmoles of dulcitol. This represents a concentration of 72 µmoles of dulcitol per gm. of lens or 117 µmoles per ml. of lens water. The level of dulcitol found here is lower than that reported by van Heyningen[2], who estimated the concentration of dulcitol by paper chromatographic procedures to be 110 µmoles per gm. of lens. The increase of water in the lenses of rats fed galactose for more than 5 days ranged from 4 to 9 mgm., representing an increase of 20–35 per cent over the normal water content of the lens. The effect of the increase in water may be more pronounced than it appears since the accumulation of both water and dulcitol is probably not distributed uniformly but confined to the superficial layers of the lens.

The results obtained here suggest that the hypertonic condition created by the accumulation of dulcitol produces a net increase in the water content, which may be sufficient to lead eventually to the rupture of the lens fibres. Further investigations are being made to determine whether this osmotic change adequately describes the clinical manifestation observed not only in galactose cataract but in the diabetic and xylose cataracts as well. The differences in the course and rate of development of these cataracts may be directly related to the properties of the enzymes involved in the metabolism of polyols.

Effect of Age and Thymectomy on Urinary 17-Ketosteroid-levels in Male Rats

THE question whether or not there is an endocrine function of the thymus is one that has been much debated. Various investigators have claimed that thymectomy caused retardation of growth and gonadal development[1] and that injections of thymic extracts induced precocious development[2]. Others[3–5] have refuted these claims. Comsa[6] reported that thymectomy of male guinea pigs caused transitory stimulation of the adrenal cortex as evidenced by significant decreases in the levels of adrenal cholesterol and ascorbic acid. The study, however, lacked comparable sham-operated controls. In view of the various claims, we tried in the present investigation to determine whether the acute and chronic effects of thymectomy on adrenal and gonadal androgenic output are reflected by alterations in urinary 17-ketosteroid-levels.

The excretion of urinary androgens has been frequently used as an index of adrenocortical activity[7,8] as well as an index of adrenal and gonadal function[9]. An advantage of the urinary procedure is that it permits total estimation of the daily ketosteroid production of the gonadal and adrenal hormones.

Albino male Wistar rats averaging 50 gm. were matched by weight and divided into 3 groups (thymectomized rats, group *A*; sham-thymectomized rats, group *B*; and normal un-operated rats, group *C*). Thymectomy was accomplished by the method of Farris and Griffith[10]. Identical procedures were utilized in the sham-thymectomized animals except for the removal of the thymus. At the 4th, 12th and 24th weeks, a 24-hr. urine sample was collected from each of the rats. Two ml. volumes were tested for 17-ketosteroid content by the method of Rappaport *et al.*[11].

Table 1 lists the data in terms of urine volume, 17-ketosteroid content/ml. and total daily 17-ketosteroid-levels. It is apparent that, at the fourth week, no significant changes were observed in either urine volumes or ketosteroid-levels when the various group differences were compared by *t*-test procedures[12].

Table 1. EFFECT OF AGE AND THYMECTOMY ON URINARY 17-KETOSTEROID-LEVELS IN MALE RATS

Group	n	Body-weight (gm.)	Daily urine (vol., ml.)	17-ketosteroid (μgm./ml.)	17-ketosteroid (μgm./day)
4 week period					
Group *A* : Thymectomized	11	197·6	4·2	6·3	26·3

P value			0·12	>0·90	0·56
Per cent differences between *A* and *C*		+1·2	+19·7	+1·7	+22·83
P value			0·03	>0·90	0·3
Per cent differences between *B* and *C*		+4·6	+34·4	—	+35·9
P value			<0·01	>0·90	0·08

However, certain changes do appear at the 12th and 24th week. It is of interest to note that, at both periods, the total ketosteroid-levels in the sham-operated rats were greater than that of the normal un-operated controls and approached the 0·05 level of significance. At the 24th week, both the thymectomized and sham-operated animals had a significantly higher urinary output than the normal unoperated rats. Nevertheless, the 17-ketosteroid/ml. values were essentially similar in all 3 groups. Probably, the total ketosteroid decrease observed in the normal un-operated group could most likely be attributed to the smaller urine volumes collected from these rats. Claims have been presented that 17-ketosteroid excretion-levels are dependent on urine volume[13]. In turn, the ketosteroid and urine volume decreases may possibly be correlated with the body-weight differences.

In general, the 17-ketosteroid determinations did not reflect any short- or long-range effects of thymectomy on either adreno-cortical or androgenic output. Consequently, the data differ from previous claims of gonadal inhibition[1] and reports of transitory adrenocortical stimulation[6]. Certainly, the significant increases observed in the 17-ketosteroid values of the three groups at the 12th and 24th week periods as compared with the 4th week suggest the predominant role the gonads assume at the later periods.

Although Comsa[6] observed that the greatest decrease in adrenal ascorbic acid and cholesterol contents occurred 12–24 days after operation, the sample sizes of the thymectomized guinea pigs killed at the various age-levels were small and the study lacked sham-operated controls. The possibility does arise, however, that species differences may exist as well as a time factor since the present study initiated the 17-ketosteroid analyses at a 28-day post-thymectomy period.

Previous investigations of thymectomy demonstrated an increase in histamine LD_{50}, reflecting an increase in the 'histamine-resistance' function of the adrenals[14,15]. Thymectomy also increased resistance to drowning stress[15], another possible reflexion of adrenal-related work performance. Whereas adrenalectomy significantly reduced rat tolerance to histamine[16], histamine tolerance was raised by thymectomy. The findings of no changes in 17-ketosteroid output following thymectomy suggest a dichotomy between absolute output of adreno-cortical hormones and the physiological effects of that output as influenced by the removal of counter-balancing endocrine organ glands, in this case the thymus.

In conclusion, following thymectomy previous evidence of an increase in adreno-cortical function as shown by histamine tolerance studies was not associated with an increase in 17-ketosteroid output. This increase in histamine tolerance following thymectomy may reflect the removal of an anti-adrenal cortical action on the part of the thymus gland with respect to histamine tolerance; and/or the limitation of 17-ketosteroid determination as a measure of adreno-cortical output. Sackler *et al.*[17,18] have postulated a physiodynamic scheme of hormonal equilibrium consisting of a synergistic and antidyne relationship between the adrenal glucocorticoid hormones on one hand and the thyroid, gonad and a possible thymic hormone on the other.

ANATOMY

Effect of Testosterone on Œstrogen-induced Bone Formation in Mice

It is now well established that the parenteral administration of large doses of œstrogens to mice results in the deposition of new bone in the marrow cavities. This change is most pronounced in the long bones. Here the new bone is first laid down at both extremities on the trabeculæ of the spongiosa and then, becoming more compact, it extends along the longitudinal axis of the shaft towards the centre of the marrow cavity. Among mammals this response to œstrogens is peculiar to the mouse. It has provided us with an important method for studying the factors which influence bone formation.

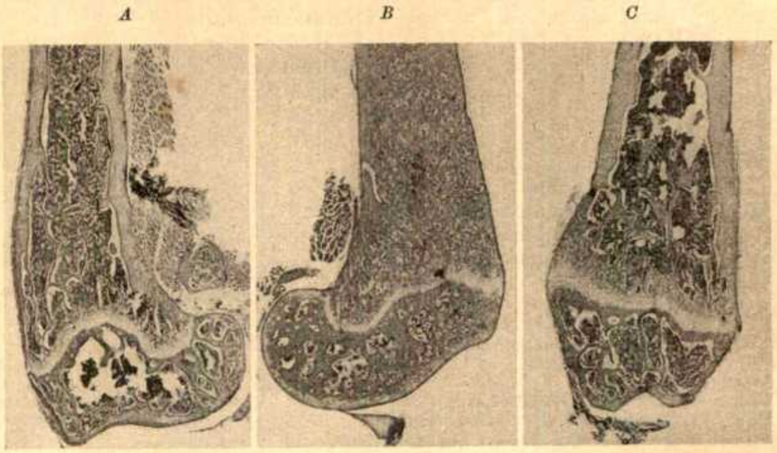

Fig. 1. Longitudinal sections of lower ends of three mice femurs. *A*, Control; *B*, 15-week-old male after 12 weeks treatment with 0·1 mgm. œstradiol monobenzoate per week; *C*, 15-week-old male after 12 weeks treatment with 0·1 mgm. œstradiol monobenzoate and 2·5 mgm. testosterone propionate per week

While many variables, such as the age and the sex of the animals, have been shown to affect the rate of deposition of endosteal bone in œstrogen-treated mice, only the parenteral administration of testosterone propionate has ever been claimed to avert it completely[1]. In 1950 Urist, Budy and McLean[2] stated that in their experiments they had found "Neither an inhibitory nor a synergistic action of testosterone upon the osteogenic action of large doses of œstrogen". In view of the possible bearing of these contradictory observations both on the role of sex hormones in the normal development of bone and on the effects of therapeutically administered sex hormones, a further investigation has been carried out.

10 litters of pure-strain mice (Guy's *C*) were subdivided into 17 litter-mate pairs. There were 10 male and 7 female pairs and each had its litter-mate control. All mice were kept under identical conditions and fed on a standard diet. Both mice in each pair were given weekly subcutaneous injections of 0·1 mgm. œstradiol monobenzoate ('Dimenformenol') while one mouse received in addition a weekly subcutaneous injection of 2·5 mgm. testosterone propionate ('Neohombreol'). Treatment was begun when the mice were between 21 and 28 days old and continued for periods ranging from 4 to 20 weeks. These dosages and the period of their administration are comparable with those used by both groups of workers cited. On completion of the course of injections the pairs, together with their controls, were killed. X-rays were taken of the femurs, which were then decalcified, cut into longitudinal sections, stained with hæmatoxylin and eosin, and mounted serially.

The radiographs of the femurs of mice treated with œstradiol alone showed an increase in the amount and density of bone, first at the distal and later at the proximal epiphysis. This is the characteristic initial response of the mouse skeleton to œstrogens. The amount of bone formation increased with the length of the course of injections. In every case the radiographs of the femurs of those mice treated with both œstradiol and testosterone showed markedly reduced endosteal bone formation when compared with those treated with œstradiol alone. But from comparison with the controls it was apparent that this inhibition of endosteal bone formation was never complete after only 4 weekly injections and not consistently complete until 12 or more weekly injections had been given. A quantitative confirmation of these observations was obtained from measurements made on the longitudinal sections of the femurs. Using a stage micrometer, the distance between the most proximal point on the distal epiphyseal cartilage and the most proximal spicule of bone which was in direct continuity with the cartilage was measured.

These observations show that testosterone antagonizes the osteogenic action of œstrogens in the mouse. This antagonism does not prevent the initial formation of œstrogen bone but appears to involve a renewal of the bone resorption which has been suppressed by œstrogen. These results contradict the findings of Urist, Budy, and McLean[2].

We thank Prof. R. Warwick and Dr. M. Brookes for their help with this work.

PATHOLOGY

Role of 3,4-Benzopyrene in Carcinogenesis by Tobacco Smoke Condensate

THAT those engaged in the chemical analysis of cigarette smoke have focused so much of their attention on 3,4-benzopyrene suggests that it has been tacitly assumed that this substance is wholly or mainly responsible for the carcinogenicity of the smoke.

The benzopyrene content of cigarette smoke has been measured or estimated by many groups of workers (for review, see ref. 1). The majority of estimates fall within the range 0·5–2·5 µgm. per 100 cigarettes. In some cases where much higher estimates have been obtained the methods of analysis have been criticized[1]. It has been pointed out elsewhere[2] that the carcinogenicity of the condensate cannot be explained in terms of the carcinogenicity of a benzopyrene content of the order 0·5–2·5 µgm. per 100 cigarettes.

Smoke condensate applied to the backs of mice thrice weekly for 60 weeks such that mice received only 0·005–0·025 µgm. benzopyrene at each application developed benign and malignant tumours of the skin[3,4]. Yet, in experiments in which graded dilutions of benzopyrene in acetone were applied to mouse skin, amounts of benzopyrene well in excess of 0·38 µgm. per application were necessary to obtain a similar carcinogenic response[5].

The discovery that the phenolic fraction of cigarette smoke promotes tumour development in mouse skin following initiation by subcarcinogenic doses of 9,10-dimethyl-1,2-benzanthracene (DMBA) led to a new explanation of the carcinogenic activity of cigarette smoke[4]. According to this hypothesis, the low activity of benzopyrene and other carcinogenic constituents of smoke is enhanced cocarcinogenically by certain irritant phenolic, and possibly other, constituents. This hypothesis is now regarded as at least plausible by several of those working in the field[6,7].

In the experiment which is reported preliminarily here, the part played by 3,4-benzopyrene in carcinogenesis by a condensate of cigarette smoke was assessed by comparing the carcinogenicity of an unadulterated sample of the condensate with that of samples to which benzopyrene had been added in various measured amounts.

Smoke condensate obtained by artificially smoking cigarettes in a special machine was kindly supplied by Dr. F. G. Bock of the Roswell Park Memorial Institute, Buffalo, New York. It was sent from the United States at approximately 6-week intervals packed in dry ice. After arrival it was stored at 4° C. until required. A sample of the condensate was analysed by Dr. A. J. Lindsey of the Sir John Cass Institute, London, and found to contain approximately 0·6 µgm. 3,4-benzopyrene/gm.

One hundred male and a similar number of female mice of a stock albino strain were divided at random into five groups containing 20 mice of each sex. At the beginning of the experiment, and thereafter as necessary, hair was removed from the backs of mice by electric clippers.

Mice of group 1 were given thrice-weekly applications of 0·2 ml. 20 per cent w/v smoke condensate in acetone, that is to say, 40 mgm. of condensate containing approximately 0·025 µgm. 3,4-benzopyrene three times weekly. Mice of groups 2, 3 and 4 were similarly treated except that 3,4-benzopyrene was added to the condensate so as to increase the amounts applied on each occasion to 0·06 µgm., 0·25 µgm. and 1·25 µgm. respectively. Group 5, on the other hand, received thrice-weekly applications of 1·25 µgm. 3,4-benzopyrene dissolved simply in acetone. All treatments were continued for 68 weeks during which period the different groups received totals of approx-

Table 1. EFFECT OF ADDED 3,4-BENZOPYRENE (BP) ON CARCINOGENICITY OF CIGARETTE SMOKE CONDENSATE FOR MOUSE SKIN

Group	Treatment Thrice weekly applications to dorsal skin for 68 weeks	Total dose of smoke condensate (gm.)	Total dose of BP (µgm.)	Survivors at time of first tumour in any group (that is, 39 weeks)	First papilloma seen (weeks)	First malignant skin tumour (weeks)
1	20 per cent smoke condensate in acetone with 'normal' content of BP (0·025 µgm. per application)	8·16	5	33	74	76
2	20 per cent smoke condensate with added BP (0·06 µgm. per application)	8·16	12	30	59	74
3	20 per cent smoke condensate with added BP (0·25 µgm. per application)	8·16	51	34	54	62
4	20 per cent smoke condensate with added BP (1·25 µgm. per application)	8·16	255	33	39	59
5	1·25 µgm. BP in acetone	None	255	30	67	—

imately 5, 12, 51, 255 and 255 μgm. 3,4-benzopyrene respectively. During treatment and after treatment was stopped all mice were examined at fortnightly intervals for benign and malignant tumours of the skin. Malignant tumours were removed at operation under ether anæsthesia when they reached approximately 1 cm. in diameter. They were examined histologically and only recorded as malignant if they showed penetration of the panniculus carnosus muscle.

The results of the experiment are given in Tables 1 and 2.

Table 2. TUMOUR INCIDENCE AT 68 WEEKS AND 84 WEEKS

	Tumour incidence at 68 weeks			Tumour incidence at 84 weeks		
Group	Survivors	Total benign tumours	Total malignant tumours*	Survivors	Mice with malignant tumours	Total malignant tumours*
1	31	0	0	26	3	3
2	21	4	0	15	4	5
3	19	0	1	15	2	2
4	24	17	5	14	9	10
5	21	0	0	14	0	0

* Cumulative total excluding recurrent tumours.

Comparison of the results in groups 1 and 5 indicates that unadulterated smoke condensate is, if anything, more carcinogenic than an acetone solution containing 50 times as much 3,4-benzopyrene. Comparison of the results in groups 4 and 5, on the other hand, shows that benzopyrene mixed with smoke condensate is far more carcinogenic than the same concentration of benzopyrene in acetone. If this were due to simple summation of the carcinogenic effects of smoke condensate and benzopyrene, the tumour incidence in group 4 should have equalled the sum of the incidences in groups 1 and 5: it is obviously well in excess of it. The high yield in group 4, thus, suggests a multiplication rather than a summation of effect. This fits the hypothesis that smoke condensate contains cocarcinogenic substances in the phenolic and possibly other fractions.

Judged by the comparison of tumour-induction times and of tumour incidence, the carcinogenic responses of groups 2 and 3 tended to be intermediate between those of groups 1 and 4.

The clear-cut nature and obvious interest of these results prompted their publication before the completion of the period of observation.

This investigation was supported by grants to the Chester Beatty Research Institute (Institute of Cancer Research: Royal Cancer Hospital) from the Medical Research Council (Tobacco Manufacturers' Benefaction), the British Empire Cancer Campaign, the Anna Fuller Fund, and the National Cancer Institute of the National Institutes of Health, U.S. Public Health Service.

IMMUNOLOGY

Immunological Identification of a Cryomacroglobulin in a Patient with Acquired Hæmolytic Anæmia associated with a Cold Antibody

PATHOLOGICAL macroglobulins are reported to b antigenically related to normal 19S as well as norma 7S γ-globulins[1,2], although recent work woul indicate that antigenic identity and cross-reactivit between normal 7S and 19S γ-globulins might hav arisen from their imperfect separation[3]. Ultracentrifugal studies indicate that the pathologica macroglobulins[1,4] are composed of 19S and a smalle proportion of 26S γ-globulin, while the pathologica cold agglutinins consist mainly of 19S component an a much smaller amount of a faster sedimenting component[5]. The present work demonstrates evidence o cross-reactivity between a cryomacroglobulin wit cold agglutinin activity and cold agglutinin macroglobulins, which were not cryoglobulins, in the ser of other patients suffering from acquired hæmolyti anæmia associated with cold antibody formation.

Materials were obtained and methods were use according to Mehrotra[6]. The cryoglobulin wa precipitated in the cold and the 19S component wa prepared in the ultracentrifuge from normal huma serum. The cryoglobulin was used as the antigen i the preparation of the specific antiserum.

The isolated cold agglutinin and cryomacroglobuli had the same electrophoretic mobility as γ_1-globulin and this corresponded to the abnormal γ_1-globuli peak in the whole serum.

The results of investigation by double diffusion i agar are illustrated in the figures, and they were th same with the whole sera as with the isolated proteins After absorption of the antiserum with 7S γ-globuli (Fig. 1) (Fraction G4 kindly supplied by the Bloo Products Laboratory, Lister Institute, and prepare by the technique of Kekwick and Mackay[7]), two line developed against the patient's cryomacroglobuli and cold agglutinin. At least one faster componen was developed with the patient's whole serum an this was probably due to the presence of anti-β_1-globulin in the antiserum. The single line develope against the 19S component from normal serum ca clearly be seen to cross-react with the faster diffusin component of the patient's cryomacroglobulin, wit the formation of a single spur. When the antiseru

Centre cup, specific antiserum absorbed with 7S γ-globulin

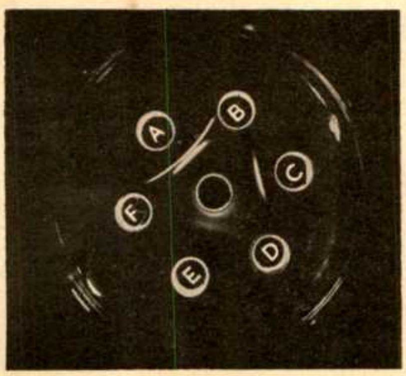

Fig. 2. *A*, Specific serum, diluted 1 in 4; *B*, normal serum, diluted 1 in 4; *C–F*, cold agglutinin serum, diluted 1 in 4. Centre cup, specific antiserum absorbed with $7S$ γ-globulin and an excess of normal serum

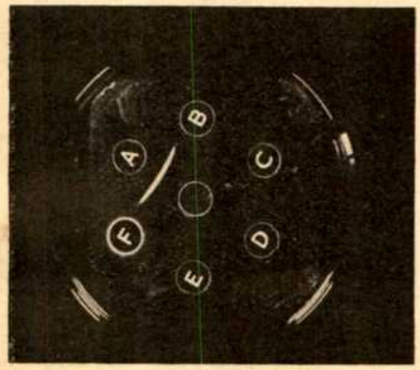

Fig. 3. *A*, Specific serum diluted 1 in 4; *B–F*, cold agglutinin serum, diluted 1 in 4. Centre cup, specific antiserum absorbed with $7S$ γ-globulin and an excess of normal serum and a cold agglutinin serum

was absorbed with an excess of normal serum (Fig. 2), two lines developed against the patient's serum, the faster component cross-reacting with three other sera containing pathological cold agglutinins. The line nearer the antigen cup was patient-specific, and no lines developed against normal serum. In Fig. 3 the antiserum has been absorbed with a mixture of normal serum and one of the cold agglutinin sera, and it is now specific for the patient, producing only a single line.

These results indicate that the cryomacroglobulin has at least two antigenic determinants not present in normal serum. One, in the faster diffusing component by agar-gel diffusion, cross-reacts with several sera containing pathological cold agglutinins (and the isolated cold agglutinins), and the other, in the slower component, is patient-specific.

This finding is in keeping with those of Habich[8] and Kanzow *et al.*[9], using tube precipitin tests. Korngold and Van Leeuwen[2], reporting on the sera of patients with macroglobulinæmia but no cold agglutinins, state that these pathological macroglobulins have at least two antigenic groups not present in normal serum proteins and that they are situated on two components. Both are macroglobulin in nature and the authors presumed that the slower was the $26S$ component, but this is difficult to establish. According to these workers exhaustive absorption of the specific antisera with normal serum proteins rendered them patient-specific, but this is contrary to the present finding. Pathological cold agglutinins have been studied in the ultracentrifuge and shown[5] to contain a major $19S$ component and a small amount of a faster sedimenting one. In an immunological investigation[6], Mehrotra concluded that the cold agglutinins were $19S$ macroglobulins and did not demonstrate any cross-reactivity between them, not shared by normal macroglobulins.

Examination of the present cryomacroglobulin suggests the possibility that the pathological cold agglutinins share cross-reacting antigenic determinants as well as having patient-specific ones, not present in normal serum. One other pathological cold agglutinin studied in the same manner has been shown to cross-react with another cold agglutinin after exhaustive absorption with normal serum proteins, suggesting that the findings presented here were not the result of an isolated exception; but this has to be tested by further work.

We thank Dr. W. d'A Maycock for the supplies of fraction $G4$, Dr. M. E. Mackay and Dr. R. A. Kekwick for the preparation of normal $19S$ component and Prof. J. V. Dacie for advice.

Inherited Immunologically Atypical Haptoglobin

THE presence of three genetically determined haptoglobin types (*Hp* 1–1; *Hp* 2–1; *Hp* 2–2) for the Caucasian race was first demonstrated by Smithies using starch-gel electrophoresis[1,2]. Only a small number of atypical haptoglobins have since been described[2,3]. Although the three *Hp* types differ with respect to molecular weight and electrophoretic mobility, they have been shown to be immunologically identical among each other[4,5], that is, to possess identical antigenic determinants.

In the course of investigations with a modified agar-gel diffusion technique[5,6] for the demonstration of the three *Hp* types, one serum was encountered which did not give the usual reaction of identity. As shown in Fig. 1, serum B. Wi. showed a distinct spur formation when tested next to normal sera of the three *Hp* types, thus demonstrating only partial antigenic identity with the normal *Hp* proteins. From the position of the spur it could be concluded that the *Hp* of this serum possessed an additional antigenic determinant. Since this patient suffered from cirrhosis of the liver it was thought that this atypical behaviour might be a result of this disease. However, the same spur formation was shown by the serum of one brother (W. Wi.) and of the son (G. Wi.) of the original patient, although these were both healthy individuals. Among each other, the

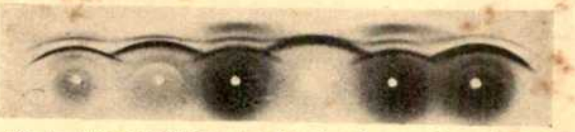

Fig. 1. Agar-gel diffusion test showing the spur formation by the Wi. sera. Antiserum in trough along upper limit of photograph. From left to right: serum B. Wi., normal *Hp* 2–1, serum W. Wi., normal *Hp* 1–1, serum G. Wi., normal *Hp* 2–2. Benzidine stain

three sera Wi. gave a reaction of identity. All three had normal *Hp* serum levels. Two female members of this family had a normal *Hp* 2–1 type.

The spur formation could be demonstrated using several antisera (horse-anti-human-serum-antisera 13412, 13414 and 13415, Institut Pasteur, Paris). One rabbit antiserum with an apparently low titre of antihaptoglobin antibodies (number 4, Behring Werke AG, Marburg/Lahn) reacted with normal *Hp* only, but did not give any reaction with the *Hp* of the three sera Wi.

The atypical nature of the *Hp* proteins of these sera was further demonstrated by absorption of the antisera with a normal *Hp* 2–1 (kindly supplied by Prof. H. E. Schultze, Behring-Werke, Marburg/L.), after which the antiserum still gave a somewhat weaker precipitate with the three sera Wi., whereas with normal sera a benzidine positive precipitate was no longer obtained. On ordinary agar-gel immunoelectrophoresis, the three sera Wi. presented the usual benzidine positive precipitin band in the α_2-region, thus showing that we were indeed dealing with Hp^s. On starch-gel electrophoresis, they showed a constellation similar to type *Hp* 2–1; however, one band in the slower migrating group seemed to be broadened. The immunological identification[6] of this band gave the same spur formation as the whole serum when tested in the same manner. This latter finding suggested that only part of the *Hp* of these sera carried the atypical antigenic determinant. It should be mentioned here that spur formation need not necessarily represent partial identity, if two precipitates of two closely related proteins are superimposed in an agar-gel diffusion experiment[7].

From the preliminary family investigation (Fig. 2) a dominant inheritance appears probable. The direct inheritance observed represents evidence against a recessive transmittance because then both parents should have had the recessive gene. There seems to be no indication for a sex bound inheritance, since female conductors are obviously not involved.

From these findings it would appear that the three sera Wi. contain a rare antigenic determinant in their *Hp* proteins. However, among the human sera used for immunization in the production of the antiser there must have been present at least one seru containing this atypical *Hp*. Another possibili might be a mere quantitative prevalence of th unusual determinant in the investigated famil where one would further have to assume that th determinant would be present in 'normal' sera amounts too small to be detected by the usu technique, failing to give a visible precipitat Further investigations aiming in the isolation of th *Hp* protein are under way.

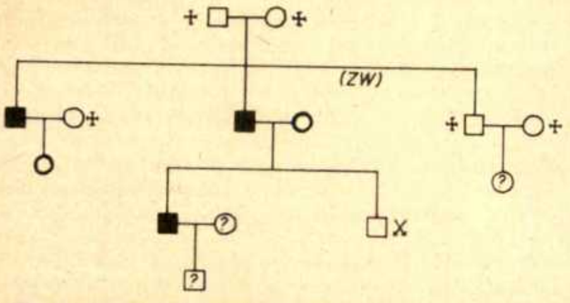

Fig. 2. Pedigree of family Wi. ■ (solid squares), members showing the atypical *Hp*; ○ (heavy circles), two investigated female family members with normal *Hp* 2–1. ? = not investigated

BIOLOGY

'Egg-dummies' as Natural Releasers in Mouth-breeding Cichlids

THERE are quite a number of African moutl breeding cichlids (*Haplochromis* and related genera the males of which bear very conspicuously yello or orange spots near the base of the anal fin. Th function of these so-called 'anal ocelli' has now bee elucidated in *Haplochromis wingatii*.

The male of *H. wingatii* digs a nest pit and the courts a female and tries to lead her there. A femal ready to spawn will follow the male and soon start to lay eggs in the pit. These eggs, however, ar snapped up into the female's mouth before the mal is able to fertilize them. The male, in his turn, slide over the spot where the eggs have been, fertilizin the empty bottom. During this movement his ana fin is strongly spread and very dark in ground colou displaying the round, orange spots in colour con trast. These spots resemble very precisely the egg of this species in colour, size and form; and indeed the female tries to grasp them with her lips, thereb taking into her mouth the sperm ejected by the male The 'painted eggs' are much more conspicuou against the dark anal fin than are the real eggs in th sand pit; but they are sub-normal objects wit respect to the female's reaction of snapping up eggs

In the literature, these egg-spots are usually calle eye-spots, or ocelli. However, true eye-spots have dark centre and a lighter area around; they are t be found on the opercula of many cichlids, in th posterior part of the dorsal or the upper part of th caudal fin in *Pelmatochromis subocellatus*, and i general they have an intimidating function. Th egg-spots are the negative of an eye-spot, having light or conspicuously coloured centre, normall ringed with dark, and attracting the partner. S both, morphologically and functionally, the latte should be carefully distinguished and not be referre to as eye-spots or ocelli (the term 'annular spot' i suggested for both types).

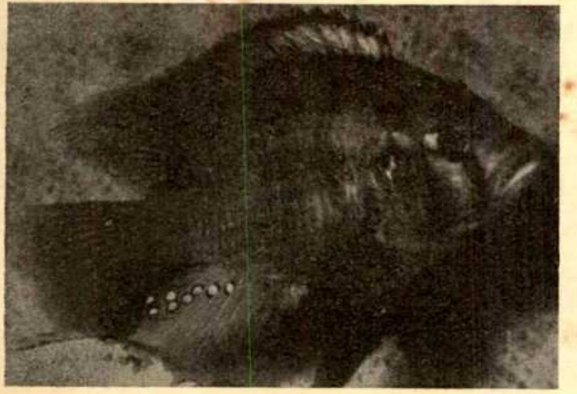

Fig. 1. Male fish of *Haplochromis wingatii*, showing eight annular spots on his anal fin

A second large group of mouth-breeding cichlids in Africa is formed by the genus *Tilapia*. Here, too, this specialization gives the same result: the female takes the eggs into the mouth as soon as they are laid. So these animals have to overcome the same difficulty of getting their eggs fertilized. Here, the females are often seen to nibble at the male's genital papilla, which is bright white or yellow, contrasting well with the dark ventral surface of the male fish. In some species of *Tilapia* the males bear 'genital tassels', long appendages of their genital papillæ, consisting of bifid semi-transparent filaments, festooned with bright orange blobs of tissue. Since in colour and form they resemble the eggs of the respective species, I believe that they function as 'egg-dummies'.

Both types of egg-models are attributes of the nuptual coloration of the male. They seem to be important taxonomic characters, distinguishing the *Haplochromis* group and the *Tilapia* group. Due to their releasing function, the reaction of the female in snapping up eggs is functionally changed into snapping up the (invisible) sperm. Most of the eggs of these species are thus fertilized when in the mouth of the female.

Weight and Length in the River Lamprey

NORMALLY the length of vertebrates (including fish[1,2]) does not become reduced even during prolonged fasting. This rule does not apply to the cyclostomes. The river lamprey, *Lampetra fluviatilis* (L.) Gray, is known to undergo a considerable shortening (up to 27 per cent[3,4]) during the months between its migration from the sea to the rivers in autumn and the spawning and ensuing death in spring. In this period the animals do not eat, and their gut is reduced.

The reduction in length during fasting of course tends to keep the proportion between weight and length of the animals constant, so it would be interesting to examine to what degree this is accomplished. Therefore the weight and length of single river lampreys were followed in this laboratory from October until spawning. One batch of animals came from Sweden and the other from Denmark. These results were combined with those of Lanzing[5], who measured batches of river lampreys in the Netherlands caught during August–March.

Fig. 1 shows that the data representing the result of fasting fall around a straight line, if plotted on double logarithmic paper. The starved animals do not differ much from the well-nourished ones just coming from the sea, so instead of becoming extremely lean like other severely fasting vertebrates, the river lampreys maintain rather normal proportions (until spawning). The straight line signifies that the reduction in weight and length is allometric (weight = $a \times \text{length}^n$); the line is likely to be identical with the growth-curve of these animals. Zanandrea[6] measured batches of river lampreys caught in sea water while still feeding; their growth is allometric, the growth-curve running parallel to the straight line in Fig. 1. It would be interesting to see how these growing animals become reduced in weight and length if they were submitted to fasting. Presumably they would follow the same curve 'backwards'.

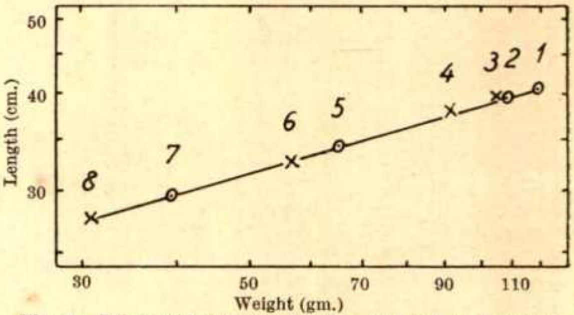

Fig. 1. Relationship between weight and length in *Lampetra fluviatilis*. ○, Recently caught, non-fasting animals; freshwater; ×, fasting for a long time. Place and time of capture and number of animals: (1) Meuse, Netherlands, October, 70 (ref. 5); (2) Meuse, Netherlands, August, 70 (ref. 5); (3) Meuse, Netherlands, January, 70 (ref. 5); (4) Meuse, Netherlands, March, 70 (ref. 5); (5) Varde aa, Denmark, October, 10, measured 1 month after arrival; (6) Varde aa, Denmark, October, 10, measured in February; (7) Dalälv, Sweden, October, 11, measured 1 month after arrival; (8) Dalälv, Sweden, October, 11, measured in February

Under certain conditions the body proportions are altered. Some time before spawning, presumably at the time of ovulation, the females gain in weight and become swollen; but their length is still decreasing, sometimes even faster than before. Moreover, animals disturbed by transport seem to gain in weight by uptake of water (increased permeability of the skin[2]); this is followed by a large decrease in body-weight observed after 2 weeks in the laboratory; these fluctuations in body-weight are accompanied by the usual slow shortening.

The relation between weight and length during the life-time of the river lampreys is thus quite different from that found in other vertebrates. The lack of a skeleton and the nature of the chorda may make the shortening possible. Shortening during fasting was observed in planarians[7] and is probably not uncommon in other animals which do not possess a stiff exo- or endo-skeleton.

Fossil Dinoflagellates and Hystrichospheres in Australian Freshwater Deposits

During investigations of algae and aplanospores in Holocene peat deposits of south-western Australia[1], fossil dinoflagellates and hystrichospheres have been found; these are the first representatives of these groups to be discovered in non-marine deposits. The dinoflagellates are referable to the genera *Gymnodinium* (Fig. 1*b*), *?Peridinium* (Fig. 1*a*), *Palaeohystrichophora* and to an undescribed genus of the family Peridiniaceae; they are found in assemblages from two localities near Lake Muir, about 40 miles north of Walpole, Western Australia, and from Myalup Swamp, 24 miles north-north-east of Bunbury, Western Australia. The hystrichospheres are referable to six undescribed species of the genus *Baltisphaeridium* (Figs. 1c and 1*d*): they are present in assemblages from the above localities and from deposits at Boggy Lake, 6 miles south-west of Walpole, Western Australia. In no case do these species afford evidence of dinoflagellate affinities.

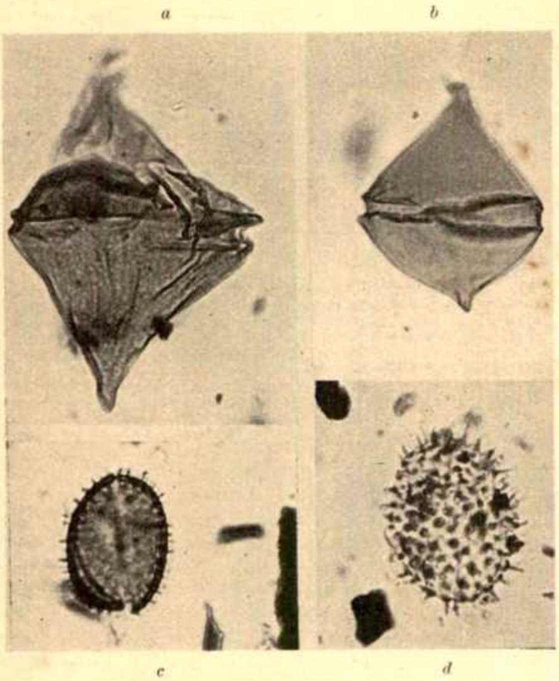

Fig. 1. Fossil freshwater dinoflagellates and hystrichospheres from south-west Australian peats. *a* (?) *Peridinium* sp. West Lake Muir at 30–40 cm. depth; *b*, *Gymnodinium* sp. West Lake Muir at 30–40 cm. depth; *c*, *Baltisphaeridium* sp. *A*, boggy lake at 90–100 cm. depth; *d*, *Baltisphaeridium* sp. *A*, at 20–30 cm. depth. (× *c*. 600)

Since the hystrichospheres have been regarded hitherto as "characteristically marine"[2] and have been considered as potentially reliable marine indices[3,4], their presence in undoubtedly non-marine deposits is of particular interest. Although there was some variation in relative salinity between the localities, in no case were the waters even brackish in terms of their absolute salinity. The assemblages may have originated by wind dispersal of cysts; evidence of the dispersal of aplanospores by this means has already been recorded[1]. The formation of the bogs was not related to any marine incursion, and the microplankton assemblages cannot be regarded as relict marine floras.

Dinoflagellates and hystrichospheres are absent from assemblages from peat profiles at other localities studied in Western Australia. There are no obvious special factors to account for the presence of these organisms in the localities listed and their absence elsewhere.

Uptake of Phenylalanine by *Tetrahymena pyriformis*

The nutritional requirements of *Tetrahymena pyriformis* are well known, and it can be cultured in a chemically defined medium. Nevertheless, some aspects of its feeding are still not clear. In nature the organisms are believed to feed phagotrophically on bacteria[1]. In synthetic media, however, food vacuoles are rarely seen. Although Seaman[2] found that vacuole formation could be stimulated by the addition of proteose peptone-yeast extract to the medium, the phagotrophic activity induced was not sufficient to supply the energy requirements of the organisms.

Uptake of amino-acids from solution has been reported for both micro-organisms and metazoans[3–5]. In some cases, membrane transport has been implicated. Since phagotrophy does not account for the obvious ability of *Tetrahymena* to thrive on a suitable mixture of small organic molecules, it seemed desirable to investigate this possibility.

Tetrahymena pyriformis B was grown axenically in 1 per cent proteose peptone, 0·05 per cent yeast extract, with added ferrous sulphate ($8{\cdot}95 \times 10^{-5}\ M$) and sodium-ethylenediamine tetraacetic acid ($6{\cdot}87 \times 10^{-5}\ M$). Cells were gathered at the end of the log phase by centrifugation and washed and suspended in $M/100$ phosphate buffer, *p*H 6·4, at a concentration of 10^6 cells/ml. DL-phenylalanine-3-^{14}C was added and samples were taken at suitable time-intervals. Samples were collected by filtering 1 ml. of the cell suspension through a 1-in. *AM*–1 Polypore membrane filter (pore size, 5μ). The filter was then washed with 8–10 vols. of phosphate buffer. Radioactivity in the organisms was determined by measuring the labelled material restrained by the filter using a thin-window Geiger tube. The technique was checked by washing labelled cells with non-radioactive buffer and measuring the radioactivity of samples dried on aluminium planchets. The results presented have been corrected for the greater self-absorption encountered in the filter disks.

At concentrations of about 1 μgm./ml., 40–50 per cent of the DL-phenylalanine was removed in the first 20 min. No additional material was removed if incubation was continued for longer periods. The rate of uptake appeared linear for the first 10 min. of incubation. The relation between the initial rate of uptake and phenylalanine concentration was determined and is presented in Fig. 1. An excellent linear relation is obtained when the reciprocal of this rate is plotted against the reciprocal of phenylalanine concentration. Hence it seemed reasonable to treat the system as formally equivalent to an enzymatic reaction for purposes of analysis. The K_m and $V_{\max}$ were calculated using a Burke–Lineweaver plot of the data. The concentration at which uptake is half-maximal (K_m) is 2·5 ± 0·25 µgm./ml. The maximum rate of uptake ($V_{\max}$) is 0·227 µgm./10^6 cells/min.

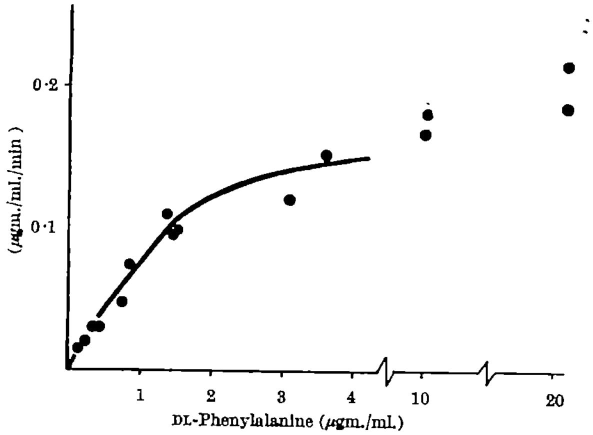

Fig. 1

The uptake process depends on temperature exhibiting a Q_{10} of 2·19 for the temperature-range 12°–20° C. and 1·63 for the range 20°–28°. 2,4-dinitrophenol acts as an inhibitor at pH 6·4. 10 per cent inhibition was observed with 5×10^{-6} M; 86 per cent with 5×10^{-5} M.

Although labelled phenylalanine was available only as a racemic mixture, observations indicate that only the L isomer is involved in this process. The addition of 100 µgm./ml. of L-phenylalanine produces a very marked decrease in the rate of removal of radioactivity from the labelled racemic mixture at low concentrations. Addition of 100 µgm./ml. of D-phenylalanine has no effect. Fresh cells suspended in medium from which radioactive phenylalanine had been previously removed by *Tetrahymena* do not show significant uptake despite the fact that approximately 50 per cent of the labelled material is still present. This residual material is presumably D-phenylalanine.

Seaman[2] determined that cells of *Tetrahymena* washed and suspended in phosphate buffer did not take in materials through the cytostome. Even under his optimal conditions for food vacuole formation, the rate of uptake of phenylalanine at low concentrations vastly exceeds observed rates of vacuole formation.

The rapidity of the uptake process, its kinetics, its stereospecificity, the fact that the process is dependent on temperature, and the inhibition of uptake by 2,4-dinitrophenol all suggest a membrane transport mechanism. Preliminary experiments with other amino-acids indicate that they are also removed from solution. We are now extending this work in an effort to demonstrate accumulation, to study possible interactions between amino-acids, and to determine if such an uptake process might be sufficient to provide for the energy requirements of the organisms.

Utilization of Ethanol-2-^{14}C by Pea Slices

STIMULATIONS in the growth of algae[1,2] and seedlings[3] by added ethanol solutions prompted Cossins and Turner[4] to report preliminary experiments which indicated that ethanol, accumulated under anaerobic conditions, can be utilized by pea seedlings under subsequent aerobic conditions.

Further experiments have now been carried out to determine the changes in the concentration of the keto and organic acids accompanying ethanol disappearance in pea seedlings. During this period, it was found by means of paper chromatography that large fluctuations in the contents of acetaldehyde, acetone and the acids of the Krebs cycle occurred, which further suggested that the ethanol might be utilized by these tissues.

Clear evidence, however, for such ethanol utilization has now been obtained in experiments where ethanol-2-^{14}C was fed to pea slices. After germination for 48 hr. at 20° C., Kelvedon Wonder pea cotyledons were hand-sliced at 2° C. and 1 gm. samples of the slices were incubated at 20° C. with 1 ml. of ethanol-2-^{14}C with an activity of 12·5 µc. Oxygen was passed over the slices and the gas stream was finally passed into barium hydroxide solution to remove carbon dioxide. At the end of the experimental periods, extracts of the ethanol soluble and the 2,4-dinitrophenylhydrazine derivatives of the carbonyl compounds were prepared and separated by paper chromatography. The radioactivity of the compounds isolated was assessed by scintillation counting using Panax *AC*/300/6 automatic counting equipment with a Panax scintillation counter with an anthracene crystal.

Samples of the slices taken after 15 and 30 min. incubation with the ethanol-2-^{14}C showed that a large number of compounds contained carbon-14, which

included those shown in Table 1. No carbon-14 was detected in the barium hydroxide traps.

These results indicate that in the slices of germinating peas, the carbon-14 of the ethanol-2-^{14}C rapidly became distributed among a large number of organic compounds. Furthermore the pattern of this labelling was similar to the changes in concentration of the organic and keto-acids occurring in intact germinating peas during the disappearance of the endogenous ethanol. This would suggest that germinating pea tissues, unlike the mature carrot disks used by Lowe and James[5], are capable of metabolizing ethanol. Therefore there is reason to suppose that at least some of the ethanol accumulated under anaerobic conditions can be utilized during the subsequent aerobic phases of germination in peas.

Variability of the Niacin Content in Coffee

IT has been found that coffee seeds contain small amounts of certain vitamins, among which niacin prevails in higher proportion. An average consumption of 3·5 cups of coffee per day could supply about one-third of the minimum daily niacin requirement for a normal adult male[1]. In order to determine the possible effect on niacin content of varying environmental conditions under which coffee is grown, as well as of the different methods of processing, two sets of specially prepared samples were analysed.

In April, 1958, four such samples were prepared: two belonged to the Bourbon Vermelho cultivar (*C* 662) and two to the Bourbon Amarelo (Jaú). The samples were derived from sun-dried beans (dried with pericarp), which is the usual system used by the majority of Brazilian coffee farms. One sample of each cultivar was taken from plants grown without shade, while the other was derived from shaded coffee plants. Table 1 shows the amounts of niacin obtained. While the niacin content seems to be similar in both cultivars, the amount of niacin obtained from samples collected from shaded coffee trees was in both cases reduced.

During November 1959 new samples were prepared from coffee plants of the cultivars Bourbon Vermelho (*LC* 408), Mundo Novo (*LCP* 379–19) and Bourbon Amarelo (*LCJ* 30), grown in shaded and unshaded environments. Some of the samples were from sun-dried beans while others were from de-pulped coffee (dried in parchment). The results obtained are given in Table 2.

Table 1. SHOWING THE AMOUNT OF NIACIN OBTAINED

Cultivar	Treatment	Niacin (mgm./gm.)
Bourbon Vermelho (*C*662)	Without shade	0 329
Bourbon Vermelho (*C*662)	Shaded	0 237
Bourbon Amarelo (Jaú)	Without shade	0 332
Bourbon Amarelo (Jaú)	Shaded	0 260

Table 2

Cultivar	Treatment	Niacin (mgm /gm)
Bourbon Vermelho (*LC*408)	Without shade, sun-dried cherries	0·329
Bourbon Vermelho (*LC* 408)	Without shade, dried in parchment	0·400
Bourbon Vermelho (*LC*408)	Shaded, sun-dried cherries	0·271
Bourbon Vermelho (*LC* 408)	Shaded, dried in parchment	0·314
Mundo Novo (*LCP* 379–19)	Without shade, dried in parchment	0·265
Mundo Novo (*LCP* 379–19)	Shaded, dried in parchment	0·226
Bourbon Amarelo (*LCJ* 30)	Without shade, dried in parchment	0·160
Bourbon Amarelo (*LCJ* 30)	Shaded, dried in parchment	0·206

With the exception of the results obtained with samples of the cultivar Bourbon Amarelo (*LCJ* 30), shade again reduced the niacin content. It can also be seen that the de-pulping operation seems to increase the amount of niacin content, although not so markedly as when coffee is grown without shade.

It is, furthermore, noteworthy that the latter three cultivars differ in niacin content, indicating that selection might be effective in isolating strains with higher amounts of this vitamin.

In order to obtain reliable comparative results when investigating the niacin content in coffee seeds, it is therefore necessary to use samples collected from coffee trees grown under identical environmental conditions and also that the samples be processed the same way.

Biochemical Contributions to the Taxonomy of the Genus *Chlorella*

SINCE Warburg's[1] work, in 1919, green algae of the genus *Chlorella* have been among the experimental organisms most frequently used for plant physiological and biochemical research. However, due to the little morphological differentiation of their more or less spherical cells, the taxonomy of these algae has been rather confused (cf. ref. 2). This holds especially true for the members of the section *Euchlorella* comprising the most common species, that is, *Chlorella vulgaris* Beijerinck, *Chl. pyrenoidosa* Chick, and *Chl. ellipsoidea* Gerneck. The criteria given by Pascher[3] for their identification (size and shape of cells and chloroplasts, visibility of the pyrenoid, etc.) have been shown to be highly variable and ambiguous, and to depend to a large extent on culture conditions and developmental stage of the cells[4]. Therefore, in most cases it is very difficult, if not impossible, to identify these species by morphological criteria. Since the characteristics traditionally used for taxonomy are obviously insufficient in this case, we propose to use mainly physiological and biochemical rather than morphological criteria for the identification of these *Chlorella* species.

The experimental material used in this work was the strains of *Chlorella* available in the culture collection of Prof. Pringsheim, Göttingen. Three biochemical properties known to be present in some, but not all, strains of *Chlorella* were chosen for our work, that is, hydrogenase activity[1], formation of secondary carotenoids under conditions of nitrogen deficiency[4], and presence in the cell and in the cell wall of carbohydrates (probably pectin or related substances) giving a red colour reaction with ruthenium red. For the hydrogenase tests, the algae grown in a medium[7] containing nitrate were suspended in phosphate buffer (4×10^{-3} *M*; *p*H 6·5) and incubated under an atmosphere of pure hydrogen in Warburg vessels (with potassium hydroxide in the centre well) at 20° C. in the dark. After 3, 6, 12, 24, 48, 72, and 100 hr., nitrite (final concentration 1×10^{-3} *M*) as the most suitable hydrogen acceptor[5,8] was poured in and the uptake of hydrogen measured manometrically. Nitrogen-deficient cultures were obtained by replacing 90 per cent of the potassium nitrate of the culture medium[7] with potassium chloride (nitrate concentration 8×10^{-4} *M* instead of 8×10^{-3} *M* in the normal medium). After four weeks of growth at a light intensity of 4,000 lux, the colour of the deficient cultures was either orange or pale greenish-yellow to white. The ruthenium red reaction was carried out by treating algae taken from agar slant cultures with a 0·2 per cent solution of ruthenium red (Merck, Darmstadt) dissolved in hot distilled water. The resulting colour of cell contents and of the empty membranes of mother cells after the discharge of the autospores was then observed under the microscope.

Table 1. BIOCHEMICAL AND PHYSIOLOGICAL PROPERTIES OF 25 DIFFERENT STRAINS OF THE GENUS *Chlorella*, SECTION *Euchlorella*

Hydrogenase activity	Colour of N-deficient cells	Reaction with ruthenium red	Strain Nos. of Pringsheim's culture collection	Species
Strong	Orange	None	211-8*b*, 8*c*, 8*e*, 11*m**, 11*n**	*Chl. pyrenoidosa*
Weak	Pale	Weak	211-8*k*, 11*g*, 11*h*. 11*k*	
None	Pale	Strong	211-11*b*, 11*c*, 11*f*, 11*i*, 11*l*, 11*p*, 11*qu*, 11*r*, 11*s*, 11*t*, 8*l*†, 1*a*‡, 1*e*‡	*Chl. vulgaris* Beijerinck
None	Pale	None	211-1*b*, 1*c*, 1*d*	*Chl. ellipsoidea* Gerneck

* *Chlorella* 11*m* and 11*n*, listed in the culture collection as *Chl. vulgaris*, were found to belong to *Chl. pyrenoidosa*.

† *Chlorella* 8 *l*, listed as *Chl. pyrenoidosa*, was found to belong to *Chl. vulgaris*.

‡ *Chlorella* 1*a* and 1*e*, listed as *Chl. ellipsoidea*, were found to belong to *Chl. vulgaris*.

The results of these investigations are summarized in Table 1. It is evident that the 25 strains of *Chlorella* studied fall into four well-defined groups. The first group, which can be identified with *Chlorella pyrenoidosa*, is characterized by strong hydrogenase activity, a deep orange colour of nitrogen-deficient cultures, and no reaction with ruthenium red (cf. ref. 9). The third group, which comprises the most common species, *Chlorella vulgaris* Beijerinck, does not possess hydrogenase, turns pale due to the loss of both chlorophylls and carotenoids under conditions of nitrogen deficiency, and develops a brilliant red colour with ruthenium red. The fourth group is identical with *Chlorella ellipsoidea* Gerneck. This species can be recognized by the strongly elliptical shape (even in agar cultures) of its cells, which do not contain hydrogenase, turn pale fairly slowly in nitrogen-deficient cultures, and do not react with ruthenium red. In addition to these well-known species, there is another group, the second in Table 1, which according to our tests seems to be uniform, showing characteristics intermediate between those of *Chlorella pyrenoidosa* and *Chl. vulgaris*. This group is characterized by rather weak hydrogenase activity, and quite a feeble reaction with ruthenium red; under nitrogen-deficient conditions, these algae turn pale. Future experiments and taxonomic considerations will have to decide whether this group must be regarded as a sub-species of *Chlorella pyrenoidosa* or of *Chl. vulgaris*, or whether it should be given the rank of a new species.

On the whole, our results seem to suggest that the taxonomy of the critical section *Euchlorella* of the genus *Chlorella* can be soundly based on some physiological and biochemical characteristics which can easily be determined. Thus an unambiguous identification of these most common and widely used algae should now be possible.

We thank Mr. W. Langner and Mr. H. Wiechmann, who carried out part of the experiments reported in this paper.

Growth and Development of Leaves from Intercalary Meristems in *Phalaris arundinacea* L.

THERE is general agreement[1-4] that the differentiation of phytomer units from the vegetative shoot apex of grasses initially involves the appearance of periclinal divisions in the dermatogen, and that these give rise to a series of alternate distichously arranged ridges which mature basipetally. The blade of the phytomer develops as a result of a combination of marginal growth from periclinal divisions and apical growth from a rib meristem. This eventually transforms the ridge into a crescent, then a collar, and finally a hood over the apex. Shortly thereafter the ligule is formed from the epidermal cells on the upper surface of the blade.

A point of disagreement is whether an active meristem persists at the base of the blade during its subsequent development. Sharman[3,4] and Esau[5] support the idea that the differentiation of the ligule marks the end of meristematic activity in the blade. They describe a basipetal wave of maturation of phytomer tissues that is initiated at the apex of the blade and generates, in turn, the fully formed blade, sheath, and internode. According to this view the enlargement of the blade that occurs after the ligule forms is attributable to the enlargement of existing cells.

Several workers in the field of range management[6-8] have expressed the view that a meristematic zone persists at the base of the blade. Although these reports do not use the phytomer concept, the inference is that this zone remains, or is potentially active after the rest of the phytomer unit is mature.

The objectives of this investigation were to establish the time at which leaf blades of *Phalaris arundinacea* L. (reed canary grass) were fully developed, and to learn whether they retained any meristematic tissue that could be activated by defoliation.

A clone of *Phalaris arundinacea* L. was propagated vegetatively and established as spaced plants in the field as a source of genetically uniform material. Only young, actively growing vegetative shoots from these plants were selected for examination of leaf growth.

In the first experiment the three youngest leaves the blades and ligules of which had emerged completely from the sheath of the next oldest leaf were individually tagged and measured. Blade-length measurements were repeated every week until elongation ceased. Concurrent defoliation treatments were applied to corresponding leaves on similar shoots, to see whether defoliation would stimulate further growth. Some blades were severed just above the ligule, while others were truncated one-third or two-thirds of the distance to the tip of the blade.

From the measurements of blade-length the following conclusions may be drawn: (1) all the three youngest undisturbed blades on the control shoots had reached their maximum length when the ligules were exposed; (2) none of the defoliation treatments caused a renewal of growth in length of any of the leaves so treated.

Thus, once a leaf-blade of reed canary grass has fully emerged from the enclosing sheath of older leaves, it no longer contains any active meristematic tissue, it has ceased to elongate, and it is not stimulated to renewed activity by partial defoliation.

A second experiment was designed to determine whether the leaf-blade was still growing as it emerged from the uppermost leaf-sheath. This was done by marking with ink the exposed section of the rolled blade, measuring its length, and repeating the measurements until the entire blade had emerged. The measurements showed that all emerged portions of the blade had completed elongation.

In order to determine whether this cessation of growth by elongation occurred at, or prior to, emergence of the blade, the length of individual epidermal cells was measured on blades prior to, and after, emergence. However, cell-length was so variable that it was not possible to determine whether growth ceased at or prior to emergence.

The apparent sudden cessation of growth of cells influencing blade-length suggests that a sudden change in their environment is responsible. The emerging blade does in fact experience such a sudden change in environment as it emerges from the protection of the sheaths of older leaves. The apparent influence of this transition on the metabolism of the cells may be another example of a reaction mediated by phytochrome, that is, a red/far-red effect controlling cell development. For the young enclosed blade is receiving only radiation transmitted through the encircling leaf-sheaths, and thus mostly in the far red, whereas on emergence it is receiving more radiation in the red. This transition would also reduce cell turgor, and together with the possible metabolic disturbances may well underlie the cessation of elongation.

These results in general support Sharman's concept of the growth and development of grass leaves. The apparent regrowth of partially defoliated blades reported by other workers may have been due to growth of the concealed basal portion of the phytomer elevating the exposed portion of the blade.

MICROBIOLOGY

Fractionation of Isotopes in Relation to the Problem of Elemental Sulphur Transport by Micro-organisms

THE mechanism of elemental sulphur transport from the medium into the cells of sulphur-utilizing micro-organisms was investigated by Umbreit, Vogel and Vogler[1]. They concluded that for *Thiobacillus thiooxidans*, the sulphur, on contact with the cells, dissolves in globules of highly unsaturated fat located at the poles of the cells. Knaysi[2] was unable to confirm the existence of polar fat globules and pointed out the difficulties involved in postulating contact between an extracellular particle and an intraprotoplasmic structure. Vishniac and Santer[3] suggested a sulphur-transport mechanism involving reduced glutathione (GSH) or a similar molecule reacting as follows:

$$S^{\circ} + 2GSH \rightarrow S^{=} + GSSG + 2H^{+}$$

the sulphide formed enters the cell in free or bound form and the GSSG is reduced by subsequent intracellular sulphide oxidation. No experimental evidence was presented to support this mechanism. It is apparent that the problem is not yet solved.

During an investigation of biofractionation patterns of stable sulphur isotopes by micro-organisms[4] results were obtained which bear on the problem. The pertinent processes investigated were the oxidation of elemental sulphur by the chemolithotrophic *Thiobacillus concretivorus*[5] and by a photosynthetic purple bacterium, *Chromatium* sp., and the reduction of sulphur to sulphide by *Saccharomyces cerevisiae*. The methods used are given elsewhere[4].

Table 1 presents the ranges of isotopic enrichments observed in various metabolic processes. The reduction of elemental sulphur by *S. cerevisiae* and its oxidation by *T. concretivorus* and *Chromatium* sp. have in common the fact that no significant isotope fractionation occurred. In contrast, there was a very great enrichment of ^{32}S during sulphite reduction by yeast and a significant enrichment during the oxidation of sulphide to sulphate, at least by *T. concretivorus*.

Little enrichment of the light isotope in sulphate was observed during photosynthetic oxidation of sulphide by *Chromatium* sp. This was probably due to difficulties encountered in controlling the very rapid oxidation process, and 15 to 50 per cent of the initial sulphide was oxidized by the time the sulphide samples were taken. That a more significant fractionation might have been observed if the oxidation

Table 1. ISOTOPE ENRICHMENT DURING MICROBIOLOGICAL METABOLISM OF SULPHUR COMPOUNDS

Organism	Starting compound	Range of isotopic enrichment			
		Intermediate		End product	
		Compound	$\delta^{34}S$*	Compound	$\delta^{34}S$*
T. concretivorus	H_2S	polythionate	+0·6 to +19·0	$SO_4^{=}$	−10·6 to −18·0
	S°	—	—	$SO_4^{=}$	−0·1 to +1·4
Chromatium sp.	H_2S	polythionate	+8·4 to +11·2	$SO_4^{=}$	−2·9 to +0·9
	S°	—	—	$SO_4^{=}$	+0·3 to +0·4
S. cerevisiae	$SO_3^{=}$	—	—	H_2S	−34·0 to −41·0
	S°	—	—	H_2S	−0·6 to +0·8

* $\delta^{34}S$ refers to the enrichment (or depletion) of sulphur-34 in parts per thousand relative to the $^{34}S/^{32}S$ ratio of the starting compound.

had been stopped earlier is suggested by the accumulation of an intermediate, most likely a polythionate, which was markedly enriched in ^{34}S (Table 1). The same was observed for *T. concretivorus*.

It is generally believed that elemental sulphur is an intermediate in the chemosynthetic and photosynthetic oxidation of sulphide to sulphate and it is possible that it is also an intermediate in the reduction of sulphite. The question then arises as to why no fractionation occurred during either elemental sulphur oxidation or reduction. Since there is no reason to believe that the same enzymes or the same rate-limiting processes are involved in the oxidation or reduction *per se*, it is suggested that the explanation for the lack of fractionation in both processes lies in the feature common to both, the manner of transport of the elemental sulphur across the cell boundary.

It was observed that *Chromatium* sp. grown on elemental sulphur contained sulphur globules within the cells which disappeared on standing in a sulphur-free medium. This, together with the observed accumulation of sulphur in vacuoles of elemental sulphur-grown *Thiobacilli*[4], suggests that the sulphur was transported into the cell without a change of valence. The absence of significant isotopic fractionation during sulphur metabolism further indicates that groups of atoms are transferred across the cell membrane, eliminating any kinetic isotope effect. The atomic groups involved could be single or multiple molecules of sulphur chains; but the evidence does not permit speculation on the size. It also suggests that all, or the major part, of the sulphur entering the cell is metabolized to sulphate without an equilibrium existing between external and internal free sulphur.

The experimental results thus support the concept of movement of elemental sulphur *per se* across the cell boundary but cast no light on the actual mechanism of transport. The suggestion of Vishniac and Santer[3] that the sulphur is first reduced to sulphide seems unlikely in view of the significant fractionation observed with sulphide as a substrate.

This research was supported by a grant from the Petroleum Research Fund administered by the American Chemical Society.

Tetramethylpyrazine: a *Bacillus subtilis* Growth Factor

WE have found[1] that a strain of *Bacillus subtilis* produced tetramethylpyrazine in synthesized media containing asparagine as nitrogen source.

The strain did not show satisfactory growth in media containing any amino-acid, except asparagine and proline, etc., as nitrogen source.

From the fact, it seems that the amino-acids asparagine and proline participate in the biological synthesis of tetramethylpyrazine, and the compound is a growth factor for the strain. In fact, growth of the strain and *Bacillus subtilis PCL* was considerably accelerated when teramethylpyrazine was added in culture media containing amino-acid, such as alanine, histidine, lysine, tryptophan and glycine, etc. The results obtained are given in Table 1.

Table 1. EFFECTS OF SUBSTANCES ON GROWTH OF THE *Bacillus subtilis* STRAIN AND *Bacillus subtilis PCL*

Substance as nitrogen source	*BS* factor	Degree of growth			
		B. subtilis strain		*B. subtilis PCL*	
		20 hr.	35 hr.	20 hr.	35 hr.
Asparagine	−	+ +	+ + +	+	+ +
	+	+ +	+ + +	+ +	+ + +
Proline	−	+	+ +	+	+ +
	+	+	+ +	+	+ +
Alanine	−	−	+	−	−
	+	+	+ +	−	±
Histidine	−	+	+	−	±
	+	+	+ +	+ +	+ +
Cystine	−	−	+	−	−
	+	±	+ +	±	+
Lysine	−	−	−	−	−
	+	−	+	±	+ +
Phenylalanine	−	−	−	−	−
	+	−	+	−	+
Glutamine	−	+	+ +	±	+
	+	+	+ +	+	+ + +
Tryptophan	−	−	−	−	−
	+	−	+	−	+
Glycine	−	−	−	−	−
	+	+ +	+ +	±	+ +
Arginine	−	+ +	+ + +	−	+
	+	+ +	+ + +	+	+ +
Tyrosine	−	−	+	−	−
	+	−	+ +	−	+
Leucine	−	−	−	−	−
	+	+	+	+	+
Methionine	−	−	−	−	−
	+	−	−	−	−
BS factor	+	−	−	−	−

As shown in the table, it might well be said that tetramethylpyrazine is a growth factor for the *Bacillus subtilis* strain and *Bacillus subtilis PCL*. We therefore suggest the name of *BS* factor (*Bacillus subtilis* factor) for tetramethylpyrazine.

From these results tetramethylpyrazine may be accepted as a growth factor for *Bacillus subtilis*.

Oxidation of Anthranilic Acid by a Species of *Achromobacter* isolated from Soil

STUDIES of the microbial decomposition of anthranilic acid have been confined mostly to work with various strains of *Pseudomonas* spp.[1-3] which oxidize anthranilic acid to catechol by an unknown pathway. The role of salicylic acid in this conversion is not clear since reported experiments based on the technique of simultaneous adaptation have yielded divergent results[1,4]. Sakamoto *et al.*[4] have further shown that cell suspensions, adapted to oxidize anthranilic acid, are inactive towards 3-hydroxyanthranilic acid and 5-hydroxyanthranilic acid. By contrast, the two last-named compounds have been clearly implicated in the breakdown of anthranilic acid by mammalian tissue since both have been isolated from the urine of animals injected with anthranilic acid or *o*-aminobenzamide[5–9].

I have isolated from the soil an *Achromobacter* sp. which adaptively oxidizes anthranilic acid. The organism may be grown in a simple mineral salts medium containing 0·05 per cent (w/v) anthranilic acid as the sole carbon source; but in practice 0·1 per cent (w/v) yeast extract is also included to give greater yields of active cells. Unadapted cells are grown in a similar medium without anthranilic acid.

Adaptation of the organism to oxidize anthranilic acid does not result in its simultaneous adaptation to oxidize catechol. Both adapted and unadapted cells oxidize catechol after a lag period (90–120 min.) when oxidation occurs at similar rates (12–14 µl. oxygen consumed/30 min./mgm. dry wt. of cells) and to the same extent (50–65 per cent of theoretical oxygen uptake for complete oxidation to carbon dioxide). Experiments using chloramphenicol provide further evidence that catechol is not an intermediate of anthranilic acid oxidation by *Achromobacter* sp. As shown in Fig. 1, the rate of anthranilic acid oxidation by adapted cells is unaffected by chloramphenicol (50 µgm./ml.); the total uptake of oxygen is actually greater in its presence due presumably to its ability to inhibit protein synthesis and hence make a greater proportion of substrate carbon available for oxidation. Chloramphenicol completely inhibits catechol oxidation. In all cases estimations of residual substrate are made by absorbancy measurements in the ultra-violet region using a 'Shimadzu *QR*–50' spectrophotometer.

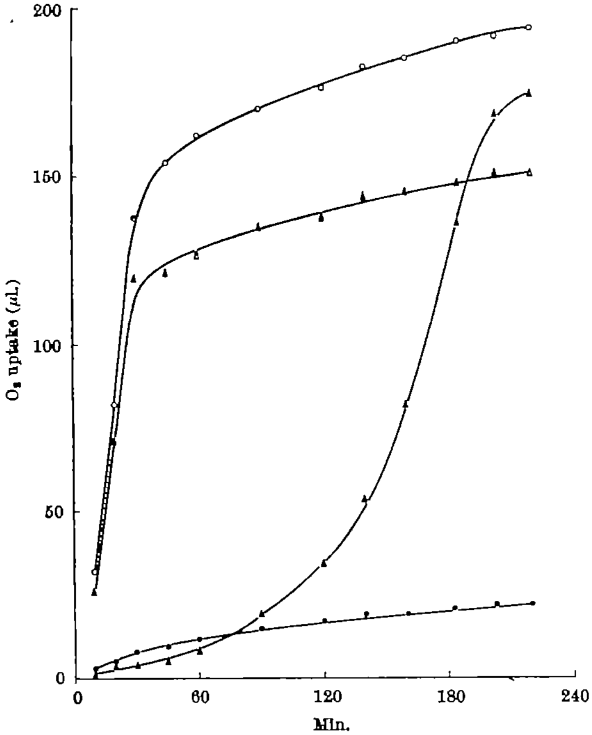

Fig. 1. Effect of chloramphenicol (50 µgm./ml.) on the oxidation of anthranilic acid and catechol by anthranilic acid-adapted cells. Bacterial suspension (= 3 8 mgm. dry wt.) pre-incubated with chloramphenicol for 15 min. before addition to 2µ mole substrate in 2·0 ml. (final volume) 0 05 *M* potassium phosphate, *p*H 6 0. temperature, 30° C. ○, Anthranilic acid + chloramphenicol; △, anthranilic acid; ●, catechol + chloramphenicol, ▲, catechol

Table 1. OXIDATION OF ANTHRANILIC ACID AND RELATED COMPOUNDS BY ADAPTED AND 'UNADAPTED' BACTERIAL SUSPENSIONS

Substrate	Rate of oxidation (µl. O_2/30 min. mgm. dry wt. bacteria) Adapted cells	Unadapted cells
Anthranilic acid	28 2	3·4
5-Hydroxyanthranilic acid	18 5	1·9
3-Hydroxyanthranilic acid	1 0	2 5
2:5-Dihydroxybenzoic acid	17 0	8·4
2:3-Dihydroxybenzoic acid	2 4	1·6
Catechol	0·5	2·2
Salicylic acid	6·3	6·5
Endogenous	1·7	1·6

Cell suspensions incubated at 30° C. in 2·0 ml. 0·05 *M* potassium phosphate *p*H 6 0 containing 2 0 µmole substrate. Substrate oxidation-rates corrected for endogenous cell respiration.

Cells adapted to anthranilic acid are simultaneously adapted to oxidize 5-hydroxyanthranilic acid and 2 : 5-dihydroxybenzoic acid (Table 1). 3-Hydroxyanthranilic acid and 2 : 3-dihydroxybenzoic acid are oxidized slowly after a lag period of negligible oxygen uptake. Salicyclic acid, *o*-aminophenol and the remaining isomers of 2 : 5-dihydroxybenzoic acid are not oxidized by anthranilic acid-adapted cells. The slight uptake of oxygen observed with salicylic acid (Table 1) occurs in the first 15 min. and is not continued; nor is it generally observed with other suspensions of either adapted or unadapted cells. It will be reported elsewhere that salicylic acid actually inhibits anthranilic acid oxidation and on these grounds is further eliminated as a possible intermediate. The results of simultaneous adaptation experiments indicate that an *Achromobacter* sp. oxidizes anthranilic acid, not via catechol, as established for *Pseudomonas* spp., but via 5-hydroxyanthranilic acid and 2 : 5-dihydroxybenzoic acid. Cell-free extracts of adapted *Achromobacter* sp. convert 2 : 5-dihydroxybenzoic acid to maleylpyruvic acid[10]. However, it must be pointed out that neither 5-hydroxyanthranilic acid, 2 : 5-dihydroxybenzoic acid nor any other aromatic derivative has as yet been detected in incubation mixtures containing anthranilic acid and suspensions of adapted *Achromobacter* sp. The pathway of anthranilic acid oxidation by *Achromobacter* sp. differs apparently from that reported for a *Flavobacterium* sp. by Ke *et al.*[11], who have implicated salicylic acid (but not catechol) as an intermediate.

I thank Prof. E. Boyland, Royal Cancer Hospital, London, and Dr. Y. Shibata, Wakayama Medical College, Japan, for gifts of 5-hydroxyanthranilic acid.

SOIL SCIENCE

Location of Water-Table Level

WITH the increasing use of irrigation in horticulture and agriculture and the developing interest in the effects of evapotranspiration, it is frequently necessary to locate the level of a shallow water-table. This can be done inexpensively and effectively, using a small-diameter observation well and an electric probe.

The observation well is constructed by inserting into an auger hole (2-in. diam.) a zinc mesh tube bound closely with strips of hessian. Zinc is preferable because it does not easily corrode, the mesh allows free movement of water through the wall of the well at any level, and the hessian acts as a filter, preventing the inwashing of fine sand and silt particles which can otherwise rapidly reduce the effective depth of the well. In order to prevent the inflow of surface water, the upper 3 in. of the well casing should be unperforated, and this section should project slightly above ground-level. Finally, precipitation can be excluded by corking or covering the open end of the well.

In an observation well of this size an ordinary dipstick would cause a considerable displacement of water. The level of the water-table can, however, be located by using a simple electric probe, similar to that described by Russell[1], whose circuit is completed by contact with the water surface. Such an instrument, incorporating a 4·5-V. dry battery and a galvanometer, can be easily constructed and obviates the necessity of using more expensive manufactured equipment. Basically, the probe consists of a stainless metal shaft which is graduated in fractions of an inch. When two contacts at the tip are closed by the water-surface the galvanometer needle is deflected and the depth can be read off against the lip of the well casing.

Twelve observation wells and a probe, constructed to the specifications described here, have been satisfactorily used by me, in soils ranging from fine clay to coarse gravel, for a period of eighteen months, in connexion with investigations of the water-table in the Thames flood-plain. It is almost certain, however, that, if necessary, these instruments would give trouble-free service for a much longer period.

PSYCHOLOGY

Effect of Age on Responses to Dichotic Stimulation

THE responses made by young normal adults to various methods of dichotic stimulation have been investigated and reported by Broadbent[1]. His observations have led him to postulate that both perceptual and storage mechanisms are necessary for the correct sequential recall of such simultaneous stimulation.

I have suggested that the defect of acquisition which has been found in elderly psychiatric patients suffering from memory disorder might be based on a breakdown of the storage mechanism postulated by Broadbent. Such patients should therefore show disturbance of recall in those half-sets of digits reproduced second in the dichotic stimulation situation, relative to the performance of a matched group of patients without memory disorder. Investigations by Caird and Inglis[2] and Inglis and Sanderson[3] show that this appears to be the case. Since increasing age in normal individuals also seems to affect learning capacity and as such impairment may also depend on changes in some short-term storage process it was anticipated that responses to dichotic stimulation might also show interesting associations with age.

Broadbent[1] has suggested that the first half-set of digits recalled from each dichotic span does not involve the storage process. If age primarily affects storage then the reproduction of the first half-set recalled should not be affected by advancing years. If the second half-set recalled must pass through the storage process then the recall of these digits should be affected by age.

Results obtained from a preliminary analysis of the performance of 120 subjects between the ages of 11 and 70 seem to support these expectations. As age increases there is no significant impairment in the ability to recall the first half-spans. Progressive, and significantly greater, difficulty is, however, shown in the reproduction of the second half-spans. Furthermore, the longer the span to be recalled the greater the difference, overall, between the first and second half-spans ($P < 0·001$). It has never before been convincingly demonstrated that short-term storage ability continuously decreases with age. The work described here will be replicated before a full report is published. If these results are confirmed we shall have come to a closer specification of a fundamental process the diminished efficiency of which may produce some of the impairments of age and the breakdown of which may underly the psychosis of senility.

This work was supported by a Federal-Provincial Mental Health grant (project No. 605-5-285). The testing was carried out by Mr. W. K. Caird.

Transfer between the Hands of a Mirror-Image Tactile Shape Discrimination

A SHAPE like that of the figure *C* is seen as a *C* in both the right and left halves of the visual field by adults. It is not seen as a *C* in, say, the right and as a Ↄ in the left half field. One may ask whether such an identity of the perceived shape in the two half fields is given by the structural organization of the sensory system, or whether it is the result of some learning process. To answer this question would require subjects without experience of shape and object discriminations, and yet able to perform such discriminations. Monkeys were selected as experimental subjects, and tactile discriminations were used in order to minimize the effect of previous experience with shape discriminations. In brief, the animals were trained to discriminate by touch with the left hand between the solid shapes *C* and Ↄ; they were afterwards tested for their preference between the same two shapes with the right hand.

Four immature rhesus monkeys were subjects. All had been housed in the laboratory for eight months, and had been trained to perform five visual discrimination tests. For a period of 10 weeks three of the animals had received tryptophan or glycine supplements to their diet (combined with iproniazid for two weeks), without behavioural effect. The fourth animal (No. 7) had served as an untreated control. Details of the previous training histories are to be found elsewhere[1].

For the experiment reported here all four animals were first trained (using conventional apparatus and procedures) to discriminate in the dark by touch between two objects differing in texture. Forty trials (non-correction) were given each day. Training was continued until the animals were successful in 90 per cent of 150 consecutive trials. During this, their first tactile test, use of the right hand was restricted by attaching a weighted ball to the right wrist. Therefore all animals learnt to discriminate between the textures by touch with the left hand. All animals were then trained to discriminate by touch between the solid shapes *C* and *Ɔ*. The shapes were exact mirror-images of each other. Choice of the shape *C* was rewarded, irrespective of its position to the animal's left or right. Training was continued until 90 per cent of 400 trials were successful. Use of the right hand was again restricted, so that this tactile discrimination between mirror-image shapes was also made with the left hand.

Next, the animals' performance with the previously untrained (right) hand was tested by restricting the use of the left hand. Forty 'transfer trials' were first given for the discrimination between textures. During these (and the subsequent) 'transfer trials', rewards were placed under both or neither test object on alternate trials. There was thus no differential reward for one of the test objects and rapid learning was prevented. After the initial 40 'transfer trials' with the right hand the animals were retrained, still with the right hand, to discriminate by touch between the objects differing in texture. Training was continued until the animals were successful in 90 per cent of 100 trials. All animals were then given 40 'transfer trials' for the discrimination between the shapes *C* and *Ɔ*. After these 40 trials with the right hand the animals were trained, still with the right hand, to make a reversal of their previous choice in the test of tactile shape discrimination: choice of the shape *C* was no longer rewarded while choice of the shape *Ɔ* was now rewarded. Training was continued until the animals were successful in 90 per cent of 100 trials.

Finally, the animals' performance with the first (left) hand to be trained was again tested by restricting the use of the right hand. Forty 'transfer trials' for the discrimination between the shapes *C* and *Ɔ* were given.

The results are presented in Table 1. Three of the four animals performed significantly above the chance expectation when they were tested for 40 'transfer trials' with the right hand for the discrimination between textures. However, all four animals performed below the chance expectation, indicating their choice of the previously unrewarded shape *Ɔ*, when they were tested for 40 'transfer trials' with the right hand for the discrimination between mirror-image shapes. In one animal performance was significantly below chance (two-tailed), in another the two-tailed probability was 0·08, giving a one-tailed probability of 0·04. Moreover, only 0–140 trials (mean of 83 trials) were required to learn with the right hand the reversal of the shape discrimination previously learnt with the left hand. Finally, all animals performed significantly above the chance expectation, indicating choice of the shape *C*, when they were tested for 40 'transfer trials' with the left hand for the discrimination between mirror-image shapes. Continued choice of the shape *Ɔ* (rewarded during reversal training with the right hand) was expected with the left hand on the basis of results for tactile discriminations not involving mirror-image shapes with intact monkeys[3]. The results indicate that for the monkey and our test conditions, a shape *C* palpated with the left hand is treated as equivalent to a shape *Ɔ* palpated with the right hand.

Table 1. RESULTS OF TRANSFER BETWEEN HANDS

Animal Original hand preference	1 Left hand	5 Left hand	6 Left hand	7 Right hand
Trials required to learn *C* vs *Ɔ* discrimination (left hand)	860	310	570	380
Percentage correct in 40 transfer trials · textures (right hand)	98*	63	98*	98*
Percentage correct in 40 transfer trials · *C* vs. *Ɔ* (right hand)	43	40	35†	20*
Trials required to learn *C* vs. *Ɔ* reversal (right hand)	140	100	90	0
Percentage correct in 40 transfer trials · *C* vs. *Ɔ* (left hand)	100*	100*	100*	95*

Original hand preferences were determined in an unrestricted but formal test situation as previously described (ref. 2). Trials do not include criterion trials during which performance was 90 per cent correct or better. Significance levels were established as two-tailed probabilities on the binomial test. * $P < 0{\cdot}01$. † $P < 0{\cdot}1$.

Opposite (reversed) discriminations may thus be concurrently acquired by the intact monkey. Trevarthen[4], also using monkeys but not mirror-image shapes, has shown that such opposite visual discriminations can be learnt separately through the two eyes after sagittal section of the optic chiasma and division of the cerebral commissures. In his experiment each cerebral hemisphere apparently controls one of the two opposite discriminations. However, in our intact monkeys the hemispheres were normally linked. Moreover, there was normal (not reversed) transfer between the hands with the discrimination between textures. We would therefore propose that the structural organization of the neural systems concerned with tactile shape discriminations by the monkey is such as to produce equivalence between laterally reversed (mirror-image) shapes when each is separately palpated with a different hand. It may be suspected that the motor systems contribute to such equivalence. However, no movements are made in certain tactile shape discriminations (graphæsthesia). It has also been shown[5] that total destruction of the motor cortex does not impair the ability of monkeys to discriminate by touch with either hand between the shapes *L* and *⅃*. This evidence does not exclude some contribution to mirror-image equivalence from the motor systems. Generalization of the present findings from the two hands to the two half fields of vision is inadvisable until the role of the motor systems in discrimination performance has been ascertained.

We are grateful to the Research Fund of the Institute of Neurology and to the Medical Research Council for financial support and to Mr. B. Babington-Smith for criticism of a draft of this communication.

London Mathematical Society (at the Royal Astronomical Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Dr. J. M. Marstrand· "A Problem on Polynomials".

Society for Endocrinology (at the London School of Hygiene and Tropical Medicine, Keppel Street, London, W.C.1), at 5.30 p.m.—Prof. Adolf Butendandt (Munich)· "Bombycol, the Sex-Attractive Substance of the Silkworm, *Bombyx mori*" (Annual Lecture).

Royal Society of Tropical Medicine and Hygiene (at Manson House, 26 Portland Place, London, W.1), at 7.30 p.m.—Fifty-fifth Annual General Meeting, followed by Sir Gordon Covell: "Reminiscences of the Campaign in East Africa 1914–1917".

Monday, June 25

British Society for the History of Science (in the Science Museum, Exhibition Road, London, S.W.7), at 5.30 p.m.—Annual General Meeting and Presidential Address.

Monday, June 25—Tuesday, June 26

Institute of Rural Life at Home and Overseas (at the Department of Technical Co-operation, 6 Carlton House Terrace, London, S.W.1), at 10.30 a.m. on Monday and 10.15 a.m. on Tuesday—Twelfth Annual Conference—"Training the Farming Community at Home and Overseas".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer (graduate in microbiology, agricultural microbiology or some related subject) in Soil Microbiology in the Department of Physiological Chemistry—The Registrar (Room 22, O.R.B.), The University, Reading (June 22).

Assistant Lecturer in Pure Mathematics—The Registrar, The University, Sheffield (June 23).

Lecturer in the Department of Biological Chemistry—The Secretary, The University, Aberdeen (June 23).

Lecturer or Assistant Lecturer in Physics at the Royal University of Malta—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (June 28).

Lecturer or Demonstrator in Chemical Pathology, for duties to be divided equally between original investigation and supervision of the hospital laboratory—The Registrar, The University, Leeds 2 (June 30).

Lecturer in Fuel Technology and Chemical Engineering—The Registrar, The University, Sheffield (June 30).

Research Demonstrator (with good honours qualifications in organic chemistry) in the Department of Chemistry—The Registrar, University College, Singleton Park, Swansea (June 30).

Research Fellow in the Surface Physics Group, to join a team investigating mechanism of photoelectric emission—The Secretary and Registrar, The University, Southampton (June 30).

Senior Lecturer (with an honours degree) in Physics, and a Lecturer (with an honours degree) in Physics—The Director of Education, The Polytechnic, Regent Street, London, W.1 (June 30)

Chair of Physics in the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Australia and London, July 7).

Lecturer or Assistant Lecturer (honours graduate in either oceanography, physics or mathematics, and willing to spend several weeks each year at sea) in the Department of Oceanography—The Registrar, The University, Liverpool, quoting OV/101/T (July 9).

Reader in Science of Materials at Queen Mary College—The Academic Registrar, University or London, Senate House, London, W.C.1 (July 11).

Associate Professor of Medical Biochemistry in the Departments of Medicine and Biochemistry, University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (July 13).

Lecturers (2) in Pure Mathematics at the University of Sydney—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (July 13).

Lecturer (with a higher degree in philosophy and preferably with special interest in the theory of knowledge and perception) in Philosophy at the University of Queensland, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (July 14).

Chair of Theoretical Physics at the Australian National University—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (July 16).

Lecturer in Biochemistry in the Faculty of Medicine, University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (July 28).

Senior Lecturer or Lecturer in Physiology at the University of Western Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (July 28).

Head of the Department of Civil Engineering—The Registrar, Bradford Institute of Technology, Bradford 7.

Vice-Chancellor of the University of Otago, Dunedin, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1.

EDUCATION IN AND FOR SCIENCE

IN the spring issue of *Daedalus*, the journal of the American Academy of Arts and Sciences, under the broad title "Science and Technology in Contemporary Society" are presented seven of the papers prepared for the centenary of the Massachusetts Institute of Technology during April 1960. Prof. R. Aron discusses the education of the citizen in industrial society, touching specifically on its bearing on problems of Government. Sir Eric Ashby is concerned more particularly with the education of the administrator, the precise function of administration and the skills it demands, while Aldous Huxley, under the title "Education at the Nonverbal Level", examines the effectiveness of modern education. Dr. L. S. Kubie, writing on the fostering of creative scientific productivity, is concerned with the fostering of creativity in the training of the scientist, while Prof. W. A. Lewis discusses education for scientific professions in the poorer countries, Dr. R. S. Morison the university and technical assistance, and Dean G. S. Brown new horizons in engineering education, including a glance at the creative element as well as the revision of curricula and interdisciplinary research centres.

There is, as might have been expected, a forthright and realistic note in all these addresses which brings the scientist and technologist into continuous contact with the changing world of to-day. However, it is equally worthy of note, though perhaps scarcely surprising, in view of the common element in the general titles, that there should be such a similarity in theme and emphasis between these papers and the eight Oxford lectures which the Conservative Political Centre has recently published under the title *Science and Society**. The first two are both concerned with problems of science and Government: Lord Hailsham under the title "Iconoclasm and Civilization" discusses the organization of research, while Sir Hugh Linstead reviews the working of the Parliamentary and Scientific Committee. Mr. Aubrey Jones, in dealing with the Soviet challenge, is also concerned with the organization of scientific, including industrial, research, and Mr. W. Rees-Mogg, in "The Conquest of Poverty", looks at the challenge presented by the under-developed countries. Sir Frank Engledow deals simply with science and farming, Mr. D. Price with the education of the scientist, and Mr. M. Howard, under the title "Security in the Nuclear Age", with defence. Only Dr. N. St. John-Stevas's lecture on "Science and Faith" goes outside the field of those given at the Massachusetts Institute of Technology, and even this is more apparent than real. Dr. St. John-Stevas, while not beguiled into sociology, has clear views of the function of religion which in his judgment has a vital part to play, by slowly moderating the passions of men and pointing to altruistic ideals, in forwarding the achievement of the human unity which science has made necessary.

Apart, however, from the extent to which once again the problems of the under-developed countries force themselves on the attention of a comprehensive survey of the problems of science and society, the feature of both these symposia is the similarity of outlook in Britain and the United States in regard to problems of science and Government, and the education of scientist or citizen. The solutions suggested are not necessarily the same, where indeed solutions are suggested, for it is fully recognized that the conditions are not the same in the two countries and that the organization of either science or Government and the system of education at all levels must take full account of the traditions of the past as of present-day trends, practices and needs. Moreover, it must be remembered that the addresses do not cover precisely the same ground: Sir Eric Ashby, for example, is more restricted than Lord Hailsham, though to a certain extent he overlaps also with Sir Hugh Linstead.

One valuable feature of Sir Eric Ashby's paper is the picture he draws of the functioning of the administrator in regard to science and from it of particular skills with which such an administrator must be equipped. This is the pragmatic approach; but unless it is grasped that the essential technique of the administrator is that of using other men's minds, we are unlikely to recognize the type of education required for an administrator or even to set up the sort of organization which allows him to practise that technique most effectively. The very term 'red tape' carries the implication that we have failed to do so.

Sir Eric Ashby himself points out that the education of administrators should be such as to minimize failure to elicit appropriate replies from the experts; inability to create a simple and persuasive decision out of the information, or failure to take viable decisions, through underestimating the political component, through overlooking the adage that politics is the art of the possible. It should fundamentally assist him to conduct a traffic in ideas, and no conceivable education could equip the administrator to make from his own knowledge many of the decisions he is called on to make. Nor can the skills required be acquired by formal education alone, though they can be encouraged by certain kinds of instruction. Sir Eric, in fact, regards the administrator as one of the chief channels through which science and society interact: depending on his qualifications he can promote or hinder that interaction and for that reason alone part of the equipment of the administrator must include some understanding of the approach of the scientist, the attitude of the scientist to time and the way he assesses the value of his work.

---

* Science and Society: Eight Oxford Lectures. Pp. 94+2 plates. (London: Conservative Political Centre, 1962.) 3s.

Such an understanding is fundamental to the formulation of any strategy of scientific advance and is scarcely less essential in the consideration of tactics. Lord Hailsham, who once again questions the practicability of scientific strategy, is equally at pains to make clear that science is a part of culture and that the relation of science and Government is one aspect of the adaptation of our institutions to change and of changes to our institutions. Science, he points out, is an inseparable and indeed the one characteristic feature of modern civilization, and while he is no less concerned than Sir Eric Ashby with promoting the traffic in ideas, it is to the problem of organization that he primarily addresses himself, and more especially the organization of research. Once again he expounds his conception of the Minister for Science as responsible for promoting the pervasion of science through industry, agriculture, the professions and the universities.

In this Lord Hailsham adds little to what he has previously expounded during the past year or so. It is, however, in his forthright condemnation of the attempt to dictate scientific projects on grounds of national prestige that he becomes less inhibited, and he gives frank expression to the belief that the mounting cost of scientific work may be taking us beyond the scope of national budgets. Lord Hailsham's belief in international co-operation in science is already well known. Here he is frankly dubious as to the extent to which we can afford to devote resources to space research in the face of projects for increasing food production, particularly in the under-developed countries. The production of proteins from fibrous plants, farming from the sea, plant breeding, desert irrigation, fresh water from salt, plastics from wood, and reducing the need for industrial crops are cited as examples for possible international co-operation in research and which may have repercussions on the present political framework, possibly even leading to new political institutions and international loyalties.

Lord Hailsham's clear recognition of the limitations of Britain's material resources is matched by his belief in the intellectual resources and the contribution that Britain could bring to the traffic in ideas. He calls for the wise selection of projects and for the readiness to face change; but he places as much emphasis as Dr. St. John-Stevas on the need for something more than material values, on the ultimates, knowledge and beauty, truth and justice, goodness and God, as part of a satisfying and constructive solution. It is left, however, for Sir Hugh Linstead to touch on the fundamental problems of Government, though even Sir Hugh is content essentially to defend the conception of a Minister for Science and to postulate what is asked of the scientist who wishes to play his part and what the politician must concede to the scientist.

Even so, Sir Hugh emphasizes the vital importance of the scientist retaining so far as possible his independence and freedom from party politics. This is too commonly overlooked. As Sir Hugh rightly remarks, the independence of the scientist should be a matter of professional pride to be jealously guarded, and while science in its search for truth cannot be subjected to the direction of authority nor prostituted to political expediencies, science can only assume its full authority in public affairs when the scientist does assert and maintain his political independence. It is then above all that his advice can be accepted without suspicion.

Nor is this inconsistent with the truth that politics itself is simply a matter of expediency, of what is practicable. Mr. Aubrey Jones's thesis that a civil scientific budget is needed and that the allocation of resources between such activities in the field of Government should be the ultimate responsibility of the Minister for Science confuses the real issue. Some advance on the present arrangements for organizing such scientific activity may well be desirable, in particular possibly something of an adequate intelligence organization, though the value of informal and personal contacts such as exist through the Research Councils and like bodies must not be ignored; to place such responsibility on the Minister for Science could destroy the whole function. He could scarcely at one and the same time satisfy himself that he had obtained and presented to the Government the soundest and most authoritative advice on the scientific and technical aspects of a problem and also undertake personally the responsibility for making decisions on the other aspects involved.

What matters especially to-day is that proper weight should be given to the scientific and technical factors in a problem or situation, not that they of themselves should determine the decision. It is, of course, essential that the scientist and technologist should be enabled to tender advice appropriate to the existing conditions, if that advice is to be appreciated in its true perspective: it is manifest that this did not happen when the University Grants Committee made its recommendations for the next quinquennium, and a good deal of the dissatisfaction with the Government's decision stems from their neglect of this principle. Mr. Aubrey Jones has other suggestions to make for raising the standards of industry—for example, by amalgamating the industrial functions of the Department of Scientific and Industrial Research with the National Research and Development Corporation.

In all this, as is freely recognized by the participants in these two symposia, we are continually facing the problem of the education of the administrator, the ordinary citizen, the scientist and technologist, and Mr. Price's lecture is particularly valuable for its insight and sanity. As Prof. Aron points out, there is a problem of communication which is inescapable and plans for Government as well as plans for education must take account of it. Even with the scientist and engineer, the concern to foster the all-important creative productive powers must not deflect attention from this element of communication. Fuller understanding of the nature of scientific work may ultimately make it easier to provide the conditions which encourage such creative work, but only on condition that there is reasonable communication between the scientist and the administrator and ordinary citizen. It is as much for the contribution which these two symposia offer to that communication and understanding as for the way in which they indicate aspects of the relations between science and society which need careful study that the Oxford lectures and those delivered at the centenary of the Massachusetts Institute of Technology deserve to be studied.

LORD CHERWELL: 'THE PROF.'

The Prof. in Two Worlds

The official life of Professor F. A. Lindemann, Viscount Cherwell. By The Earl of Birkenhead. Pp. 383 + 12 plates. (London: William Collins, Sons and Co., Ltd., 1961.) 45*s*. net.

IN reviewing an earlier book on Lord Cherwell (*Nature*, 184, 1752; 1959) I had speculated that no man in Britain since Francis Bacon had combined such a deep interest in natural science with so high a public office. I would now revise this speculation, having in the meantime read the *Memoirs and Correspondence of Lyon Playfair* (1818–1898), for there are several parallels between Playfair's career and that of Cherwell. Both men studied in Germany, both held science chairs in British universities, both stood for Parliament (Playfair successfully, Cherwell not), both fought for the expansion of education in science and for the development of technology, both were involved in monetary policy (Playfair against bimetallism, Cherwell against convertibility of sterling) and in food policy (Playfair with legalizing margarine, Cherwell with war-time rationing), both achieved ministerial rank (Playfair postmaster-general, Cherwell paymaster-general) and both received peerages.

Careers of such complexity and breadth are a stimulating challenge to biographers; and in Lord Cherwell's case there is the additional challenge of depicting the unusual combination of warmth and reticence in his character. Moreover, any attempt by a biographer to give an impartial assessment is bedevilled by the fact of Sir Charles Snow's partial account of the unfortunate relations between Cherwell and Sir Henry Tizard; happily, Snow to some extent redressed the balance in his recent rectorial address at St. Andrews; but Lord Birkenhead had to complete his biography of Cherwell while Snow's charges stood unmoderated.

Lord Birkenhead has given a good account of Cherwell's work as a member of the Government, which included such administrative measures as resisting the restoration of the convertibility of sterling in 1952 and as disestablishing the Atomic Energy Authority from the Ministry of Supply in 1954, besides much advice on economic matters to Mr. Churchill during the Second World War.

Lord Birkenhead's greatest difficulty has been to give an assessment of Cherwell's work in physics, and in science applied to warfare and particularly to air defence. Here he has had to rely on the evidence of a comparatively few witnesses, including myself; despite this limitation, I believe that the book conveys an accurate impression of Cherwell, both as an individual physicist and as head of the Clarendon Laboratory. His faults are not obscured; but his merits as a physicist, too often overlooked, emerge particularly in the quotations from Sir Cyril Hinshelwood, Sir George Thomson, and Prof. D. A. Jackson. His work in building up the Clarendon is well depicted: it is not easy for any physicist whose experience is limited to after the Second World War to realize the obstacles that any head of a laboratory had to overcome before 1939.

This book gives a good account of the work on recovering aircraft from spins in 1917. This makes it clear that while Lindemann was not the first man to recover an aircraft from a spin, he was the first man to reason how to do so; and his courage in undertaking the practical trials himself amply merits its legendary place in the history of science applied to flight.

As regards Cherwell's work on air matters connected with the Second World War, Lord Birkenhead has given telling evidence to show that this was much more positive than some accounts have suggested. In the attempt to correct the account given by Sir Charles Snow, there is occasional unfairness to Sir Henry Tizard, notably in suggesting that he was liable "to resent the submission of new ideas", which is contrary to my own experience; but the quotations from Cherwell's letters and reports of 1935 and 1936 effectively refute the sensation-seeking charge that Cherwell was anti-radar, and that the Royal Air Force might therefore have lost the Battle of Britain if Winston Churchill had been Prime Minister in 1935.

As regards 'The Prof.'s' character, Lord Birkenhead's account is sympathetically presented, and it rings true. 'The Prof.', by an extraordinary inversion of human nature, exposed his faults and concealed his personal virtues. "No man", said Marshal Catenat, "is a hero to his valet"—but 'The Prof.' most certainly was. Mr. James Harvey was the Prof.'s valet and secretary for thirty years, and Lord Birkenhead most fittingly quotes from Mr. Harvey's tribute: "The world is much the poorer for his passing—only people like myself, whose appreciations are rarely made public, will know how much poorer".

For me, much of the interest in this enjoyable and well-illustrated book is in the light that it throws on the inner life of 'The Prof.', from boyhood onwards. Much of this is new to me, even though 'The Prof.' would sometimes tell me of such personal matters as, for example, his proneness to write rude letters when he had been annoyed, in order to save me from developing similar faults myself. I wish that I could have read this book while 'The Prof.' was still alive.

R. V. JONES

TWO SUB-CULTURES?

The Cell and the Organism

Essays presented to Sir James Gray. Edited by J. A. Ramsay and Prof. V. B. Wigglesworth. Pp. viii + 350. (Cambridge: At the University Press, 1961.) 52*s*. 6*d*.

THIS volume contains contributions from twenty eminent zoologists who are working, or have worked, in the Department of Zoology, University of Cambridge, and it was presented as a mark of their appreciation to Sir James Gray for all that he has done for zoology during the past forty years. It can therefore be considered as a summary of the work of an experimental school which has been for long of paramount importance in the teaching of and research in zoology in Britain. The range of contributions is wide; there is Thorpe's stimulating discussion of the interrelationships between animal behaviour and neurophysiology on one hand, and on the other Picken's thoughtful consideration of molecular biology in relation to the future of zoology. In between these extremes most of the expected contributions will be found; there are, for example, Rothschild on sperm, Wells on lugworms, Swann on cell division and Munro Fox on the various coloured bloods. As would be expected, they nearly all give a clear account of their selected topic with, on occasion, the levity appropriate to the occasion, and it would be presumptuous of me, a not very satisfactory student of this illustrious department, to consider these contributions in detail.

What else is there to be said? Pantin in his introductory essay discusses the development of the experimental approach forty years ago, when morphologists and embryologists, concerning themselves almost entirely with a search for homologies, were dominant in zoology, and he feels, indeed, that the only satisfactory definition of experimental zoology is "those varied and extensive parts of animal biology which certain influential senior zoologists disliked in 1920". Zoology, as an academic subject to-day, seems to be faced with a similar crisis. In addition to the older disciplines, like biochemistry, new subjects, like molecular biology, biophysics and microbial genetics, attract able students and financial support, and part of their attraction is that they combine the promise of immediate usefulness with the synthesis of a wide range of scientific disciplines, while at the same time it is rightly claimed that their findings are of general significance to the older branches of biology. There are other more mundane symptoms; there is a decline in interest in the zoological side, at least, of the only general biological society with an experimental approach, and it is a common experience that meetings on protein synthesis, molecular structure or the genetic code usually command greater support than most of the subjects discussed here.

Must we then conclude that this volume represents a final flowering of a glorious era in biological research? Picken in his chapter argues strongly that this need not be so, and that zoologists and botanists are essential for the future progress of the more analytical subjects. He argues his case on two counts: first, the practical aspect that zoologists and botanists know about animals and plants, and about the vast range of complexity in the organization of their parts. They can therefore provide this information and even keep laboratory animals alive.

Secondly, by constantly keeping the concept of the organism as a whole before the biochemist and biophysicist, the zoologist and botanist can indicate the next step in the hierarchy of cells, tissues and organisms which must be explained by the function and structure of constituent macromolecules. Zoologists might, by their critical presence, hope to curb a facile generalization from simple to more complex organisms.

Good examples of both aspects are found in this book. No one interested in the problems of the control of protein synthesis can fail to be stimulated by Wigglesworth's account of the many changes which occur in insect epidermal cells in response to external and internal stimuli, and he must immediately ask himself whether any of the methods for investigating molecular structure now available could make use of all the detailed information available on these cells. Again, Mitchison considers the several cellular structures, such as the centriole and nucleolus, for which we can at present assign no exact function. They are all of the same order of complexity as mitochondria, the structure and function of which may soon be interpretable on a molecular basis, and it is very proper that we should be reminded that they may have no less importance in the cell's organization, despite the difficulty of isolating them for biochemical or biophysical investigation.

It would seem, however, that to cast themselves as keepers of zoological lore for the benefit of the molecular biologist or as goads to remind him of ever more complex systems to investigate is to cast these eminent scientists in altogether too lowly a role. Perhaps their fault lies in the ready acceptance of the premise, explicitly stated in this book, that zoologists and botanists are, as scientists, a different kind of people from biochemists, biophysicists and physiologists—so different, indeed, that training cannot remedy the matter. Is this so and is there nothing we can do about it? No such differences were present in the early nineteenth century, when, as Pantin points out, biologists were widely concerned with experimental investigations. Adding a little physics and chemistry to overloaded courses will not, of course, bridge the gap between the two sub-cultures, but a unitary subject, biology, could be taught in which the now 'peripheral' subjects would share in teaching and research in an atmosphere of mutual tolerance. Perhaps in this way an era can be initiated in biology as fruitful as that for which Sir James Gray was so largely responsible. P. M. B. WALKER

THE EXPANDING SCOPE OF ANIMAL PARASITOLOGY

Introduction to Animal Parasitology

By Prof. J. D. Smyth. Pp. xx+470. (London: The English Universities Press, Ltd., 1962.) 37*s*. 6*d*. net.

NO aspect of zoology appeals more to the student than that which concerns the intimate relationships between animals and their parasites. There is popular antipathy towards the importunate hanger-on and his cringing pose, but the manifold ways and devious means whereby parasites and their hosts have acquired mutual tolerance during many millennia of close and still closer association is a source of wonderment and a challenge to our understanding. In this small and inexpensive book the author scans a wide horizon, surveying the phyla Protozoa, Platyhelminthes, Acanthocephala and Nematoda, regrettably omitting parasitic crustaceans, insects and molluscs. He uses a 'type' system and deals largely with parasites which can be obtained from common hosts and examined alive, including some human parasites, and he makes a special effort to expound little-known physiological aspects of parasitism. By reducing ponderous morphological and taxonomic data to mere diagnostic criteria and by the use of clever diagrams to expand information concerning life histories, he has been able to introduce physiological data which impart a 'new look' to his subject and at the same time provide a sound basis for its expanding scope. He deals also with the nature of the host's reactions against its parasites, with the important subject of immunity and, at greater length, with the techniques for the *in vitro* culture of parasites.

This has been done with great skill but not without some loss of perspective, historical continuity having been sacrificed to modern developments. There is no mention in this book of Looss or Leiper, Thomas or Leuckart, or Dobell, Fuhrmann, Pintner, Railliet, Sinitsin, Skrjabin and a host of other dedicated pioneers whose classical researches illuminate the subject of parasitology and inspire the student to greater effort. There are sometimes lapses in matters which carry considerable weight of reliable opinion. In the account of ciliated Protozoa, for example, there is no mention of E. Fauré-Fremier and J. O. Corliss, who created a new classification of the Ciliophora during the past decade, and the problem of coccidiosis is discussed without mentioning the researches of E. E. Tyzzer and C. Horton-Smith. This criticism applies to groups other than the Protozoa; the author-index of the book is imposing but the chapter references often fail to indicate classical researches about which the student should know something.

The author's special fields of research are given the emphasis we would expect and they deserve, but the results of physiological researches with parasites are as yet so tenuous as to make unsatisfactory reading because areas of doubt and ignorance remain. There is some information about the chemistry and the mechanism of formation of egg-shell in the digenetic trematodes and the pseudophyllidean cestodes which requires revision, and the function of Mehlis's gland "remains obscure", while "how the operculum is formed remains a mystery". Statements about the blood-feeding habits of *Fasciola*, *Clonorchis* and *Dicrocoelium* are unsound and fail to harmonize with findings for *Paragonimus*, which has been studied in much greater detail. Another lapse is a failure to mention the *in vivo* technique using germ-free hosts, which, like *in vitro* culture methods, holds out great promise for the future. Axenically reared larvæ of *Nippostrongylus muris*, *Nematospiroides dubius* and *Hymenolepis nana* develop to normal fertile adults in germ-free guinea pigs, which are generally regarded as abnormal hosts for these parasites[1]. *H. nana* was more successful in the germ-free host than in conventional hosts, which has interesting implications in the nutrition of this tapeworm. The use of germ-free hosts will also tend to improve the quality of our knowledge about host-specificity.

What can or cannot be included in an introduction to parasitology is a moot point, and the present is catching up with the future now. Apropos of the axenic culture of *Neoaplectana glaseri*, the author states: "a number of media have been used to maintain *N. glaseri*, but these have been of biological origin and little attempt has been made to develop a defined culture medium". This end has been achieved already[2]. A chemically defined medium containing eighteen amino-acids, a fatty acid, urea, Krebs cycle intermediates, purines, pyramidines, B-group vitamins, glucose and also various inorganic constituents has fostered the development of third-stage larvæ of this nematode to the adult stage, with low but consistent level of reproduction. Incidentally, Jackson's aphorism should be memorized by all who enter this field of research: "cultures are as axenic as sterility tests are sensitive; and the media as defined as glassware is clean and chemicals pure".

It should be remarkable if any book were published free of typographical errors, and this book is not remarkable in that respect. A few elegant pages are marred in this way but, apart from mentioning the erroneous spelling of the names Dollfus (pp. 236, 238, 437) and Heyneman (pp. 255, 438), I shall rest content to forward a list to the author. In spite of such blemishes and some other shortcomings, the author is to be complimented on the production of a progressive book which points the way to profitable future developments in the expanding scope of animal parasitology, a book which will do much to assist the progress of a generation of students so long as they do not neglect the finer details of morphology and taxonomy in their quest for physiological knowledge.

A GUIDE TO ISOTOPES

The Radiochemical Manual

Part 1: Physical Data. Pp. 102. (Amersham: The Radiochemical Centre, 1962.) 15*s*.

THIS handbook presents a great deal of accurate information about the availability and radiation characteristics of those radioactive isotopes, now numbering more than one hundred and fifty, which are in general use to-day. The bulk of the information is contained in a table extending to some 60 pages which lists the isotopes in alphabetical order and gives for each the basic data of half-life, nature and strength of radiation, method of production, intensity available, and chemical form. Subsidiary tabulations summarize and slightly extend the data in special ways (for example, Table 6 lists beta-particle emitters in order of half-life). There are also graphs giving exposure data for the radiation from some isotopes commonly used in radiography.

It is inevitable in such an extensive compilation that there should be a number of slips, typographical and otherwise; these appear to be rather few and trivial. A more important criticism concerns the arrangement of the book as a whole. The order in which the six sections appear does not seem to be very logical; for example, Section 6 on the definition of terms might very well have been placed first and Section 1 on production of isotopes might very well have been combined with Section 3 on special irradiations in reactors. The intervening Section 2 on characteristics and availability of radioisotopes (pp. 3–84) is made rather top-heavy by Table 1 referred to above ("Physical Characteristics and Availability of Important Isotopes"); as one result of this, the explanation for the appearance of some of the isotopes tabulated in Tables 6 and 7 (pp. 78–81) in bold type is to be found on p. 3. Incidentally, the criteria for promotion of certain entries into bold type (importance of the radiation concerned) do not appear to have been consistently applied. The tables of sources of various kinds (Tables 10–14) deserve a place in the list of contents. These slight flaws in presentation of the data are redeemed, however, by a good index.

The *Manual* richly deserves a place by the side of the well-known *Radiochemical Centre Catalogue* on the desk of everyone concerned with the production and use of isotopes. The printing is excellent and the binding adequate.

K. F. CHACKETT

EDWARDIAN SCIENCE AND TECHNOLOGY: THEIR INTERACTIONS*

By Prof. A. R. UBBELOHDE, F.R.S.

Imperial College of Science and Technology, London

As is well known, the history of science views things past with two quite different perspectives. One of these is for the specialist, since it deals with the quiet emergence of new discoveries, in the deliberate seclusion of the study or the laboratory. In most known instances, several years, or even decades, have elapsed before a scientific discovery could be recognized as being really influential and far-reaching in the advancement of natural philosophy. But the other perspective of history deals with the impact of new applications of science to satisfying human needs in the market place. Developments of technology concern a much wider diversity of studies, in economics, in social affairs, and even in international politics. Time-lags are also inevitable in the application of new discoveries of science to practical uses. Under normal conditions, it is interesting to note that the time-lag between the purely scientific discovery of the element chlorine by Scheele in 1774, and its application on a wide industrial basis in bleaching powder by Charles Tennant in 1788, was only fourteen years, not much longer than the reputed average for new discoveries in the chemical research laboratories of progressive modern firms. Time-lags in the interaction between science and technology are obviously amenable to outside stimuli.

It so happens that both perspectives in the history of science show the Edwardian era to have been a period of revolutionary changes, the consequences of which we are still working out in our time. The First World War brought some of the trends to be discussed into sharp and even agonizing focus In the normal developments of science and technology of the nineteenth century this War introduced a deep cleft or Grand Canyon.

It is convenient to deal first with fundamental scientific discoveries. As in other periods of our scientific age, the decade of Edward's reign had its share of new advances in knowledge, too numerous to detail fully. But three of these advances have since proved to be quite cataclysmic. They have completely revolutionized physical theories of the world we observe by measurement. Einstein's theory of relativity was first published in 1905. Planck's quantum theory of radiation first emerged in the scientific literature in 1900. Both these theoretical developments stemmed from active and fertile German schools of theoretical physics. The third revolutionary discovery was experimental and British. It established the spontaneous disintegration of atoms, and was published in 1902 by Rutherford and Soddy as their theory of radioactive atomic disintegration.

In discussing reasons why these three innovations have completely revolutionized physics, the aspects to be viewed obviously depend on the onlookers. For the non-specialist, two facets of Einstein's theory of relativity warrant special comment. One of these is of great interest for the philosophy of time. In the realm of mathematical physics opened up by Isaac Newton, time was a framework common to all beholders. But Einstein postulated that each observer of Nature constructs his own local time-scale. His special theory of relativity based on the velocity of light as a common medium of communication permitted the matching of time-scales at different parts of the Universe. Philosophy is sometimes regarded as of little practical importance, which makes the second facet of Einstein's relativity theory part of the irony in the history of science. This theory first demonstrated the equivalence between energy and mass. In 1905, this equivalence seemed to be a mathematical curiosity, but we now know its fundamental importance for the generation of nuclear energy by the destruction of atomic mass, in atom bombs, and in our nuclear power stations.

Although Planck's quantum theory first emerged during the Edwardian era, its revolutionary importance for modern physics was not fully established until the formulation of Heisenberg's Uncertainty Principle in 1927. For the non-specialist, this innovation is particularly interesting in focusing attention on the nature of physical measurements as a means of acquiring experience about the world we live in. Man has practised measurement for thousands of years and, during the Victorian era, bold new developments were made in metrics. But the quantum theory revealed hitherto unsuspected limitations to the practices of measurement, which are of fascinating philosophical interest. In one sense, this development has corrected a sometimes excessive confidence in the power of metrical science.

Rutherford's theory of the spontaneous disintegration of atoms threw overboard all the inheritance of concepts about indestructible atoms in an everlasting universe of matter, which had attracted speculative thinkers from the time of the Indians and Greeks, and probably even earlier. Already in 1904 Rutherford had observed that large quantities of heat are liberated when atoms such as those of uranium or radium disintegrate spontaneously. At that time, and indeed until Otto Hahn's discovery of a nuclear chain reaction in 1939, there was no means of controlling atomic disintegration from without. But a far-seeing Edwardian scientist, Sir William Ramsay, had already announced the importance of atomic disintegration as a peaceful source of energy in the service of man, at the annual meeting of the British Association for the Advancement of Science in 1911. Ramsay estimated that through various applications of inanimate energy each British family by then had an average of twenty 'helots'—we now call them energy slaves—in its service. He stressed that stores of energy known at that time were not unlimited. The tides, the winds, the internal heat of the Earth, the heat of the Sun, the power stored with water, or in coal, in peat and in the forests all have their foreseeable limits as sources of energy to be harnessed by man. Ramsay's hope, induced by Edwardian discoveries of radioactivity, was to find catalysts for the exceedingly slow radioactive disintegrations which had been observed in naturally occurring elements, with the view of liberating their stored-up energy at a rate which could be utilized practically. We are the somewhat apprehensive inheritors of this Edwardian hope. Its realization in terms of the atom bomb and in terms of nuclear power stations has been accomplished in a way characteristic of so much technological aspiration and prophecy.

---

* Substance of a lecture delivered on May 16 at the University of Oxford in the series "Science and Economics in Chemical Technology".

Even this brief mention of some of the striking advances of Edwardian science points to the fact that there was no lack of interest in practical applications of new knowledge among British scientists. But for reasons which it is important to study, this interest was often abortive. Various records show how the Edwardian era marked the culmination of obstacles and frustrations arising from Government inertia in promoting fruitful interactions between science and technology. This situation was particularly galling for those British scientists who could appreciate its dangers, and who were pointing to contrasts in Germany at that time.

Even a very brief survey of Edwardian applied science, or technology, to use that ugly but fashionable word, must include several far-reaching transformations in the material conditions of existence, which first became viable during that brief era. At least two of them have shifted the balance of world power, and world population, but before dealing with these it is pleasant to remind ourselves of some of the less-disturbing advances that helped to make life even more comfortable in those comfortable times. Motor-cars had been adopted by the wealthy before 1900. Kipling, for example, tells us of his first car, a typical gentleman's car hired from a Brighton firm in 1899, together with an engineer at 3½ guineas a week. This was "Victoria hooded, carriage sprung, carriage braked, single cylinder, belt driven, fixed ignition". At times this embryo could cover eight miles in an hour (Kipling), but by 1902 Kipling decided that a single cylinder engine was too easily defeated by the Sussex hills and bought a Lanchester car.

What was new was the advent of motor-cars deliberately produced for the masses. Henry Ford began his production lines in Detroit around 1903. Before the First World War nearly 21,000 Ford cars were in use in Britain in a total car population of about 132,000. The tide was clearly rising, as is shown by the following figures: 1910, 570; 1912, 3,200; 1914, 8,352.

For public transport, motorized vehicles were beginning to displace horse-drawn contraptions in an unmistakable way, both as taxi-cabs and as omnibuses. Five motorized omnibuses were touting for customers in 1897; by 1906 their number had grown to 700. The first motor-driven taxi-cab began to compete with the horse in 1904. One can visualize some of the conflicts between horse and motor in public transport; stirring but unrecorded encounters in a London fog, for example.

The cinema was likewise being developed with clear intentions to provide mass entertainment. Short motion pictures had been projected as part of the traditional variety entertainment since before Queen Victoria's jubilee. Probably the first show of motion pictures for which a special admission fee was charged was given at Olympia in 1896. By 1912 cinemas were available in most of the cities and large towns in Britain and the issued capital of cinema companies was about £3 million. Their bias towards mass-audiences was linked with aims to refine as well as attract the masses, as is shown by the publicity given to amenities such as plush carpets, bevelled mirrors, soft lights and usherettes. Some of the early 'news' to be shown in motion pictures included Derby Day 1896, Queen Victoria's jubilee 1897, Queen Victoria's funeral 1901, and Edward's coronation 1902. Names given to the early picture palaces illustrated the same trend, with glittering specimens such as Olympia, Bijou, Empire, Jewel, Gem, Mirror, Picturedrome, Pallasino and Palace-adium. There may be rarities still to be added to this collection. Cinemas were not at first aiming to attract the wealthy or even the educated classes. It is on record, for example, that Herbert Asquith first visited a cinema in 1911. On this occasion his behaviour must have irritated humbler patrons, with his hearty laughing, and continually making witty comments to his companions.

British enterprise was well ahead in the earliest days of the cinema, when films could still be produced by small organizations, on a scale about comparable to the first motor-cars built by William Morris. For various interesting reasons, which cannot be detailed here, the early British lead was not maintained as films became longer and more consequential. This in itself hampered possible fruitful interactions between science and technology.

British leadership was also prominent in the early developments of wireless telegraphy. The Irish–Italian Marconi took out his first patent in England in 1896. In view of the many other frustrations to be recorded about this era, it is noteworthy that Marconi received important early support from the Post Office engineers, in particular, its chief engineer, Sir William Preece.

German and American competition caught up, and the first passenger steamships to be fitted with wireless were U.S.S. *St. Paul* (1899) and the German *Kaiser Wilhelm der Grosse* (1900). However, it is pleasant to note that wireless was one of the very few technological developments that ever received active support from King Edward. When he was still Prince of Wales, and was confined about the Royal yacht at Cowes by an injured knee which prevented him from joining his "Mamma" at Osborne, it is recorded that he tapped out personally many messages to the general effect that "H.R.H. the Prince of Wales has passed another good night and the knee is in good condition"—less exciting this than Kipling's famous tale, "Wireless", but more comfortable.

Marconi's drive exploited world communication by wireless telegraphy, using what we now regard as a chancy and by no means well-understood effect, based on the coherence of metal filings under the action of wireless waves. The 'coherer' had, in fact, little or no future, the first electronic valve was invented in 1904 by a professor of electrical engineering at University College, London, Ambrose Fleming. Fleming's invention formed the basis of the modern electronics industry, the economic importance of which does not yet even seem to have reached its asymptote.

Motors for the masses, the cinema, and wireless, all became viable in the Edwardian era. Scientific attention had been given to aviation much longer. Even Dr. Johnson mentioned balloons with petulance. While it is true that successful flights with powered machines heavier than air were first made during this era, prominently by the Wright brothers at Dayton, Ohio, during 1903–4, and more spectacularly by Blériot's first crossing the English Channel in July 1909, developments in aviation technology were much more gradual. They cannot be regarded as specifically Edwardian. The deliberate secrecy and small scale of developments in various countries worked against any strong interactions between pure and applied science.

Two developments of applied science which have had a particularly direct influence on world power and world population in different ways illustrate how backward Edwardian Britain was, even by contemporary international comparisons, in public support for scientific education and research. One of these refers to work on tropical diseases, and can be focused by biographical facts about a British leader in this field. Sir Ronald Ross migrated to biological research, starting with a classical education, by way of medicine. His essential contribution to the control of malaria was linked with accurate and tenacious observations of how the malaria parasite was tied up with the habits and life-cycle of the mosquito. It is staggering to find that, for a number of years, this research—the consequences of which were to be so vital for the tropical portions of the British Empire, not to speak of the world—was a spare-time effort on the whole discouraged by the Indian Government Service in which Ross was employed.

Fortunately, Ross was exceptionally tenacious. After he had achieved some success, the physician Sir Patrick Manson wrote to the India Office in 1897 with the aim that Ross be given more time for his work. "To our national shame be it said that few, very few of the wonderful advances in the science of the healing art which have signalized recent years have been made by our countrymen. This is particularly apparent in the matter of tropical diseases in which we should, in virtue of our exceptional opportunities, be *facile princeps*. But even in tropical diseases Frenchmen, Italians, Germans and Americans and even Japanese are shooting ahead of us. We have to get a Kock to find for us the cholera germ, and a Haffkine to protect us from it, a Laveranto to teach us what malaria is . . . ."

Ross was eventually appointed to special duty by the Government of India in January 1898 and was given a laboratory consisting of two rooms, an office and a verandah. The first meeting of a tropical medicine section of the British Medical Association was held in Edinburgh in July 1898. At this meeting the work of Ross was described by Manson, in particular the mode of infection by the mosquito. Practical measures to apply the new knowledge about the life-cycle of the malaria parasite began on an extremely modest scale, at Freetown in Sierra Leone, where Ross and a very small handful of colleagues studied the breeding grounds of mosquitoes and successfully organized ways of suppressing them. Dramatic success was obtained in 1902 at Ismailia, where Ross for a derisory fee showed the administrators of the Suez Canal how to stamp out the spread of malaria locally. In 1903 follow-through work by W. C. Gorgas at Colon first made possible the building of the Panama Canal. Consequences of this backroom work have been particularly great for world population and cannot even yet be fully appreciated.

A second major advance in technology, which almost threatened to become of decisive importance in the conflict between Britain and Germany in the First World War, was the German development sometimes known as the 'fixation of nitrogen'.

Since early studies on agricultural chemistry inspired by the German chemist Liebig, the need for supplementing traditional manuring operations by bulk additions of nitrogen compounds, in order to maintain yields of agricultural crops, was well appreciated. Attention to this requirement to feed rapidly increasing populations had been drawn in a dramatic way by Sir William Crookes at a meeting of the British Association in 1898. Demands on food-producing land could only be met in an acceptable way by the production of synthetic fertilizers. Many of the soil's requirements are restored by good systems of agriculture Components such as potash or lime which are removed by the crops can be restored in the form of mineral fertilizers; but even the most conservative use of manures and organic waste matter does not adequately restore nitrogen compounds in forms that plants can assimilate.

Only three solutions could be seen by Crookes—to accept a diminishing supply of foodstuffs and progressively lower the standard of nutrition, which would not be acceptable in technologically advanced communities; to import most of Britain's main food requirements from countries with abundant land, which was the solution adopted in the latter half of the nineteenth century by Britain. like ancient Rome in this respect; or to supplement any natural manure returned to the fields with other readily assimilated nitrogen compounds added to the soil after each crop. Prior to the First World War. this growing need was met largely by importation of nitrate of soda from Chile, 1,350,000 tons in 1900. Much of this went to Germany and its consumption like other imports was theoretically under threat of interruption in war by the British Navy. But, in addition to their peaceful application for increasing crop yields, nitrates were being used for manufacturing large tonnages of the new high-explosives based on picrite and TNT. It is said the failure of the British to capture 300,000 tons of nitrate of soda in the docks at Antwerp saved Germany's explosives supplies in the early years of the First World War

What was new in German applied science was their discovery of industrial processes for converting the nitrogen in the atmosphere into nitrates and other useful compounds, thereby releasing their explosives industry and agriculture from serious risk of attrition by naval blockade. By 1918, 200,000 tons of synthetic ammonia a year were being made in Germany for conversion into nitric acid and high explosives based on it. The Allies had no factories for this process until after the end of the First World War.

It is important to stress that this note of unfavourable comparison between British and European, chiefly German, scientific progress was being sounded with increasing insistence by leaders of British science throughout the Edwardian era. Presidential addresses to the British Association included strong complaints almost every year of the Edwardian decade. However, unlike the reception given to political agitation about the threat from the German Navy, only small and not very influential groups could understand the repeated warnings by British scientists about the threat from German industry. Since mid-nineteenth century and even earlier, enlightened support for scientific education and research by the German Government was building up a strong technological and commercial empire. In Britain there were frustrations which one would like not to term characteristic of Edwardian complacency.

Particularly full and informative comment about the impenetrability of the governing classes to the importance of science for the nation's welfare was made to the British Association by its president for 1906, Prof. E. Ray Lankester:

"It is unfortunately true that the successive political administrators of the affairs of this country, as well as the permanent officials, are altogether unaware to-day, as they were twenty-five years ago, of the vital importance of that knowledge which we call science, and the urgent need for making use of it in a variety of public affairs. Whole departments of Government in which scientific knowledge is the one thing needful are carried on by ministers, permanent secretaries, assistant secretaries, and clerks who are wholly ignorant of science, and naturally enough dislike it since it cannot be used by them, and is in many cases the condemnation of their official employment. Such officials are, of course, not to be blamed, but rather the general indifference of the public to the unreasonable way in which its interests are neglected. A difficult feature in treating of this subject is that when one mentions the fact that ministers of State and the officials of the public service are not acquainted with science, and do not even profess to understand the results of their importance, one's statement of this very obvious and notorious fact is apt to be regarded as a personal offence. It is difficult to see wherein the offence lies, for no one seeks to blame these officials for a condition of things which is traditional and frankly admitted. . . . The reason, I think, is to be found in the defective education, both at school and university, of our governing class, as well as in a racial dislike among all classes to the establishment and support by public funds of posts which the average man may not expect to succeed by popular clamour or class privilege in gaining for himself—posts which must be held by men of special training and mental gifts. Whatever the reason for the neglect, the only remedy which we can possibly apply is that of improved education for the upper classes, and the continued effort to spread a knowledge of the results of science and a love for it amongst all the members of the community . . . members of the British Association . . . might do a great deal by insisting that their sons, and their daughters too, should have reasonable instruction in science both at school and college . . . the trifling with classical literature and the absorption in athletics . . . is considered by too many schoolmasters as that which the British parent desires as the education of his children."

To explain the more than ordinary deafness of the Government and Civil Service to such warnings, I think we may adduce the almost complete lack of integration of science into the education of Britain's leaders.

By Edwardian times, Britain probably showed the greatest lag relative to Germany in its indifference to the role of science in the education of its leaders, and of the rank and file. For a nation the practical and empirical grasp of realities of which has often been shown in other matters, this deflexion of educational trends is curious. Some light is thrown on it by the famous comment of an eighteenth-century schoolmaster—or should I say educationist ?—on an equally famous seventeenth-century pedagogue—I refer to Dr. Johnson's *Life of Milton*, where he explains how this deflexion began.

Milton's purpose as a schoolmaster, which was: "To teach something more solid than the common literature of schools, by reading those authors that treat of physical subjects; such as the Georgick, and astronomical treatises of the ancients. This was a scheme of improvement which seems to have busied many literary projectors of that age. Cowley, who had more means than Milton of knowing what was wanting to the embellishments of life, formed the same plan of education in his imaginary College", meets with a criticism from one who, like Milton, had tried schoolmastering not very successfully as a way of life. Johnson leaves no doubt about his own very different judgment:

"The truth is, that knowledge of external nature, and the sciences which that knowledge requires or includes, are not the great or the frequent business of the human mind. Whether we provide for action or conversation, whether we wish to be useful or pleasing, the first requisite is the religious and moral knowledge of right and wrong; the next is an acquaintance with the history of mankind and with those examples which may be said to embody truth, and prove by events the reasonableness of opinions. Prudence and Justice are virtues and excellencies of all times and of all places; we are perpetually moralists, but we are geometricians only by chance. Our intercourse with intellectual nature is necessary; our speculations upon matter are voluntary and at leisure. Physiological learning is of such rare emergency, that one may know another half his life, without being able to estimate his skill in hydrostatics or astronomy; but his moral and prudential character immediately appears. Those authors therefore are to be read at schools that supply most axioms of prudence, most principles of moral truth, and most materials for conversation; and these purposes are best served by poets, orators and historians."

In support of Dr. Johnson, it would not be difficult to trace the benefits of prudence, attention to moral truth, and skill in human conversation, in more than one page of British history. But it is not unfair to attribute some of the heavy British losses in the First World War to the inertia of the Edwardian Governments which led to a perilous, but by no means unforeseen, lag in scientific and technological leadership. Prime generations of youth had to pay a bloody price in that War to make up for it. Directly, and by the loss of the contributions this generation might have made, their loss was one of the many factors making the end of the Edwardian era very clearly the end of a period of smooth historical evolution and the beginning of rapid social and economic changes the travail of which is our present experience.

NATURE OF THE BIOLOGICAL CODE

By Dr. CARL R. WOESE

General Electric Research Laboratory, Schenectady,
New York

UNTIL recently the nature of the biological code was a matter for theoretical speculation and a few experimental attempts, themselves fundamentally inexact and inaccurate, to place some limits on the parameters of the code[1-6]. Within the past year spectacular advances in an experimental approach to elucidating the code have been reported. In the first place, an *in vitro* system capable of synthesizing specific proteins on the addition of specific RNA 'messages' has been developed[7]. This plus the capability of synthesizing very simple RNA 'messages' by use of the enzyme nucleotide phosphorylase provide the long-sought direct experimental approach to a solution of the biological code[8]. Secondly, elegant genetic experiments have made it almost certain that the coding ratio (that is, the number of nucleotides corresponding to an amino-acid) is three for all amino-acids[9]. These experiments also demonstrate that the code must be rather highly degenerate.

A great deal of progress has been made in a very short time in obtaining coding nucleotide triplet assignments for the amino-acids[10-13]. The results obtained at first glance seem to pose as many new problems as they answer old ones. For, although the experimentally determined coding assignments invalidate all published theoretical speculations concerning the nature of the biological code, the true code which seems to be emerging from this approach ostensibly is in conflict with what we know concerning the composition of the coding substances, that is, DNA and RNA (ref. 14). However, I feel that this is not the case in actuality, but that it is certainly now possible to develop a theory which will encompass all the existing facts regarding the code, which the present preliminary communication attempts to do.

Consider first the following theoretical argument. Coding is in all probability accomplished in terms of the purine and pyrimidine bases on the nucleic acid. Each of the four naturally occurring bases is uniquely defined by the substituents it carries on the 2 and 6 positions in the ring, adenine (A) being 2-H, 6-NH$_2$; cytosine (C) being 2-OH, 6-NH$_2$; guanine (G) being 2-NH$_2$, 6-OH; and uracil (U) being 2-OH, 6-OH. It appears possible, then, that coding may also be done in terms of the 2 and 6 positions only. (The bases can also be distinguished in part by the fact that two, the purines, have a double, rather than single, ring structure; but I shall disregard this for the present discussion, suggesting only that the main purpose of the double rings may be to bring about the correct electronic configurations necessary to produce desirable tautomeric shifts in the 2 and 6 positions, which are the points of essential interest.) Confining attention to the four major naturally occurring bases one can inquire as to the information content of the 2 and 6 positions. Since only two substituents occur in the 6 position, its information content is 1·0 bits. In the 2 position three substituents occur, making its information content 1·6 bits. When one considers 2 and 6 positions taken together, one defines the four bases; therefore, the information content here is 2·0 bits. Now there are twenty amino-acids in protein to be specified, and probably one must also specify the end (and/or beginning) of a molecule, or at least 21 things, which requires 4·4 bits. The closest approach one can make to 4·4 bits using the purine and pyrimidine bases is 1·0 + 1·6 + 2·0 or 4·6 bits.

This, then, suggests the following coding scheme. Coding is accomplished by a triplet of nucleotides. One member of the triplet codes according to its 2 position on the ring only, a second member codes according to its 6 position only, while the third member codes according to both 2 and 6 positions. A degenerate code composed of 24 distinguishable triplets is thus produced. In other words, when using just the 2 ring position, U and C are indistinguishable so that only three different symbols are possible; when using just the 6 ring position, U is indistinguishable from G and C is indistinguishable from A, so that only two different symbols are possible. The product of 3 × 2 × 4 gives 24 distinguishable triplets.

Before developing this theory further, let us now turn to the experimental facts relevant to coding. The first concerns the DNA composition of various organisms, particularly the micro-organisms. It is known that the DNA of any one species of micro-organism is quite homogeneous in its composition, but different species may differ from one another in G + C content by extremely wide margins[15]. For example, the highest known G + C content of a naturally occurring DNA is that of *M. lysodeikticus* at 72 per cent G + C, while at the other extreme 25 per cent G + C is observed in *T. pyriformis*[16]. Further, the overall amino-acid compositions of a variety of micro-organisms the DNA's of which span the range of G + C contents is known[16]. The second group of facts concerns the 'neighbour frequency' in DNA, that is, the frequency of occurrence of one base adjacent to another base. As before, this type of measurement has also been made on a variety of DNA's which span the range of known G + C values[17]. The third and most important group of facts concerns the composition of coding nucleotide triplets as determined in the above-mentioned *in vitro* system. At present coding assignments have been determined for nineteen of the twenty amino-acids[10-13,18]. Although there are minor disagreements between the two groups active in the field, there is complete agreement between them regarding the fact that for all nineteen of the amino-acids reported there is at least one U in each of the corresponding triplets. Many triplets contain 2 U's. This means that the composition of a coding nucleic acid strand is extremely high in uracil, which would make the coding nucleic acid of a composition that has rarely if ever been observed in Nature. Although this high uracil content at first sight is an anomaly, it is, as seen below, exactly what would be expected on the present coding scheme; and, further, this coding scheme makes the observed coding triplet assignments compatible with the wide variations in G + C content of the DNA of micro-organisms.

Table 1

OBSERVED AMINO-ACID CODING ASSIGNMENTS FITTED TO A THEORETICAL DEGENERATE CODE

The particular observed assignments are in italics

1.	*UUU*, CUU, UUG, CUG	phe
2.	*UUC*, UUA, CUA, CUC	ser (or leu)
3.	*UCU*, CCU, UCG, CCG	leu (or ser)
4.	UCA, *UCC*, CCA, CCC	pro
5.	*UGU*, UGG, CGU, CGG	val
6.	*GUU*, GUG	cys or try ?
7.	*GGU*, GGG	gly
8.	*UAU*, CAU, UAG, CAG	ilu
9.	*AUU*, AUG	tyr
10.	*AAU*, AAG	lys
11.	*AUA*, *AUC*	asn
12.	UAA, *UAC*, CAA, CAC	thr ?
13.	*UGA*, UGC, CGA, CGC	met
14.	*GAU*, GAG	asp
15.	*AGU*, AGG	glu
16.	*GCU*, GCG	ala
17.	GUA, *GUC*	arg
18.	*ACU*, ACG	his
19.	GCA, GCC	—
20.	GGA, GGC	*
21.	ACA, ACC	—
22.	AAA, AAC	*
23.	AGA, AGC	gln
24.	GAA, GAC	—

* Proposed triplets for end-of-molecule.

Table 1 gives the 24 distinguishable coding triplets predicted by the above theoretical code. It is seen that eight are four-fold degenerate, while the remaining sixteen are two-fold degenerate. The table also shows the coding assignments determined by Lengyel, Speyer, Basilio and Ochoa placed in this scheme. Where there are ambiguities as to assigning the experimental unoriented nucleotide triplets to this scheme, we have utilized amino-acid replacement data to make the choice[19-22]. (The assignments given here are to a high per cent compatible with existing replacement data—a point which will be discussed in greater detail elsewhere.) With very few exceptions the present theoretical code accommodates the experimental results very well. The most prominent exception is that either cys or try cannot fit into the scheme. Also, one of the codings for thr, 1U2C, does not fit; but this coding is in doubt (Ochoa, S., personal communication); whereas the other thr coding is not. Further, of the three codings for leu (2U1C, 2U1A, 2U1G) only 2U1C fits the present scheme. (It seems that perhaps the assignment for ser and leu in the present scheme could possibly be interchanged, which would improve the situation.) The coding for gln has not been observed experimentally. Tentatively it has been assigned 1U1C1G[18]. We have assigned it 1A1C1G in order to fit it into the present scheme, a coding which would also account for the fact that the gln code has not been observed experimentally. With the few exceptions noted then, all the experimental coding assignments are compatible with the present theoretical degenerate code, leaving five code places to be accounted for, some of which could be used as the code for end (or beginning) of molecule.

At this point it is interesting to attempt to determine a coding for end (or beginning) of molecule. If the present coding scheme is correct, this should fall into one or more of the five as yet unfilled code places. To determine end-of-molecule it is necessary to find two closely related proteins the chain-length of which differs. The amino-acid in the longer one opposite the termination of the shorter one should give a clue to end-of-molecule, for single mutation in the triplet corresponding to the amino-acid in question should have produced a triplet meaning end-of-molecule. Such a case as we are loooking for occurs in the melanocyte-simulating hormone–adrenocorticotropin series[22]. Here we find two cases of gly opposite to end-of-molecule and two cases of lys opposite to end-of-molecule. Comparing this to the above scheme, it is found that both GG^{A}_{C} (one mutation distant from the gly triplet) and AA^{A}_{C} (one mutation distant from the lys triplet) are yet available to code end-of-molecule, a satisfying result.

We are now in a position to evaluate the present theoretical code in terms of the data on G + C content of various DNA's. As can be seen, due to the degeneracy condition most amino-acids can be coded by a triplet low in G + C as well as one high in G + C. This suggests that the experimentally determined coding assignments can be reconciled with the observed wide variations in G + C. Using the amino-acid composition for *M. lysodeikticus* determined by Sueoka and coding the amino-acids in a form which maximizes G + C, one finds that G + C = 79 per cent, a result which is more than sufficient to account for the observed 72 per cent reported for *M. lysodeikticus*. Using the amino-acid composition for *T. pyriformis* and coding amino-acids in a form which maximizes A + T(U), one finds G + C = 25 per cent, which is the experimentally observed G + C content of this organism. Thus *T. pyriformis* seems to be at (or near) the one extreme of the G + C scale, if the present theory is correct. The wide variations in G + C of the DNA observed in micro-organisms is completely accounted for on the present theoretical code. In the present communication I shall not discuss in quantitative detail the fit of the 'neighbour frequency' data of Josse *et al.* Suffice it to say now that agreement between this set of data and the present code is good at least to a first approximation.

This article, then, outlines a particular degenerate coding scheme derived from an information point of view, which scheme fits to a high degree the existing data on the experimentally observed nucleotide coding assignments, agrees rather well with existing amino-acid replacement data, and reconciles the experimentally determined composition of code triplets with the very wide variations in the G + C content of various DNA's. In further publications I shall attempt to elucidate more fully the points raised here and the question of the molecular basis for the coding scheme.

ELECTRON MICROSCOPIC OBSERVATIONS ON ROUS SARCOMA VIRUS AND CELL MEMBRANES

By Dr. R. R. DOURMASHKIN, Dr. R. M. DOUGHERTY and Dr. R. J. C. HARRIS

Division of Experimental Biology and Virology, Imperial Cancer Research Fund,
London, N.W.7

SOME progress has already been made[1] in the elucidation of the ultrastructure of Rous sarcoma virus. On rare occasions structures resembling sub-units were seen, but it was not clear whether these were associated with the external membrane, internal membranes or the nucleoid. Methods were therefore sought to remove the membranes and uncover the nucleoid.

It has long been known that ether and sodium deoxycholate inactivate and disrupt Rous sarcoma virus particles, but neither of these reagents has released recognizable fragments. Rous and Murphy[2] had shown, however, that saponin, in high dilution, inactivates Rous sarcoma virus. This surface-active agent damages the outer membrane of this virus particle in a characteristic manner. It has been suggested[3] that the outer membrane of this virus is similar to the membrane of the cell which produces it. It was not unexpected, therefore, to find that the membranes of Rous sarcoma cells and of chicken liver cells showed a similar pattern of damage by saponin. So, too, did the membranes of human and guinea pig erythrocytes.

Materials and Methods

(*a*) *Rous sarcoma virus preparations.* Rous sarcoma virus, strain *B* (ref. 4), was used throughout. High titre infected culture fluids were prepared in tissue cultures of chick embryo cells using the method described by Crawford[5]. Infected tissue culture medium was clarified by centrifugation at 2,000*g* for 20 min.; the virus was sedimented at 78,000*g* for 30 min. in a Spinco model *L* ultracentrifuge and the pellet suspended in 1/100 the original volume of distilled water. This material was immediately subjected to the various reagents, then either sprayed directly for electron microscopy or diluted in buffered saline for infectivity assay. The virus was assayed by the focus method[6] as modified by Dougherty and Simons[7].

(*b*) *Cell membranes from chicken liver, and from Rous sarcoma, cells.* Membranes were prepared substantially by the method of Herzenberg and Herzenberg[8].

(*c*) *Human, and guinea pig, erythrocyte ghosts.* The washed cells, suspended in isotonic saline, were lysed by pouring into aqueous or saline solutions of saponin, digitonin, 'Triton 165', 'Triton 100', Gurr's '7×' detergent, sodium deoxycholate or 0·01 *M* phosphate buffer at *p*H 7·2 ('control' ghosts). Hæmolysis was completed at 37° C. for 30 min.

(*d*) *Electron microscopy.* Negative staining with 2 per cent potassium phosphotungstate at *p*H 5 (ref. 9) containing 0·05 per cent bovine plasma albumin (to permit spreading of the micro-drops) was used. Virus or cell-membrane preparations in distilled water were mixed directly with this solution. The erythrocyte ghosts were washed in 0·01 *M* phosphate buffer at *p*H 7·2 before adding the negative stain. The preparations were sprayed on grids coated with carbon films made by evaporating carbon on freshly cleaved sheets of mica. A drop of glycerol was placed on the carbon rod point and evaporated on to the mica in order to allow easy flotation of the carbon film. A Siemens Elmiskop 1 electron microscope was used with the double condenser, 200μ centrable condenser aperture, 50μ centrable objective aperture, and was operated at 80 kV. throughout. Micrographs were taken at magnifications of 20,000 and 40,000.

Results

(1) *Saponin treatment of Rous sarcoma virus.* The external membrane of untreated Rous sarcoma virus was intact. Incubation of the virus with 0·001 per cent saponin (37° C. for 60 min.) produced no recognizable change in appearance. At a concentration of 0·005 per cent some holes, or pits, appeared in the outer membrane. The number of these increased with increasing saponin concentration and also varied from particle to particle. Each pit was 80 ± 10 Å. in diameter and, for example, at the periphery of the particle, was some 35–50 Å. deep. With 0·01 per cent saponin the pits were found to be arranged hexagonally (Fig. 1). The pits were each surrounded by a ring, and the 'outer layer' peripheral to the external membrane[1] was not found in those particles which showed pits.

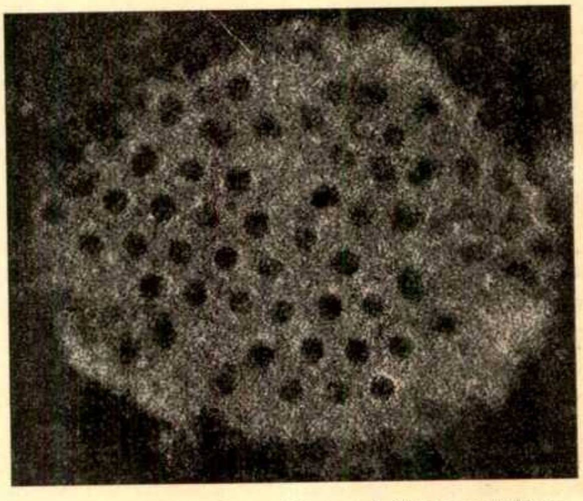

Fig. 1. Rous sarcoma virus particle treated with saponin, 0·01 per cent. The pits are arranged in a hexagonal array, and the edge of the particle shows indentations. The outer layer is not seen in particles showing holes. (× 400,000)

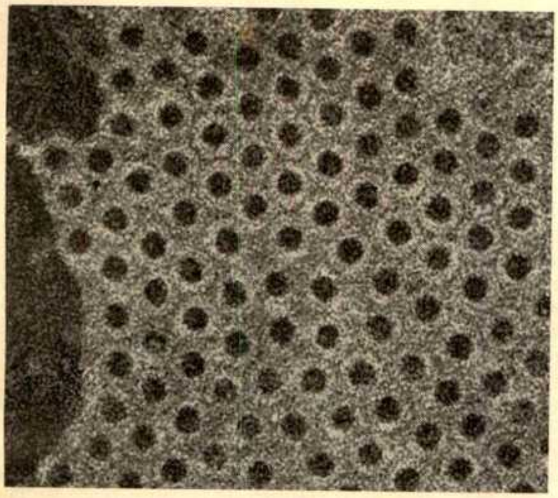

Fig. 2. Rous sarcoma cell membranes treated with 0·05 per cent saponin. There is a single layer of membrane, which shows a hexagonal array of pits surrounded by rings. (× 400,000)

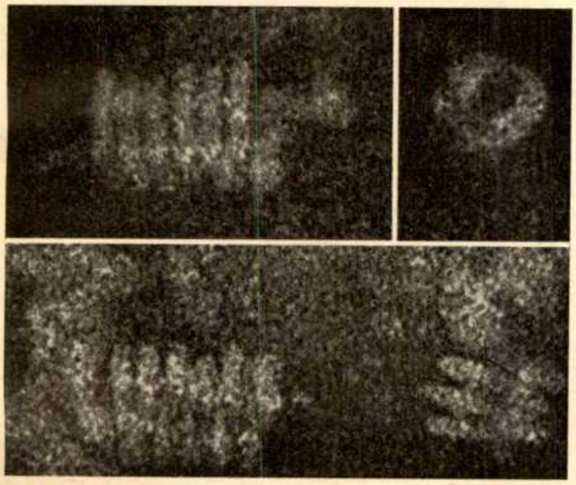

Fig. 3. Chick liver cell membranes treated with saponin. Helices and an individual ring are shown. (× 640,000)

At still higher saponin concentration (0·017 per cent) greater breakdown of the virus membrane led to the formation of a mesh of rings and strands. Saponin at 0·01 per cent at 37° C. for 60 min. reduced the virus titre from $1{\cdot}8 \times 10^8$ focus-forming units/ml. to $3{\cdot}8 \times 10^5$ focus-forming units/ml., that is, by a factor of 500.

(2) *Digitonin treatment of Rous sarcoma virus.* Digitonin reacts stoichiometrically with cholesterol, and also brings about the lysis of erythrocytes. Cholesterol is known to be a component of cell membranes and to be present in Rous sarcoma virus. It was anticipated, therefore, that digitonin, like saponin, might react with the external membrane of the virus.

A Rous sarcoma virus preparation was incubated sequentially in water followed by water (control A); 0·01 per cent digitonin, followed by water (B); water and 0·01 per cent saponin (C) or 0·01 per cent digitonin and 0·01 per cent saponin (D).

The control virus assayed at $6{\cdot}6 \times 10^7$ focus-forming units/ml.; B, 6×10^2, C, $1{\cdot}8 \times 10^5$ and D, $< 2 \times 10^2$. Subsequent treatment with saponin did not change the appearance of Rous sarcoma virus treated with digitonin. It would seem, therefore, that digitonin binds the material with which saponin normally reacts in the virus membrane. Nevertheless, as the titration shows, digitonin inactivates Rous sarcoma virus more effectively than saponin at the concentrations used.

(3) *Saponin treatment of chicken liver, and Rous sarcoma, cell membranes.* Untreated, negatively stained membranes showed an 'outer layer' of material of low contrast with fairly regular projections. No pits were seen. On incubation with 0·05 per cent saponin, some of the Rous sarcoma membranes showed a hexagonal array of pits similar to that observed in Rous sarcoma virus (Fig. 2). The effect of saponin on chicken liver cell membranes and Rous sarcoma cell membranes was the same.

The centre-to-centre spacings were approximately 140–160 Å. At the edges of the membranes the network appeared to be unravelling. Strands were formed, often curled into helices, and separate rings were observed (Fig. 3). The strands had a width of about 50 Å. in one dimension and a thickness of about 40 Å. in the other. Increasing concentrations of saponin increased the extent of the total breakdown of the membranes into strands and helices.

Incubation with 0·1 per cent digitonin (37° C. for 30 min.) appeared to make the membranes more rigid. They were homogeneous with no apparent structure and with slightly curved edges and sharp angles (Fig. 4).

After fixation in Palade's buffered osmium tetroxide, embedding in methacrylate and thin-sectioning, saponin-treated liver cell membranes showed no evidence of pits.

(4) *Saponin treatment of human, or guinea pig, erythrocyte ghosts.* At concentrations of saponin less than 0·03 per cent no changes in the membranes were apparent. At a greater concentration (0·05 per cent) large numbers of pits were seen, and the numbers increased with increasing amounts of the reagent (Fig. 5).

Where there was a single layer of pits they were 85 ± 10 Å. in diameter and the maximum centre-to-centre distance varied between 140–160 Å. At the edges of the membranes the indentations corresponding to profiles of the pits were 40 ± 20 Å. deep. The pits were frequently found in a hexagonal array and

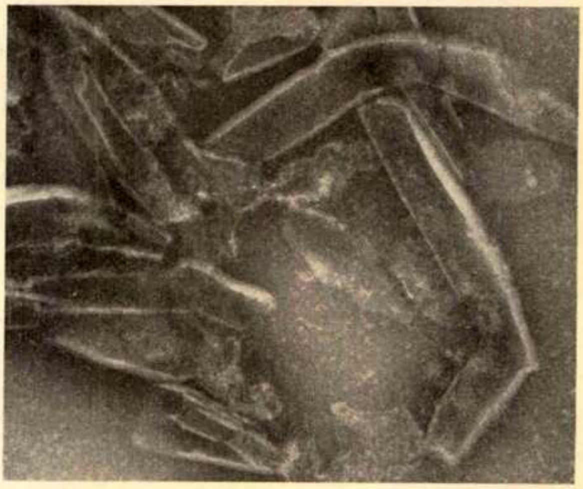

Fig. 4. Chick liver cell membranes treated with digitonin. Note the slightly curved outlines of the membranes. (× 100,000)

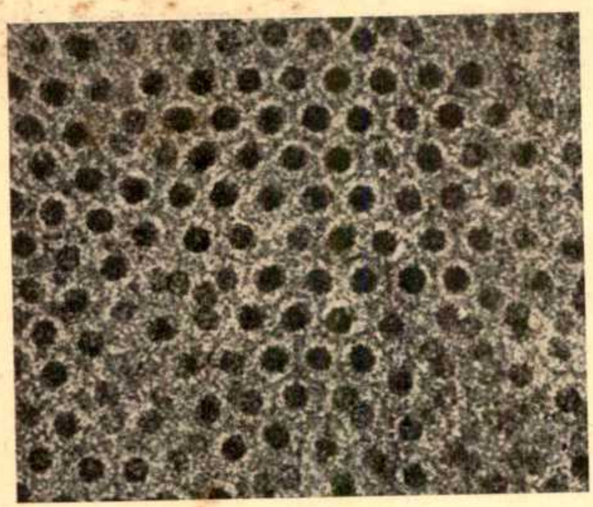

Fig. 5. Erythrocyte suspension in saline treated with 0·05 per cent saponin, then treated with 0·01 per cent trypsin for 1 hr. at 37° C. The surface of the ghost membrane shows a hexagonal array of pits surrounded by rings similar to that seen in Rous sarcoma cell membranes illustrated in Fig. 2. In this picture, two superimposed layers of membranes are seen. (× 400,000)

surrounding each was a ring, 30 ± 5 Å. thick. The rings were hexagonal in outline and separated from each other by a minimum distance of 10 Å.

Larger amounts of saponin (0·09 per cent) caused complete dissolution of the ghosts and the appearance of masses of curled threads and rings. Ghosts prepared by lysing the erythrocytes in hypotonic phosphate buffer had no pits in their membranes.

The protein nature of the residual membrane after saponin treatment was investigated by prolonged peptic and tryptic digestion. The appearance of the ghosts was unchanged—or possibly the micrographs showed more contrast (Fig. 5). Trypsin (or pepsin) treatment of 'osmotic' ghosts did not produce pits (Fig. 6).

(5) *Digitonin treatment of erythrocyte ghosts.* Incubation of human red cell ghosts in 0·01 per cent digitonin in isotonic saline at 37° C. for 30 min. was followed, after washing, by 0·05 per cent saponin at 37° C. for 30 min.

Digitonin prevented the formation of the pits, and the membranes resembled in appearance the chicken liver cell membranes treated in the same way. The inhibition of pit formation by digitonin is quantitative. 1 ml. of packed guinea pig erythrocytes required about 6 mgm. of digitonin to 'block' all the pits against the action of saponin. (One pit was found in one membrane in 5 micrographs magnified 20,000 times.) This again suggests that the digitonin is reacting with a specific component of the cell membrane such as cholesterol.

The biochemistry of the membranes is being investigated by Dr. G. F. Marrian and his colleagues.

(6) *Treatment of human erythrocyte ghosts with other surface-active agents.* Concentrations of 30 per cent '7 ×', 0·8 per cent 'Triton 165', 0·8 per cent 'Triton 100', and 1 per cent sodium deoxycholate were sufficient completely to disintegrate the ghosts. No pits, etc., were observed after treatment with these, or any lower, concentrations of these reagents.

Discussion

The action of saponin on the outer membrane of Rous sarcoma virus on chicken liver or Rous sarcoma cell membranes, and on human, or guinea pig, erythrocyte ghosts is to produce a hexagonal array of pits each of which is surrounded by a more or less distinct circular, or hexagonal rim. With increasing amounts of saponin these membranes are destroyed and masses of strands, or rings, are produced. Prior treatment of the membranes with optimum amounts of digitonin inhibits the action of the saponin. The almost identical appearance of the saponin-treated cell membranes from such disparate species as chicken, guinea pig and man lends credence to a general theory for the structure of the cell membrane. The pauci-molecular theory as first proposed by Danielli and Davson[10] suggested that the cell membrane was made up of a bimolecular leaflet of lipid sandwiched by external and internal layers of protein. By the use of permanganate fixation and thin-sectioning techniques in electron microscopy, it has been possible to demonstrate the existence of a unit structure that is found in cell membranes, endoplasmic reticulum, and mitochondrial membranes[11]. The unit membrane was seen as two dense lines 20 Å. wide, separated by a gap of 25 Å.

Danielli[12] later suggested a mosaic structure of lipid and non-lipid areas, and Parpart and Ballentine[13] proposed an arrangement in which a mosaic of cylinders containing phospholipid and cholesterol were surrounded by a protein meshwork. The diameter of their proposed cylinders was about 90 Å., and the centre-to-centre spacing some 150 Å. In cross-section the lipid-containing areas penetrated the entire thickness of the membrane, while the protein frame-work was conceived to be in two opposed layers. The experimental results obtained here by saponin treatment are in fair agreement with this type of structure. The digitonin inhibition of pit formation suggests, too, that such areas may indeed contain cholesterol.

The similar effect of saponin on the external membrane of Rous sarcoma virus to that on chicken liver cell membranes and Rous sarcoma cell membranes provides evidence for the suggestion that Rous sarcoma virus derives its outermost membrane from the cell's membranes as it is secreted. The sub-units which Dourmashkin and Simons[1] found occasionally in Rous sarcoma virus particles are quite different

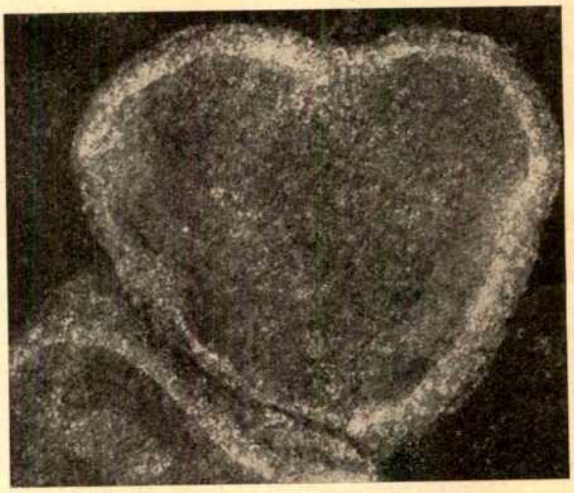

Fig. 6. Control experiment for Fig. 5. Erythrocyte suspension in saline lysed in 0·01 M phosphate buffer at pH 7·2 for 30 min. at 37° C., then treated with 0·01 per cent trypsin for 1 hr. at 37° C. There are no pits in the membrane. (× 200,000)

from those described here. They are smaller, more closely spaced and represent positive rather than negative features, that is, they displace the negative stain. The hexagonal array of pits formed in the external membrane when Rous sarcoma virus is treated with saponin implies another mosaic ultrastructure for this virus. It will be of interest to know whether other viruses with external membranes derived from the cell's membranes behave similarly on treatment with saponin.

It is disappointing that the pits in the cell membranes have not been seen in thin sections of saponin-treated, osmium tetroxide-fixed preparations. It is difficult, otherwise, to decide whether they are, in fact, holes through the membranes or merely pits.

We thank Prof. J. F. Danielli for an opportunity to discuss these results with him, and Miss L. Bates and Mr. A. J. Pringle for technical assistance.

ROYAL SOCIETY EXPEDITION TO TRISTAN DA CUNHA

PRELIMINARY REPORT

THE aims of the Royal Society Expedition to Tristan da Cunha were to examine the active volcano, to make a geological survey of the Tristan da Cunha group and to investigate the effect of the present volcanic activity on the flora and fauna of the island. The Expedition was composed of twelve members: Dr. I. G. Gass (leader), Dr. P. G. Harris, Dr. R. W. Le Maitre and Mr. P. E. Baker (geologists); Mr. J. H. Dickson (botanist); Mr. D. E. Baird (zoologist); Lieut. Commander A. B. Crawford, S.A.N.R. (meteorologist and deputy leader); Mr. D. Simpson (agriculturist); Staff/Sergeant R. Shaw and Corporal T. McCormack (Royal Corps of Signals); and Mr. Joseph Glass and Mr. Adam Swain (Tristan islanders). Landing on January 29 from the South African Navy frigate S.A.S. *Transvaal*, the Expedition spent seven weeks on the island before embarking on the Royal Navy ice patrol vessel H.M.S. *Protector*.

Fig. 1 is a sketch map of Tristan da Cunha prepared by the Directorate of Overseas Surveys, Tolworth, Surbiton, Surrey, from aerial photographs taken by the Royal Air Force. The stippled area indicates the position of the new volcano and the extent of its lava field.

Geology and Vulcanology

The main geological aims of the Expedition were to study the new volcano and to relate its activity to the geology of the Tristan da Cunha group of islands as a whole.

Previously, the most complete study of these islands was that of Dunne[1]. Since this is mainly a petrographic account it was desirable that the geology should be re-examined with emphasis on structure and volcanic history and mapped in greater detail than before.

Tristan da Cunha consists of a central peak (6,760 ft.) from which the land falls away with diminishing gradient to about 2,000 ft. Below this are almost vertical cliffs, often to the sea. In places, at the foot of these cliffs, are fringing strips of relatively flat land about 100 ft. above sea-level: one such platform is that on which the settlement stands. Local terms for the major topographic features used in this report are: 'the Peak', for the steeply inclined central area above 3,000 ft.; 'the Base', for a gently inclined area between 2,000 ft. and 3,000 ft.; and 'the Main Cliffs', for the 2,000-ft. high cliffs.

The peak and its slopes are dissected by radial valleys or gulches the gradient of which lessens outwards to the edge of the base over which they plunge in a series of waterfalls. At first sight, these pronounced hanging valleys seem incompatible with an origin of the main cliffs by normal marine erosion alone. But since the drainage of the island is almost entirely underground, through permeable ash and lavas, water flows down the gulches for only a few hours after heavy rain. Hence, river down-cutting is very slow and is unable to keep pace with intense marine erosion.

New volcano. The recent volcanic eruption occurred on the settlement plateau, its centre being about 300 yards to the east of the settlement. The eruption was preceded by a series of earth tremors commencing on August 6, 1961. These tremors, sometimes of about force 5 or 6, were highly localized in the settlement area, being very weak at a distance of 4 miles and undetectable 7 miles away. The second phase, on October 9, was the development of rifts 200 yards long and 2 yards apart, parallel to the coastline. The seaward side was uplifted 30 ft. and heavy falls of rock occurred in the cliffs behind, particularly in a well-joined, old, volcanic neck immediately overlooking the settlement. That night, at about 2 a.m., a red glow was observed and next morning a mound of solid incandescent lava had appeared which continued to grow during the next four days, attaining a height of about 250 ft. (summit 480 ft. above sea-level). This mass began to expand northwards, and it is believed that a stream of fluid lava was emitted, carrying with it the seaward wall of the dome which lay in its path. The remnant of the initial dome now formed a horseshoe-shaped crater about 400 yards long by 200 yards wide. Within this crater, a central cone was built up by the pyroclastic activity and from its summit a lava stream poured northwards, lobes extending along the coast to the east, then to

the west, as well as out to sea. The seaward front of the lava field is at present about 1,300 yards long, is about 900 yards from its source and in places as much as 500 yards beyond the former coastline. It has a thickness of up to 80 ft. The flows are mantled with partly rounded, bruised and abraded lava fragments, with massive undisturbed lava appearing only in the lower part of the seaward margin and near the origin of lava streams.

When the Expedition arrived on January 27 the emission of fluid lava from the central cone appeared to have ceased. Sulphurous vapour was still being emitted from the cone and from a subsidiary crater lying behind the main cone on the rim of the outer wall of the volcano. The spasmodic bursts of vapour and dust, which in December[2] had occurred at about 10 minute intervals, had now become very infrequent and ceased altogether after a few days. At night, a red glow was emitted from the central cone and from cracks in the congealed lava mass which had flowed from it. Ephemeral glowing patches were revealed when blocks fell from this region. These features had ceased by the end of February.

After January, the chief change was the pushing up of a large dome of solid lava about 260 yards long, more than 100 yards wide and up to 100 ft. above the surrounding lava. The long axis of the dome followed the former course of the lava from the cone. The formation of the dome was accompanied by the peeling of sheets and breaking of blocks from its flanks, often exposing red-hot material beneath. This updoming appeared to have ceased by mid-March and the emission of vapour had been greatly reduced. Red-hot rock, formerly visible in deep fractures at the summit of the dome, had cooled by mid-March.

Intensive erosion of the lava along its seaward edge has already occurred, particularly during strong winds in March. The north-western corner of the field has retreated about 20 yards and was cut back about 5 yards during the first day of heavy seas. During the same period, the north-eastern corner underwent a very marked change, and a boulder and gravel spit now extends south-eastwards from this point, running into the coast below Pigbite and encloses behind it a shallow lagoon approximately 140 yards long.

Fumaroles and steam vents occur on the lava field and in the vicinity of the crater. Their activity is diminishing especially in the latter area, and the formation of encrustations of sulphur, common around the second vent, has been curtailed.

General geology of Tristan. For the most part, the island consists of alternate layers of lava and pyroclastic material derived largely from the central conduit. The rocks appear to be chiefly of basaltic composition, though nearer the centre the proportion of trachytes increases. Scoria also becomes more abundant towards the centre. This may be attributed, in part, to the presence of secondary scoria cones on the slopes of the Peak.

In common with most volcanoes, the dip of the flows diminishes away from the central vent. This may be due either to the increase in the proportion of pyroclastic material near the central vent, or to the fact that the more viscous trachytic lavas, flowing relatively short distances, formed steep slopes near the summit crater, while the more mobile basalts flowed longer distances and over a wider front to build the lower slopes.

Dykes are numerous and usually radiate from the centre of the island. They are well exposed in the Main Cliffs, in some of the gulches and in the vicinity of the Peak, where they often stand up as walls up to 40 ft. high. Also exposed in the cliff sections are necks and conduits which have characteristic jointing and are sometimes associated with irregular sills.

Superimposed on the flanks of the central volcano are more than twenty secondary cones, principally of pyroclastic origin though often with thin flows interbedded with the scoria. Most of these cones have summit craters often breached on the seaward side and sometimes with a small crater lake. Usually, in cases where the crater has been breached, a hummocky lava field could be identified beyond it. Centres entirely of effusive origin are limited to Stony Hill and the new volcano.

The absence of weathering and paucity of vegetation on Stony Hill strongly suggest a very recent origin, perhaps 200–300 years ago. The form of this volcano and its lava field, and the nature of the lava itself, bear a striking resemblance to the new volcano. The present eruption is therefore believed to be the second of its type on the island, suggesting perhaps that Tristan is in a new phase of secondary effusive activity, as opposed to the secondary explosive activity which hitherto had been characteristic.

The present volcanic eruption appears to be merely another episode in the long volcanic history of the island. The well-preserved forms of the scoria cones and of Stony Hill indicate that there have been repeated eruptions from widely distributed centres within the past few thousands of years. With only 200–300 years having elapsed between the eruptions at Stony Hill and the present volcano, it is possible that further eruptions from new centres could occur at intervals, probably of a few hundred years.

Botany

Vegetation before the eruption. The only detailed study of the flora of Tristan da Cunha was carried out by the Norwegian Scientific Expedition (1937–38), many of the results of which remain unpublished. The sole comprehensive description of the vegetation so far published is by Wace and Holdgate[3]. These authors recognize a series of clearly defined altitudinal zones; the lowermost is characterized by the 'island tree' *Phylica arborea* Thouars and extends upwards to about 2,000 ft. Next, on the edge of the Base at 2,000–2,300 ft., comes a belt dominated by the small tree-fern *Blechnum palmiforme* (Thouars) C.Chr. and then zones of *Empetrum rumbrum* Vahl, grasses and alpine moss communities.

Early accounts confirm that the settlement plain was formerly covered in the normal low-level *Phylica arborea* scrub, together with tussock grass (*Spartina arundinacea* Carm.) and *Blechnum palmiforme*[4]. Since human colonization in 1810, burning and grazing have led to the replacement of this vegetation by a short, heavily grazed grassy sward largely dominated by introduced species, of which the chief are *Cynodon dactylon* Pers, *Holcus lanarus* L., *Agrostis* spp. and *Plantago lanceolata* L. Vegetation of this type adjoins the new volcanic cone. Immediately to the west and north, *Cynodon* is the only dominant of the grassland, while to the east for about 300 yards there is an area of blown sand sparsely colonized by this species. The Main Cliff immediately behind the volcano has a patchy covering of *Phylica* (formerly cut by the islanders for fuel) with *Empetrum rubrum, Blechnum penna-marina* (Poir) Kuhn, and *Polystichum adiantiforme* (Forst.) J. Sur. conspicuous in the field layer.

Effects of the eruption. Only the lowermost vegetation zones, artificial grassland, *Phylica* scrub and *Blechnum palmiforme* vegetation have been affected by the eruption. The lava itself has covered about 20 acres which were once grassland, and ash has been deposited between the cinder cone and the Main Cliffs. Apart from this direct covering of the ground, the eruption has affected the vegetation in three ways: (1) Numerous minor landslides have cleared strips of vegetation and soil from the Main Cliffs near the volcano. (2) Pyroclasts have set fire to small areas of *Phylica* bush on the cliffs immediately behind the cinder cone. (3) Sulphurous gases, produced in large quantities during the early stages of the eruption, have done considerable temporary damage to the vegetation over a wide area, especially behind and to the east of the volcano. This damage extends about 6 miles eastward around the cliffs, but only 2 miles westward. This asymmetry is due to the prevalence of westerly winds.

The damage is made evident by the browning and withering of the foliage and is accompanied by the cessation of growth. Besides the dominants, *Phylica* and *Blechnum palmiforme*, *Acaena sarmentosa* Carm., *Blechnum penna marina*, *Elaphoglossum succisifolium* Moore, *Empetrum rubrum*, *Scirpus thouarsianus* Schult. and the cultivated New Zealand flax *Phormium tenax* are obviously affected. The damage declines with distance from the eruption, and it was noted that on the Base only *Phylica* and *Blechnum palmiforme* are seriously affected.

Very few, if any, of the *Blechnum palmiforme* plants have actually been killed. New unharmed fronds are now growing on almost every plant examined. On the other hand, it is difficult to assess the full nature of the damage done to the *Phylica* trees. Although a great number are completely brown and have every appearance of being dead, the trees may still survive, as this species has the ability to grow shoots from the widely spread roots.

Recolonization. Even in the most affected areas of the Main Cliffs, where the majority of the trees may be dead, recolonization is likely to be rapid. *Phylica* seedlings have already been discovered growing through 1 cm. of ash on the lower slopes behind the cinder cone. Shoots of *Cynodon* have already pushed up through as much as 15 cm of ash and are spreading over the surface and over volcanic rubble. Moreover, the first plant colonization of the new lava flow has occurred. Where a stream cascades over the former sea cliffs to the west of the new flow and splashes on to the fresh lava, filamentous green algae are growing.

Permanent quadrats have been set up close to the periphery of the volcano in order that the development of vegetation on and around the fresh lava may be recorded.

Zoology

The effects of the volcanic activity on the fauna of Tristan fall into two classes: the direct effect in the form of physical damage and the indirect effects resulting from the evacuation, with consequent decontrol of pests and domestic animals and cessation of fowling. No signs of the last can be expected to appear in so short an interval of time.

(1) *Direct effects*. Some 650,000 sq. yards of mostly invertebrate habitat have been covered by the volcano and its flows. Observations of a comparable site of eruption at the southern end of the island suggest that soil and vegetation will not be re-established for two to three hundred years, during which period the fauna of the area will probably remain impoverished. A further small area has been covered by falls of rock and ash deposits; sulphurous fumes have damaged the vegetation over a wider area. Beyond a few hundred yards from the volcanic centre, soil invertebrates remain fairly numerous: phytophagous species have probably suffered more severely. Plant recolonization is proceeding rapidly and these peripheral effects are likely to be short-lived. Birds and mammals are affected by the eruption to a surprisingly small degree.

(2) *Indirect effects*. (i) *Decontrol of pests*. Principal invertebrate pests during habitation were the noctuid *Peridroma margaritosa*, the aphid *Myzus persicae*, and the calliphorid *Lucilia sericata*. None of these was a serious pest, and none was restricted to the settlement area, but control measures were in force against them all. Of the three, only *L. sericata* appears to have increased, and this may be temporary resulting from the abundance of refuse and carrion which followed the evacuation. In the absence of the potato crop, *M. persicae* is particularly numerous on *Rumex obtusifolius*, and *P. margaritosa* is widespread and numerous on a variety of food-plants. The flea *Pulex irritans* has survived the three months absence of man. Among vertebrates, the only serious pest is the black rat *Rattus rattus*. In the absence of man it has not increased in the settlement area, where it was formerly most abundant, though whether this is due to predation by cats or loss of food supply is not certain. There is no reason for supposing any change in status on other parts of the island.

(ii) *Domestic animals*. There are wild cattle at Stony beach and Cave point, and domestic cattle at Sandy point (non-breeding) and in the settlement area, only the last having been affected. Out of more than a thousand acres, the volcano has deprived them of only 20–30 acres; but their breeding success was severely cut by the dogs. All the cattle are in good condition and should over-winter well in absence of competition from sheep. The sheep have been drastically reduced from more than 700 to less than 50; many appear to have been chased over cliffs by the dogs. Numbers of donkeys are about the same as before, though no young animals have been added; again, probably due to dogs. Fifteen dogs were found, concentrated in the settlement area. The effect of evacuation on these had been to allow them free access to almost all parts of the island and undisturbed predation on other animals. Some damage was done to moulting penguins *Eudyptes cristatus* and to albatrosses *Diomedea chlororhynchos* (and possibly *Phoebetria fusca*); feather and bone fragments were found in the dog-fæces. About twenty cats have survived in the settlement; twelve were found dead around the houses and more may have migrated to swell the number of feral animals on the Base. The hens were found to have suffered little setback, but there was no trace of more than fifty geese which had been left on the island.

(3) *Control measures taken*. On the basis of obvious and deduced damage to wild and domestic animals, it was decided to destroy the dogs. Fifteen were found and killed. A possible sixteenth, an adult male, may have survived on the Base. All bulls and bull-calves in the settlement were killed or castrated, which, even allowing for some *in utero*, will provide a temporary check to any increase in number of the cattle, while the future of the island is undecided.

The results given in this report are based solely on field observations as specimens collected have not yet been subjected to laboratory examination. The scientific members of the Expedition are responsible for the sections of this report covering their own fields of study and will publish detailed accounts elsewhere in due course.

Undoubtedly, the success of the Expedition was largely due to the invaluable assistance it received from many quarters, especially from the South African Navy and the Royal Navy, to whom members of the Expedition extend their sincere thanks.

INTAKE OF IODINE-131 FROM MILK IN ITALY DURING THE PERIOD OCTOBER–DECEMBER 1961

By DR. A. CIGNA and DR. C. POLVANI
Comitato Nazionale per l'Energia Nucleare, Roma

DURING the last months of 1961, following the renewal of the nuclear tests, some determinations of the concentration of iodine-131 were carried out on cow's milk distributed to the population of various cities, representing one-fifth of the entire Italian population (Fig. 1). Measurements were not numerous and systematic in the first weeks of October (therefore those results are scarcely representative); but later many more were carried out following a well-defined programme. Daily samples were taken in six cities; weekly samples in seven (Fig. 1).

Fig. 2 gives the pattern of the atmospheric precipitation and of the monthly radioactive fall-out. It must be emphasized that the amount of atmospheric precipitation is usually high in Italy during autumn; for the 90 days under examination the rainfall amounted to 400 mm., out of 872 mm. recorded throughout 1961.

In Italy at the end of the three months under consideration the milk cattle are fed a high percentage of dry fodder as compared with other months, when fresh grass prevails. This change of diet occurs earlier in northern Italy (November) and later in southern Italy (December); however, at least in some areas of northern Italy, the administration of a certain amount of fresh grass is maintained even in December.

The course of rain and fall-out and the change in the diet influenced the concentration of iodine-131 in the milk. The results of the measurements carried out, averaged at intervals of three consecutive days, are given in Table 1 and Fig. 3. (The correction for radioactive decay of iodine-131 was effected with reference to the second of the three consecutive days.) A peak can be observed at about half-way through November : this follows, after a few days, the rainy period which occurred everywhere in Italy between the third and the fifteenth day in November. It must be realized that the figures reported are the arithmetical averages of the determinations on samples collected in various cities; on single samples, in the same period, values of 300 and more pc./l. of iodine-131 were observed.

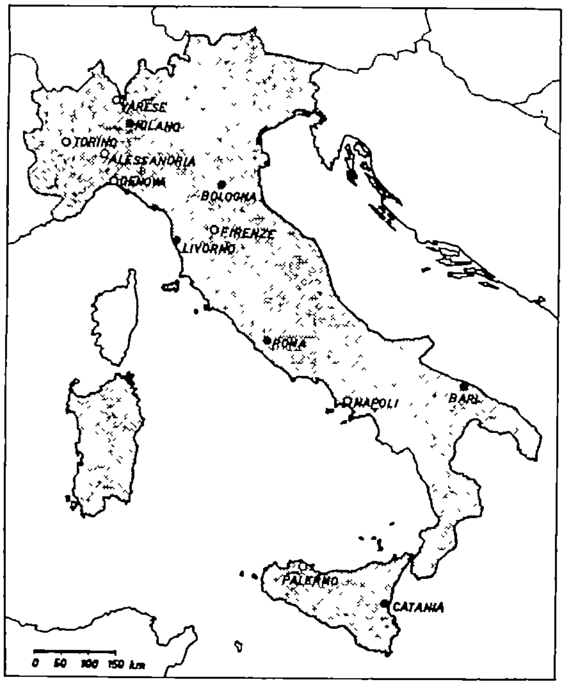

Fig. 1. Map of Italian cities and towns, where the samples of milk were collected. ●, Daily samples, ○, weekly samples

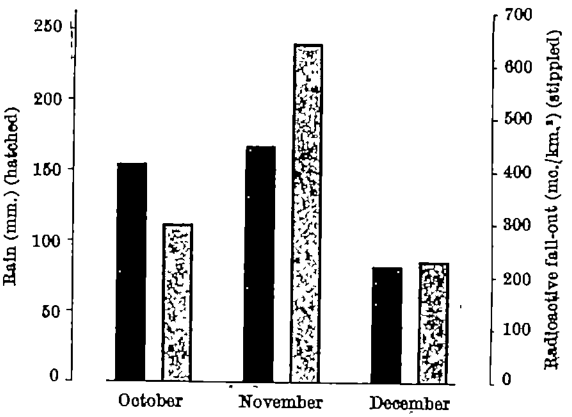

Fig. 2. Monthly atmospheric rainfall (ref. 3) and radioactive fall-out (ref. 4). The data of radioactive fall-out were corrected for self-absorption and radioactive decay (with reference to the fifteenth day of the collection month); the correction factors are roughly approximate

Table 1. CONCENTRATION OF IODINE-131 IN THE MILK DISTRIBUTED DURING THE PERIOD OCTOBER–DECEMBER 1961

Days	^{131}I (pc./l.)	Days	^{131}I (pc./l.)	Days	^{131}I (pc./l.)
Oct. 1–3	(153)	Oct. 31–Nov. 2	80	Nov. 30–Dec. 2	99
4–6	(148)	Nov. 3–5	79	Dec. 3–5	80
7–9	(139)	6–8	84	6–8	71
10–12	(138)	9–11	90	9–11	63
13–15	(119)	12–14	108	12–14	53
16–18	103	15–17	125	15–17	42
19–21	97	18–20	155	18–20	37
22–24	91	21–23	158	21–23	41

28–30	84	27–29	117	27–29	(28)
				30–31	(28)

The values in the first half of October are in brackets on account of their lesser significance (see text).

The values of the last days of December (also in brackets) must be taken as representing a maximum concentration.

Gamma spectrometers with sodium iodide (thallium) crystals (5 cm. diam., 5 cm. in height) were used for measuring the iodine-131 content of the milk samples (1 litre each). The resolution of the photoelectric peak of iodine-131 (at 0·360 keV.) was about 11 per cent, and the gamma efficiency for the same photopeak 4 per cent. The lowest concentration of iodine-131 which could be measured in such conditions was 10 ± 2 pc./l., when the time of measurement ranged from 3 to 4 hr. The channel shift was not higher than 20 keV. a week.

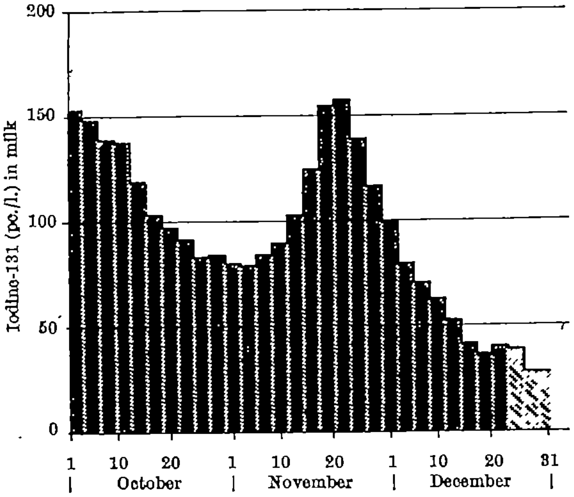

Fig. 3. Concentration of iodine-131 in milk distributed in the period October–December 1961. The values corresponding to the first half of October are shown with a dashed line owing to their lesser significance. The histograms concerning the last days of December are dashed and must be regarded as representing a maximum concentration

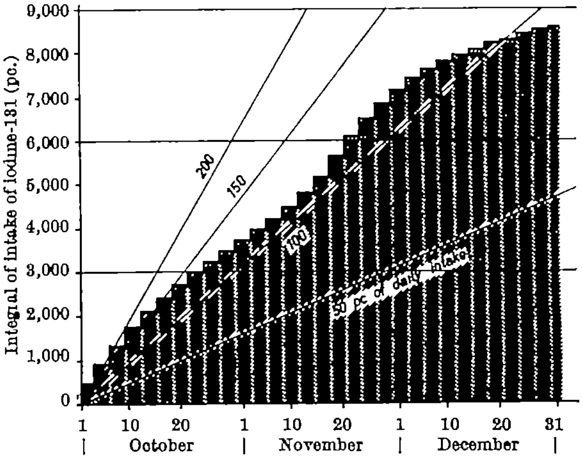

Fig. 4. Graph of the integral, during the months of October, November, December 1961, of the intake of iodine-131 (persons fed with 1 litre of milk a day)

If we consider the babies fed with about 1 litre of cow's milk a day (this figure is the maximum), it is possible to draw the integral, during the months under consideration, of the amount of iodine-131 ingested. A diagram of the integral is given in Fig. 4. It can be seen that the value of the integral of the intake actually occurred in the babies fed with the sampled milk lies for a long period between the straight lines representing the integrals of the assumed intakes of 100 and 150 pc. a day. At the end of the considered period the mean intake amounted to 8,600 pc. of iodine-131.

Even taking into consideration the poor significance of the measurements of the first weeks of October and the limiting factors involved in the sampling, these figures may represent the mean intake of iodine-131 in Italy during the last months of 1961, for the persons fed with 1 litre of milk per day. Considering the dispersion of the observed values in the different cities, it is most likely that in some areas the intake over the quarter exceeded the value of 10,000 pc. of iodine-131.

The C.N.E.N. (Comitato Nazionale per l'Energia Nucleare) authorities organized the measurements over the country; the measurements were carried out by the C.N.E.N. Laboratory for Environmental Radioactivity; those measurements for Livorno were carried out by Centro Applicazioni Militari Energia Nucleare, while those for Bologna were made at the Institute of Physics, University of Bologna.

NEWS and VIEWS

Nuclear Fuel Director at Atomic Energy Authority, Risley: Dr. N. L. Franklin

Dr. N. L. Franklin has been appointed nuclear fuel director in the U.K. Atomic Energy Authority Production Group at Risley. Dr. Franklin, who was formerly technical director, will be responsible for the Group's commercial activities and for technical aspects of the Group's work on civil magnox fuel elements. Dr. Franklin was born in Leeds and was educated at Batley Grammar School and the University of Leeds. In 1945 he joined the staff of the British Coke Research Association as a technical officer. From 1948 until 1955 he was assistant lecturer and later lecturer in chemical engineering at the University of Leeds. In 1955 Dr. Franklin joined the Technical Policy Branch of the U.K. Atomic Energy Authority and in 1958 was appointed assistant director of technical planning. In 1959 he was made technical manager, Chapelcross, and in 1960 appointed deputy technical director of the Production Group at Risley. In 1961 Dr. Franklin was appointed technical director, Production Group.

Responsibility for the Production Group's technical and development work on chemical processes, isotopic separation, reactors and fuel other than magnox, and for planning and programming, will remain with the Group's Technical Directorate. Mr. C. Allday, the deputy director (technical), will be responsible for this work.

Industrial Sociology at Northampton College of Advanced Technology: Mr. R. G. Stansfield

Mr. R. G. Stansfield has been appointed reader in industrial sociology in the Department of Management and Social Science, Northampton College of Advanced Technology, London. Mr. Stansfield took the Natural Sciences Tripos at Cambridge in 1936, obtaining first-class honours in Part I and second-class in Part II physics. He worked in the Cavendish Laboratory during 1936–39 and gained a B.Sc. (London) in special physics with first-class honours in 1936 as an external student. During 1939–45 he carried out operational research with the Royal Air Force. During 1945–48 he was a senior scientific officer with the Ministry of Works and was technical officer to the Human Efficiency Panel; then for a year he was with the Board of Trade on a special research unit. In 1950 he became a principal scientific officer and worked with H.M. Treasury for a year as assistant to the chairman of the Panel on Human Factors. In 1951 Mr. Stansfield transferred to the Department of Scientific and Industrial Research, and until 1959 was leader of a team concerned with human sciences in industry. In 1959 he was made head of the Human Sciences Section of the Warren Spring Laboratory at Stevenage.

Clinical Nutrition at Beirut : Prof. D. S. McLaren

DR. D. S. MCLAREN has been appointed research professor of clinical nutrition and director of the nutrition programme in the American University of Beirut, Lebanon. This new appointment and the development of research and research training activities in the Schools of Medicine, Public Health and Agriculture at this University in collaboration with the Institute of Nutrition Sciences at Columbia University, New York, have been made possible by a grant of a million dollars over a period of five years from the U.S. National Institutes of Health. Dr. McLaren graduated in medicine at the University of Edinburgh in 1947 and after five years in India gained the M.D. of that University in 1955. Since then he has specialized in nutritional diseases of the eye, was awarded the Ph.D. of the University of London in 1957 and has published more than thirty papers in this and other related fields. He is Oliver Hawthorne, Ciba Foundation and Barraquer Institute prize-winner, and has acted as World Health Organization consultant in Indonesia and Central America. Previously he was for four years on the staff of the East African Institute for Medical Research in Tanganyika.

Industrial Research and Development in the United States

INDUSTRIAL firms in the United States, according to a survey recently published by the National Science Foundation, devote by far the largest share of their research and development funds to development. Only 4 per cent of the total is spent on basic research and 20 per cent on applied research, whereas 76 per cent goes on development. This heavy concentration on applications of science to production techniques reflects the heavy costs required to translate basic and applied research findings into practical means of producing new products and processes. Development frequently involves large numbers of scientific, technical and other supporting personnel as well as expensive materials and equipment in the construction and testing of models or prototypes. Increased expenditure on research and development has been undertaken by firms not merely as a means of holding their competitive positions in domestic and foreign markets but as a means of promoting long-range economic growth by developing new and improved products or introducing more efficient techniques of production. Some firms, especially smaller undertakings, find it financially advantageous to contract their research and development projects to outside organizations such as commercial laboratories, educational institutions and non-profit research institutions. The survey estimates that some 11,800 industrial firms undertook research and development work in the United States and that funds for these purposes amounted to 9·6 thousand million dollars, of which 41 per cent came from industry's own resources and the remaining 59 per cent from the Federal Government. In addition, a further 3,000 million dollars was spent on research and development by the Federal Government, colleges and universities and other non-profit-making organizations (*Surveys of Science Resources Series*, NSF 62-3. *Funds for Research and Development in Industry* 1959—*Performance and Financing*. Pp. xi+109. Washington, D.C.: Government Printing Office, 1962. 60 cents).

Science in Parliament :
Engineering and Nuclear Power

IN answering a series of questions in the House of Commons on May 28, the Parliamentary Secretary for Science, Mr. Denzil Freeth, said that the Council for Scientific and Industrial Research has delegated to the National Engineering Laboratory the power to place research and development contracts of up to £2,500. Larger contracts in the Laboratory's field are placed by the Department's headquarters and technically supervised by the Laboratory. Regarding the Dounreay Experimental Fast Breeder Reactor, completed during 1959, he said the final capital cost of the reactor and of its associated fuel element fabricating and re-processing plants was £12·5 million. The present delay in raising the power in the reactor to about 30 MW. had been caused by the difficulty of reducing the oxide impurity in the coolant to the desired 4 p.p.m. Mr. Freeth also said that owing to increasing requirements for funds for nuclear physics and in particular for the CERN programme, it has been necessary to review the prospective needs of nuclear physics research as a whole before reaching a decision on the recommendation, in July 1961, of the National Institute for Research in Nuclear Science for provision in Great Britain of a 4-GeV. electron synchrotron to supplement the work of *Nimrod* now under construction.

Coal and Petroleum

AT present, no research is in progress in Government laboratories into the microbiology of coal or petroleum, but the Department of Scientific and Industrial Research will consider on its merits any application for a grant for such research.

Meat Research

ON meat research Mr. Freeth said that in carrying out its plans for the establishment of the Meat Research Institute, the Agricultural Research Council is giving first priority to finding a director-designate of meat research so that he can take as full a part as possible in the detailed planning. A decision whether and where sub-stations should be set up is unlikely to be taken until after his appointment. The Council considers that the organization of meat research in this wider sense will call for a considerable degree of correlation in the programmes of agricultural research institutes: the basic studies of dead meat, which will mostly be done at Bristol, must be related to what is being done elsewhere on breeding nutrition and management. Consequently, the Council's plans for meat research in general must involve Scottish stations, such as the Animal Breeding Research Organization at Edinburgh and the Rowett Research Institute. The Advisory Committee on Meat Research will be appointed by the Agricultural Research Council, and it is intended that its membership will include meat producers, processors and scientists.

Training and Research Grants

On April 1, 2,648 training awards of the Department were currently held, of which a small number are being held overseas; of those held in Great Britain, 10·1 per cent were held in Scotland. Of 724 grants for special researches awarded in the year ended September 30, 1961, 81 were in response to applications from Scotland.

Scientific Manpower

Concerning manpower, Mr. Freeth reported that the third triennial survey of scientific manpower is in progress, and in the course of this the Committee on Scientific Manpower will be able to take into account any changes in the estimated output of the universities since its last review. The Department of Technical Co-operation obtains advice on scientific matters from a wide range of experts, including scientists from the Department of Scientific and Industrial Research and the Nature Conservancy. An important way in which this advice is provided is by making the staff of these organizations available for membership of advisory committees of the Department of Technical Co-operation.

Promoting Civil Science

Mr. Freeth said that a Committee had been set up under the chairmanship of Mr. B. St. J. Trend to review the organization for the promotion of civil science by Government agencies. The other members of the Committee are: Sir Keith Murray, Sir Thomas Padmore, Lord Todd, Mr. F. F. Turnbull, Prof. C. H. Waddington and Dr. E. G. Woodroofe, with Miss K. Whalley as secretary. The terms of reference are to consider: (1) whether any changes are desirable in the existing functions of the various agencies, for which the Minister for Science is responsible, concerned with the formulation of civil scientific research, and whether any new agencies would be created for these purposes; (2) what arrangements should be made for determining, with appropriate scientific advice, the relative importance in the national interest of the claims on the Exchequer for the promotion of civil scientific research in the various fields concerned; and (3) whether any changes are needed in the existing procedure whereby the agencies concerned are financed and required to account for their expenditure.

Industry and Space Research

In a written answer on May 28, Mr. Freeth stated that British industry will continue to benefit from work carried out under contracts for the development and construction of experimental equipment for use in scientific space research and also for the development and construction of satellite launchers. The technological benefits to be derived from this work will strengthen the competitive power of British industry, particularly in electronics and the technology of new materials. It was proposed to hold an inter-governmental conference in the middle of June, at which the European Space Research Organization Convention and its associated protocols would be open for signature.

D.S.I.R. Developments

Both branch offices of the Department of Scientific and Industrial Research in Edinburgh and Cardiff have been strengthened recently, and six regional technical information centres are now operating, in Newcastle, Liverpool, Manchester, Birmingham, Bristol and Portsmouth. A seventh is being established in Leeds.

The Esso Review

The Esso Review for 1961 is a model of how a big company can present information about its activities for the benefit of its employees scattered in many countries. The growth of the oil industry is well described in pictorial form and shows how world crude oil production reached a total of 1,120 million tons, some 70 million tons more than in 1960. This 6·5 per cent increase was only slightly less than the average growth-rate of the past ten years, the outlook being for continued growth. The Middle East produced as much oil in 1961 as was produced in the whole world in 1939. In Europe, the increase in oil consumption was particularly marked, although the rate of growth in the United Kingdom was less than the European average. The *Review* shows that United Kingdom energy demand was about the same in 1961 as in 1960 because of the small rise in economic activity and above-average temperatures, but that demand for oil in the United Kingdom rose by about 7 per cent and oil contributed 27 per cent of the total energy needs. There are also many illustrations of Esso's activities inside Great Britain, including the construction of the pipeline from Fawley to Severnside.

Canadian National Parks

The Geological Survey of Canada has issued two attractive brochures describing various geological features of two Canadian national parks (*Miscellaneous Report No. 2*: *Rocks and Scenery of Fundy National Park*. Pp. iii+32. Ottawa: Queen's Printer, 1962. 50 cents. *Miscellaneous Report No. 3*: *Prince Edward Island National Park—The Living Sands*. Pp. 56. Ottawa: Queen's Printer, 1961. 50 cents). They have been written by David M. Baird, who, in the first, explains the part played by the rocks of Fundy National Park in determining its scenery. In the second brochure he shows how the waves of the Gulf of St. Lawrence have evened out the irregular lines of the north shore of Prince Edward Island to form long sandy beaches and bars across the headlands and the mouths of bays; the latter have been set aside as the Prince Edward National Park. Both brochures are illustrated and add to the value of well-written publications which should give pleasure to many visitors to the parks.

Birds Around Winchester

A short account of the birds of the Winchester district has been prepared from the records of the Winchester College Natural History Society during the past ten years (*Birds of the Winchester District*. Pp. 39 (5 maps). Winchester: Winchester College Natural History Society, 1962. 5*s*.). The gaps in observations resulting from school holidays, particularly those relating to the early migrants, have been largely filled from the records of the Hampshire Field Club and Archæological Society. The publication is not intended to be a guide to bird identification. Rather it is an attempt to bring together. within a small compass, information about birds to be found at different times of the year within a ten-mile radius of Winchester. The various maps included with the text are sufficiently detailed for the identification of most of the bird habitats described. The School's Natural History Society is to be commended for a publication which should be well received by all bird lovers.

Sound—Its Uses and Control

Noise Control, the bi-monthly publication of the Acoustical Society of America devoted to the discussion of the problems of noise and methods of combating noise, has now been discontinued and replaced, as from the beginning of 1962, by a new bi-monthly magazine entitled *Sound—Its Uses and Control* (American Institute of Physics, 335 East 45th Street, New York 17. 5 dollars for Acoustical Society members and 8 dollars for non-members). The editor is Dean R. Bruce Lindsay and the managing editor H. A. Erf, of the H. A. Erf Acoustical Co. Associate editors include members of Bolt Beranek and Newman, Inc., the National Bureau of Standards, K. W. Johnson and Co., Inc., and the Baldwin Piano Co. In his editorial to the first number (1, No. 1; January–February, 1962) Dean Lindsay states that the new magazine is intended "to provide an appreciation and understanding of the importance of sound in all its aspects in the life of man among the widest possible audience, and practical information on the uses and control of sound unencumbered by the heavy mathematical analysis of the conventional research paper".

Biennial Oscillations of the Equatorial Stratosphere

The apparent 26-month oscillation of the wind field at 50 mbars and above over equatorial latitudes continues to mystify meteorologists (*Nature*, 189, 791; 1961). J. K. Angell and J. Korshover, of the U.S. Weather Bureau, have confirmed the results of Ebdon and Veryard, of the Meteorological Office, concerning the existence of this unusual period of 26 months between maximum westerly and easterly winds. The oscillation decreases in amplitude at levels below 50 mbars, becoming almost undetectable at 100 mbars. The oscillation appears to be in phase at all longitudes, but there is a phase variation with height, with the maximum westerly wind taking about 4 months to work down from 25 to 50 mbars and another 6 months to go from 50 to 100 mbars. There is evidence that the maximum westerly wind occurs about 6 months earlier at 30° N. and moves towards the equator. Angell and Korshover suggest that the biennial oscillation may be first noted at between 40° and 50° N., from whence it propagates northward and southward. A great deal more wind data must be analysed before a rational explanation of this unusual phenomenon will be forthcoming.

Psittacosis in Japan

The recent discovery of psittacosis in various avian species in Japan led to an extensive survey on human infections with the virus, utilizing the complement fixation and hæmagglutination inhibition tests. In the survey, a number of psittacosis cases was found and evidence was obtained showing widespread dissemination of the virus in the general population in the areas investigated. A paper by Toshio Goto *et al.*, of the Sagamihara National Hospital, Sagamihara, Kanagawa Prefecture and the Institute for Infectious Diseases, the University of Tokyo, describes clinical observations in forty-two serologically diagnosed human cases (*Jap. J. Exp. Med.*, 31, No. 4; 1961). The cases were diagnosed in a survey of acute respiratory infections carried out at the Sagahimara National Hospital near Tokyo during 1956–58. Of the forty-two cases, thirty-three showed a clinical picture of primary atypical pneumonia, and seven that of acute bronchitis. The remaining two cases showed middle-lobe syndrome of Graham *et al.* Analysis of the clinical findings in each case supported the serological diagnosis and most of the cases were mild with no complications. In one of the pneumonitis cases a transient transparent area was observed in a pulmonary infiltrative shadow, and in another case acute transient middle-lobe disease was revealed by X-ray photography. Spontaneous recovery took place in most mild cases. In severe cases, penicillin, chloramphenicol and tetracycline were administered with favourable effects and no fatality occurred.

Batshioko (Tshokwe) Negro Decorative Art

This recent monograph by Dr. Marie-Louise Bastin, of the Centre National d'Ethnologie des Peuples d'Outre-Mer at Tervuren, is likely to remain for some time the authoritative work on Batshioko (Tshokwe) decorative art, and all those interested in African Negro sculpture will be grateful to the Diamond Company of Angola for its publication in such a sumptuous manner. It forms No. 55 in the Dundo Museum's series of scientific and cultural monographs and consists of two large volumes (Companhia de Diamantes de Angola (DIAMANG) Servicos Culturais. Dundo–Lunda—Angola, Museu do Dundo. Publicacoes Culturais No. 55: Subsidios para a Historia, Arqueologia e Etnografia dos Povos da Lunda. *Art Decoratif Tshokwe*. Vol. 1: Pp. 267. Vol. 2: Pp. 273–394+277 planches. Lisboa: Companhia de Diamantes de Angola, 1961). The first gives a brief historical and ethnographical account of the Tshokwe and a more detailed analysis of their decorative art, supported by 125 plates, 2 maps, 3 tables and numerous sketches and drawings. The second contains 275 pages of excellent photographs by M. A. Oliviera of representative examples of Tshokwe art from the collection in the Dundo Museum. They are preceded by 120 pages of detailed notes on each of the objects photographed, which range from baskets and pots through weapons, musical instruments and chairs, stools, and other domestic utensils to masks and statuettes. The carvings illustrated in plates 153–275 are particularly impressive and apart from some of the masks have never been previously published.

Feldberg Foundation Prizes

Prof. K. J. Ullrich, director of the Physiological Institute of the Free University of Berlin, and Prof. D. Whitteridge, professor of physiology in the University of Edinburgh, have been awarded the Feldberg Foundation Prizes for German–English scientific exchange for experimental medical research (set up by Prof. W. Feldberg, of the National Institute for Medical Research, Mill Hill, London). A prize is awarded each year to one German and one British scientist, and in recognition of this gift the German recipient gives a lecture in Britain, and the British recipient a lecture in Germany. Prof. Whitteridge gave his lecture at the Free University of Berlin on May 28 on "The Visual Pathway". The details concerning Prof. Ullrich's lecture will be announced at a later date.

The Textile Institute: Elections

Dr. J. G. Martindale (Scottish Woollen Technical College) has been elected a vice-president of the Textile Institute by Council. Dr. Martindale fills the vacancy caused by election to the presidency of Prof. J. B. Speakman (see *Nature*, 194, 435; 1962). Dr. A. R. Urquhart (the Cotton, Silk and Man-Made Fibres Research Association) has been re-elected as chairman of Council for the forthcoming year. Vice-chairman elected is Mr. A. W. Bayes (Ashton Bros. and Co., Ltd.), in place of Mr. J. A. Nasmith (Leesona Holt, Ltd.), who has been elected honorary treasurer in place of Mr. A. F. W. Coulson. Mr. J. C. H. Hurd (head of the Department of Textiles, Leicester College of Technology) has been re-elected honorary secretary. Lord Barnby, immediate past-president of the Textile Institute, has been elected to be an honorary life member.

Index Medicus and the U.S. National Library of Medicine

THE note on *Index Medicus*, appearing in the March 31 issue of *Nature*, p. 1236, unfortunately fails to give credit to the National Library of Medicine, U.S. Department of Health, Education and Welfare, Public Health Service, Washington, D.C., which publishes *Index Medicus* each month. Not only does the National Library of Medicine publish the *Index Medicus* but also it renders valuable service to references in medical literature.

The Night Sky in July

NEW moon occurs on July 1d. 23h. 53m. U.T., full moon on July 17d. 11h. 41m. and new moon on July 31d. 12h. 24m. The following conjunctions with the Moon take place: July 5d. 07h., Venus 0·6° N.; July 18d. 13h., Saturn 0·7° S.; July 20d. 18h., Jupiter 2° N.; July 27d. 00h., Aldebaran 0·9° S.; July 27d. 04h., Mars 4° N. In addition to these conjunctions with the Moon, Venus is in conjunction with Regulus on July 12d. 00h., Venus being 1·1° N., and Mars with Aldebaran on July 23d. 13h., Mars being 5° N. There is a penumbral eclipse of the Moon on July 17 and an annular eclipse of the Sun on July 31, both invisible at Greenwich. Mercury is a morning star, but is not favourably placed for observation. Venus is an evening star, visible in the west after sunset. It sets at 22h. 20m., 21h. 55m. and 21h. 15m. on July 1, 15 and 31, respectively; its stellar magnitude is −3·6. Its distance decreases during the month from 109 to 88 million miles and the visible portion of the apparent disk decreases from 0·757 to 0·642. Mars rises at 1h. 30m., 0h. 40m. and 0h. 10m. at the beginning, middle and end of the month, respectively. It is at a distance of 177 million miles from the Earth on July 15, and its stellar magnitude is +1·4. Jupiter rises at 23h. 00m., 22h. 00m. and 21h. 00m. on July 1, 15 and 31, respectively. It is in Aquarius, its stellar magnitude is −2·3 and its distance from the Earth in the middle of the month is 400 million miles. Saturn is in Capricornus, rising at 21h. 50m., 20h. 55m. and 19h. 50m. at the beginning, middle and end of the month, respectively. Its stellar magnitude is +0·4 and its distance from the Earth on July 15 is 835 million miles. Occultations of stars brighter than magnitude 6 are as follows, observations being made at Greenwich: July 15d. 21h. 35·5m., μ Sgr. (*D*); July 21d. 00h. 30·4m., ψ^1 Aqr. (*D*); July 21d. 01h. 35·2m., ψ^1 Aqr. (*R*); July 21d. 02h. 22·0m., ψ^2 Aqr. (*R*). *D* and *R* refer to disappearance and reappearance, respectively. The Delta Aquarid meteors are active at the end of the month, the maximum being on July 29; the radiant is at R.A. 22h. 36m., Dec. −17°, and conditions are favourable. The Earth is at aphelion on July 4, its distance from the Sun being 94·6 million miles.

Royal Society Appointments

MR. R. W. J. KEAY has been appointed deputy executive secretary to the Royal Society of London. Mr. Keay is at present director of the Federal Department of Forest Research in Nigeria.

Dr. J. N. Murrell, Department of Chemistry, University of Sheffield, has been awarded a Mr. and Mrs. John Jaffé Donation Research Fellowship to enable him to continue his work on theoretical chemistry at the University of Sheffield.

Announcements

MR. P. H. EVANS, of Consolidated Beryllium, Ltd., has been appointed the fifth Robert Horne Memorial Lecturer of the Society of Chemical Industry. His lecture, entitled "Production Problems associated with the Element Beryllium", will be delivered in Swansea on January 18, 1963.

THE following officers of the Nutrition Society have been elected: ***President***, Dr. D. P. Cuthbertson; ***Hon. Secretary***, Miss D. F. Hollingsworth; ***Hon Treasurer***, Dr. A. E. Bender; ***Ordinary Members of Council***, Mr. A. E. Boyne, Dr. G. N. Jenkins, Miss J. W. Marr, Mr. D. S. Miller and Dr. J. A. B. Smith.

A MEETING of the Biochemical Society will be held in the Department of Biochemistry, University of Cambridge, during July 12–13. The programme will include a colloquium on "Control of Protein Biosynthesis—the Role of Nucleic Acid". Further information can be obtained from Dr. H. R. V. Arnstein, National Institute for Medical Research, The Ridgeway, Mill Hill, London, N.W.7.

A CONFERENCE on "Preparation of Case Studies for Education and Training in Administration and Management", arranged by the Welsh College of Advanced Technology in collaboration with the Comparative Administration Trust, will be held at the College during July 5–7. Further information can be obtained from Z. M. T. Tarkowski, Comparative Administration Trust, 30 St. George's Street, London, S.W.1.

THE fourteenth conference of the British Occupational Hygiene Society on "Control of Airborne Particles and Fumes" will be held in King's College, Newcastle upon Tyne, during September 19–20. Topics under discussion will include: the work of an occupational health service in environmental control; some observations on asbestosis; control of the vanadium hazard in two industries; an experimental Diesel-exhaust filter; some problems in the large-scale handling of beryllium; dust and fume control—the implementation of current legislation. Further information can be obtained from Dr. J. Steel, Department of Industrial Health, Medical School, King's College, Newcastle upon Tyne.

ERRATUM. Due to an oversight in proof, Dr. J. B. Birks and L. G. Christophorou state that the following changes should be made to their article "Excimer Fluorescence of Aromatic Hydrocarbons in Solution" which appeared on p. 442 of the May 5 issue of *Nature*: Table 1. 3 : 4-Benzpyrene, $D_1 = 514$ mμ, $\nu'(M_1 - D_1) = 5{,}350$ cm.$^{-1}$ (values for specimen of higher purity); Table 2. Anthranthrene, $D_1 = 594$ mμ.

INJURY, INFLAMMATION AND IMMUNITY

THE first section of an international symposium on "Injury, Inflammation and Immunity" was held on May 5, at the Miles-Ames Research Laboratories, Stoke Poges, under the chairmanship of Sir Howard Florey.

This section covered the anatomical, physiological and pharmacological aspects of inflammation.

The symposium was opened by Prof. H. Ruska (Dusseldorf) with a paper on the structure of capillaries and response to chemical injuries, discussing the electron microscopical study of capillaries. He said that capillaries from different tissues varied greatly in respect of the presence or absence of a basement membrane, vesiculation or pores. The presence or absence of these structures appears to be correlated with the permeability of the vessels.

The effect of various chemical agents on capillary permeability was correlated with the changes in capillary wall as assessed by the electron microscope.

Dr. R. Robineaux (Paris) showed a film of the microscopical appearance under phase contrast of cells in spleen explants using the 'Cellophane'-strip tissue culture technique, between the eleventh and twenty-first day of culture. Up to the sixteenth day of culture lymphocytes and plasma cells were seen in close cellular relation to macrophages and reticular cells. Plasma cells were seen in mitosis. After 21 days the culture was transformed into macrophages which absorbed the other cells. Explants were from guinea pig spleen and plasma cells developed under the antigenic influence of chick embryo extract in the culture fluid.

Prof. G. Asboe-Hansen (Copenhagen) discussed the connective tissue response to injury, especially emphasizing mast cell degranulation and the accumulation of chondroitin sulphate and other mucopolysaccharides in ground substance as a result of tissue injury. The increase in chondroitin sulphate was demonstrated by the uptake of sulphate labelled with sulphur-35 in the ground substance.

The effect of various hormones (for example, thyroid-stimulating hormone and corticoids) on the repair mechanism were discussed with reference to their effect on mast cells and the accumulation of acid mucopolysaccharides in the ground-substance.

Dr. W. G. Spector (London), in a paper on endogenous inflammatory mechanisms in the rat, described experiments on the pharmacological content of the turpentine-induced pleural effusion in the rat. He described two phases: an early phase associated with the presence of histamine and serotonin lasting 1 hr. was succeeded by a delayed phase associated with pharmacological agents resembling *SRS–A* and bradykinin. The early phase was retarded by antihistamine drugs without affecting the development of the later phase.

The role of peptides in the first stages of inflammation was the subject of the next paper, by Dr. G. P. Lewis (London), which discussed some of the protein-breakdown products responsible for the effects of inflammation. Among these he laid particular emphasis on bradykinin, a nonapeptide produced by the action of certain enzymes on plasma globulin. Bradykinin was capable of producing all four of the cardinal signs of the inflammatory response—vasodilation, increased capillary permeability, pain and the accumulation of leucocytes. He also discussed the enzymes capable of breaking down globulin to the active peptide and enzymes, kininases, which were in their turn capable of breaking down and controlling the concentration of these plasma kinins. Histamine was shown to play a part in activating plasma-kinin-forming activity and also enhanced the passage of these peptides into the tissues by increasing capillary permeability.

Prof. C. de Duve (Louvain) discussed lysosomes and cell injury. Lysosomes are small cytoplasmic sack-like structures surrounded by a lipoprotein membrane containing a number of enzymes. These enzymes, including cathepsin β-glucuronidase and acid phosphatase, are those which take part in all autolysis but are inactive so long as the lipoprotein membrane remains intact. They could be shown to be released under a number of pathological conditions, that is, in the liver after ligation of a lobe, or in the comatose animal, in the thymus after treatment with cortisone or in the spleen after X-irradiation. They also accumulated in states of physiological autolysis, for example, the regression of Mullerian ducts in the male chick embryo and in the regression of the tadpole tail. He postulated four possible mechanisms of the action of lysosomal enzymes in tissues: (1) the intracellular release of enzyme attacking the cell; (2) diffusion of these enzymes out of the cell, attacking other cells; (3) selective retention of phagocytes rich in lysosomes; (4) colonization of the tissue with phagocytes rich in lysosomes.

The final two papers were on the inflammatory and biochemical aspects of burns. The first was on inflammatory changes in burned skin by Dr. S. Sevitt (Birmingham), who discussed three types of increased capillary permeability, an immediate transient type which was due to release of histamine and was abolished by antihistamine drugs, an early form which was more severe leading to stasis and a delayed form occurring around and deep to the early response. He found that the critical temperature at which capillaries leaked protein was 41°–44° C. and this correlated with the critical temperature for formation of bradykinin. The critical temperature for capillary stasis was 47°–48° C.

The last paper was by Dr. J. Kohn (London) on biochemical and immunological aspects of human burns, discussing the electrophoresis of enzymes in blister fluid, the increased concentration of histamine and a bradykinin-like substance in the urine of patients with burns. Following the reports of the beneficial effect of convalescent serum in cases of severe burns attempts were made to demonstrate precipitating antibodies in the serum of patients with burns against antigens derived from the burned tissues, but these had met with very little success. However, he had found an unusually high level of precipitating antibody against staphylococcal antigens in the serum of patients with severe burns.

The second section of the symposium was at the Instituto Miles de Terapeutica Experimental in Mexico City during May 10–11, and the final section at the Miles Laboratories, Inc., Elkhart, Indiana, during May 15–16.

J. L. TURK

SHELTER RESEARCH IN AGRICULTURE AND HORTICULTURE

MANY agricultural improvers of the eighteenth and early nineteenth centuries attached considerable importance to providing sheltering woodlands for exposed farmland, while horticultural enterprises in mild but windy coastal areas of the United Kingdom have long appreciated the need for shelter. The actual benefits of shelter have, however, remained difficult to evaluate.

On the reconstruction of the Agricultural Improvement Council in 1952, the problems of shelter were raised and in 1955 its Land Management Committee decided that more information was needed about the nature of shelter itself and its effects on stock and crops. The Shelter Research Planning Group was formed to assess these problems and indicate the order of priority with which these might be investigated. It was clear at the outset that many aspects requiring investigation encroached on different spheres of scientific activity and cut across existing fields of scholarship and study: biology, meteorology, aerodynamics and even engineering.

During 1952–53 the Forestry Commission financed research at the University of Edinburgh into the influences of shelter-belts on microclimate, with the ultimate object of designing appropriate types of windbreak for different purposes in agriculture, horticulture and forestry. In the spring of 1953 pilot investigations of horticultural shelter were begun at selected experimental horticultural stations in conjunction with the Agricultural Branch of the Meteorological Office. Afterwards, on the Agricultural Improvement Council's recommendation, the Ministry of Agriculture sponsored projects concerned with livestock shelter at the University College of Wales, Aberystwyth, University College of North Wales, Bangor, and King's College, Newcastle.

A good deal of research, directly and indirectly relevant to the question of shelter, continued to be pursued in separate but allied fields, and in 1959 the Shelter Research Planning Group appointed Dr. J. M. Caborn, University of Edinburgh, to keep in touch with this work and act as a focal point to which information might be sent or inquiries addressed.

It was also realized that, in a comparatively new field of study, much time and effort were inevitably duplicated, particularly during the 'teething troubles' of devising experimental techniques and equipment. Any concerted or co-ordinated attack on the basic problems could only come from closer communications between research workers in the various fields involved. Accordingly, a symposium on shelter research was organized recently at Aberystwyth by the Shelter Research Planning Group.

After the opening by Mr. R. G. A. Lofthouse, chairman of the Group, the first session was devoted to "The Shelter Needs of Horticulture, Methods of Providing Shelter and Plant Response". Mr. F. W. Shepherd, deputy director, East Midland Region, National Agricultural Advisory Service, and former director, Rosewarne Experimental Horticulture Station, examined the case for shelter based on long experience of the horticultural areas of south-west England and presented results of trials of tree and shrub species for shelter hedges. Mr. W. H. Hogg, senior meteorological officer, attached to the N.A.A.S., Bristol, outlined the experiments with horticultural shelters which have continued at Rosewarne and other centres, reviewing Continental experience in this field and concluding with a description of wind survey techniques derived to assess the need for further shelter, other than that contributed by topography.

Shelter for livestock occupied a major part of the programme, and the discussion was opened by Dr. K. L. Blaxter of the Hannah Dairy Research Institute, Ayr, with a paper on "The Reactions of Cattle and Sheep to the Stress of Cold Environments". This dealt with precision studies of physiological and nutritional responses of animals exposed to controlled conditions in calorimeters and preliminary extension of these techniques to outdoor conditions. He concluded that, while quantitative expression can now be given to the effects of still-air environments on the metabolism of sheep and cattle, similar information is urgently needed for the effects of wind and rain. It was also emphasized that the separation of the direct stresses of climatic environment from the indirect ones, for example, lack of food, while instructive in laboratory studies, does not occur under field conditions. Prof. J. E. Nichols, University College of Wales, discussed the more pragmatic approach to the problem, for example, continued observation of individual and flock response to adverse weather conditions under normal systems of management.

A third session heard a paper by Dr. R. W. Gloyne of the Meteorological Office on "Meteorological Techniques in Shelter Research", especially in relation to livestock in hill areas. This included details of instrumentation available for measuring weather phenomena, illustrated by an account of methods applied for investigating long-term influences of introducing a series of shelter plantations on an exposed hill at Bangor. Mr. R. Lines of the Forestry Commission followed with an account of certain shelter experiments on tree growth, and described the technique of assessing comparative exposure by means of observing the rate of tattering of unhemmed linen flags. Finally, Dr. J. M. Caborn spoke on "Assessing the Efficiency of Shelter", dealing with methods of measuring the shelter performance of shelter-belts and windbreaks and discussing the value of shelter on the farm. Although there seemed little prospect of being able to forecast shelter effect on arable crop production from the basis of particular levels of wind, a plea was made for preliminary investigations into the effect of existing shelterbelts on the yield of field crops under Britain's climatic conditions.

Closing the proceedings, the chairman referred to the considerable exchange of information, ideas and experiences made possible by this meeting, in both formal and informal discussion. It was generally felt that the whole subject had gained momentum and that various sections of activity, though independent, promised to dovetail in the future and present a more composite picture of this very diffuse question of shelter.

J. M. CABORN

THE WORLD HEALTH ORGANIZATION

THE communicable diseases are still, for most countries of the world, the greatest obstacle to the achievement of higher standards of health. Developments in the struggle against these diseases, and in many other aspects of the work that is directly assisted or co-ordinated by the World Health Organization are discussed in the annual report of its Director-General for 1961*.

Perhaps the best known of the Organization's activities is the world-wide malaria eradication campaign. During 1961 the campaign grew in scope and complexity. By the end of the year operations ranging from preliminary pilot schemes to the surveillance of vast areas already cleared of infection were proceeding in 85 countries and territories. The Organization's assistance took many forms: it included, for example, special courses for the training of staff, the production of manuals on various specialized techniques of value in the campaign, advisory services to Governments and evaluation of the efficiency of their programmes, and trials on the dosage and frequency of application of insecticides. Research was continued on new insecticides to replace those to which mosquitoes have become resistant and on other problems such as that of resistance to anti-malarial drugs. Through meetings of technical experts and contacts with research centres receiving grants, the Organization continued to stimulate, guide and co-ordinate such research.

In the report on other communicable diseases many advances are described and some setbacks noted. Many countries participated in the world-wide campaign to eliminate smallpox. In Asia, where the highly endemic areas still exist, intensified control measures, pilot projects and mass vaccination campaigns were carried out. Progress was reported from certain countries of Africa and from the few in Latin America where endemic foci are still to be found. In the work on tuberculosis, pilot projects were started in order to find the best application, under different epidemiological and socio-economic conditions, of recent advances in the control of the disease. The continued increase in venereal diseases gave concern, as did outbreaks of cholera, yellow fever and sleeping sickness in countries where they had not apparently been present for some time. Good progress was made in the control of yaws, endemic syphilis, leprosy and trachoma. Poliomyelitis, which is still increasing in countries where mass vaccination has not yet been applied, also received much attention, as did a wide range of other virus diseases.

In its work on environmental sanitation the World Health Organization has been paying particular attention to the improvement of community water supplies. Assistance to Governments has included guidance on the financing, management and organization of water and sanitation schemes, as well as in their design and operation. Other topics dealt with in the same chapter include work on air pollution, as well as the varied activities on insect and vector control, the development of new insecticides research into insect resistance, and studies of the toxicity of pesticides to man.

The accounts of recent developments in many fields of activity provide numerous examples of the benefits derived from medical research. The Organization's assistance to research during the past year has covered a wide range of subjects, including comparative studies of leukæmias and effect of smoking, air pollution and occupation on lung cancer, controlled field trials of anti-leprosy drugs, testing of insecticides, a five-year co-ordinated programme on onchocerciasis in West Africa and Latin America, research into the ætiology of iron deficiency anæmia, and comprehensive field trials of new methods for controlling bilharziasis—a disease of growing importance in newly irrigated areas. These are co-operative activities, co-ordinated by the Organization, and in which institutes and, in some cases, industrial concerns in many different parts of the world take part.

Lack of qualified medical and auxiliary staff is still a major obstacle to progress in health in many parts of the world, and it is clear from the report that education and training is, directly or indirectly, an integral part of nearly all the work of the World Health Organization. Details are given of training courses organized in many parts of the world on almost all aspects of health work, of the provision of professors and teaching staff to medical, nursing and other training schools and of the 1,731 fellowships awarded by the Organization during the period covered. Although the policy is to award fellowships for short periods of study, the special conditions of countries with no medical schools, and where the shortage of doctors is particularly acute, have made it necessary to grant some fellowships for undergraduate medical studies.

Much of the Organization's work is carried out in co-operation with other international agencies working in allied fields, and the report contains references to joint programmes being undertaken with one or several other organizations. Thus, for example, it is working with the Food and Agriculture Organization on nutrition and milk hygiene and on the zoonoses; with the International Labour Organization in occupational health and on the health of seafarers; with the International Atomic Energy Agency on the disposal of radioactive waste and on other aspects of radiation protection; with Unesco on cell biology, training programes for newly independent States, and health education in schools. Work with the United Nations itself covers a wide range—from such traditional activities as the control of addiction-producing drugs, to work in the Congo (Leopoldville) and co-operation in programmes for economic and social development, including the Expanded Programme of Technical Assistance, programmes financed from the United Nations Special Fund and from the United Nations Children's Fund. The report also contains many instances of work with regional inter-governmental agencies and with non-governmental organizations concerned with health.

APPARATUS FOR TEACHING SCIENCE IN SCHOOLS

IN the second part of his articles on "Science Education Today"[*], J. L. Lewis of Malvern College examines what has been done by the Esso Loan Service of Scientific Apparatus to Preparatory Schools. This has been applied only in the limited field of preparatory schools in Britain, but the influence it has had suggests that the methods could be applied more widely with remarkable effect.

In the past only a small number of preparatory schools taught any science: boys from most schools went on to their public schools at the age of 13 and began science there. For various reasons it was felt that science should be introduced into preparatory schools. The problems appeared insuperable: there were no laboratories, no apparatus, no scientists to teach. The Esso Scheme was tried as an experiment in about thirty schools. An existing series of science books was chosen; the schools were supplied with quantities of these, together with units of apparatus to enable every experiment described in the text to be performed by the teacher. In addition, it was assumed that many of the schools would not get the services of a qualified scientist to teach science, so that experienced teachers were invited to write a teacher's guide, specially to help the non-scientist in the presentation of the subject.

Such was the initial enthusiasm that it was soon developed and supplied, without any cost at all, to more than 150 schools. It has since been offered to every Associated Preparatory School in Britain. The result has been remarkable. From September next. more than 400 schools, which formerly were teaching no science at all, will be teaching it. Units on *Weather and the Earth*, *Hearing and Seeing*, *Energy and Engines*, *Electric Currents*, *Freshwater Life*, *Earth and Universe*, *Heating and Cooling*, *Air and Water* will be going to all parts of Britain to remain in a school for a term, enabling a course to be run until another unit arrives to take its place.

Another service has been rendered by Esso's Senior Loan Service of Scientific Apparatus to Schools This, too, has grown from small beginnings to something much valued in the educational world Under this, the Company has made available certain items of apparatus, usually of the more expensive type, which is often beyond the means of many schools, such as pH meters, double-beam oscilloscopes, ratemeters, signal generators, optical pyrometers and viscometers. These are loaned to a school free of charge for one term. The scheme has enabled pupil and teacher alike to become familiar with less-usual apparatus; it has enabled more sophisticated experiments to be carried out, and even small research projects.

A most important development of the Loan Service is now planned, a development likely to be of the greatest value, as its influence will ultimately be of benefit to all schools. Another helpful service is the proposed film on the teaching of modern physics which the Esso Film Unit is planning.

HEART DISEASE IN THE BANTU

THE annual report of the South African Institute for Medical Research[*] is noteworthy, besides a number of other interesting features, for a series of investigations bearing on coronary heart disease in the Bantu.

Studies by Dr. F. W. Fox on two rural Bantu groups, namely, Pedi Bantu (Sekhukhuniland region) and Tswana Bantu (south-west Bechuanaland) indicate that, in view of the extremely low incidence of myocardial infarction found among both rural and urban Bantu, it would seem that intensive nutritional and other investigations should be concentrated on that fraction of urban Bantu living closest in diet and manner of life to South African Whites; and that fraction of very poor Whites whose environment factors conform in measure to those of the Bantu.

The present belief that diets very high in animal fat are necessarily promotive of atherosclerosis and mortality from ischæmic heart disease may not be valid irrespective of the dietary setting, and it is suggested that investigations of indigenous nomadic groups in north-east Africa, who subsist largely on milk from camels, goats and sheep, may be rewarding from the point of view not only of their very high intake of animal fat but also of animal protein and calcium.

Electrocardiograph studies have been carried out on groups of rural Pedi and Baralong Bantu; among 1,100 subjects only four gave evidence of infarction. all of whom were more than 75 years of age. Of Urban Bantu, among 385 Johannesburg pensioners (virtually all more than 60 years), one positive was found, aged 63 years. Apart from the foregoing study, there is little doubt that the results of electrocardiograph observations on Bantu populations at risk are in complete harmony with the conclusion reached from several large series of necropsies on Bantu undertaken at different centres in the Union, that is, the occurrence of, and mortality from, acute episodes of coronary heart disease among these people is virtually nil. The critical population next to be considered is the most sophisticated group of Bantu available. If the latter conforms to the reaction of Yeminite immigrants in Israel, and Japanese immigrants in California, then an increasing incidence of myocardial infarction would be expected.

Reports from Durban suggest that local Indians are as prone as local Whites to die from coronary heart disease and, incidentally, diabetes. Mortality from this disease, however, appears to be much lower among Indians in India. The situation regarding Durban Indians is unexpected; electrocardiograph, blood pressure, dietary and other investigations are being carried out by Indian research assistants on Indian population groups in Johannesburg and Pretoria.

---

[*] The South African Institute for Medical Research. Annual Report for the year 1960. Pp. 191. (Johannesburg: The South African Institute for Medical Research, 1961.)

Death certificates suggest that South African Whites are probably as prone as overseas White populations to die from coronary heart disease. To give perspective to the electrocardiograph investigations on the Bantu, and to learn something of the incidence of myocardial ischæmia in representative local White populations with the co-operation of the authorities, electrocardiograph and other investigations have been carried out on 248 White persons. Assessment of tracings is still in progress. Permission from the relevant authorities has been obtained to carry out an investigation of 'total heart disease' in a group of workers—a study which will require intensive short-term co-operation from several physicians and other workers.

Other investigations have also shown the commonness of hypertension in the Bantu, a feature associated with a high incidence and mortality from cerebral vascular disease, but with virtually no mortality from coronary heart disease. In endeavours to throw light on hypertension in these people, a number of investigations have been carried out. Blood pressure and other investigations have been undertaken at schools previously visited for nutritional and biochemical studies in the Rustenburg, Hartebeestpoort and Witkoppen regions. It is apparent that blood pressure at one particular school is significantly lower than that of the others. Investigations on blood pressure have also been carried out on groups of mineworkers from different regions. Some differences are apparent; for example, hypertension occurs less among Xhosa compared with Shangaan and Tswana Bantu.

Some Bantu groups are habituated to very soft water; others add plant ashes of variable composition to their food. There is one Bantu group, however, habituated to an unusually high intake of salt, the sole source of water (wells) having a salinity of about a quarter that of sea-water. This group, at Kukong, Southern Kalahari Desert, is being studied from the point of view of blood pressure, electrocardiograph, blood biochemistry and other aspects. Observations will be compared with those on another group dwelling nearby, but habituated to soft drinking-water. This possibly unique natural situation should shed light on the influence of an unusually high intake of salt on hypertension in the Bantu.

EURYHALINE EUGLENOID FLAGELLATES

A RECENTLY published pamphlet* is Part 8 of a series which, when completed, will be the first attempt to give a comprehensive account of the unicellular, mostly motile, algae occurring in British coastal and estuarine waters. It is the second part to appear, Part 1, containing the general introduction to the series, definitions, bibliography and the taxonomic section on Chlorophyceae having been published in 1959. Part 8 consists of the taxonomic section on euryhaline Euglenineae. Since the series will deal with organisms of great importance for fishery and sea-food investigations, and since a taxonomic account of these organisms is not otherwise available, it is to be regretted that the pamphlet under review contains so many inaccuracies that its use cannot be recommended.

In the short description of the class Euglenineae with which the pamphlet begins there are omissions, misconceptions and several factual errors. For example, "Flagellum one or two" is incorrect for the Euglenineae, modern cytological studies having established the taxonomically important fact that all euglenoid flagellates have two flagella. Apart from the genera with two externally emergent flagella (for example, *Distigma, Eutreptia, Peranema*), most genera (for example, *Astasia, Colacium, Euglena, Lepocinclis, Phacus, Trachelomonas*) have one long flagellum which is emergent from the canal and functional in swimming, and a second flagellum which ends within the reservoir. This short flagellum is an independent organelle though its tip may be apposed to the longer flagellum, an arrangement which led to the old, erroneous description of a single flagellum bifurcate at the base. Other points needing correction are that emergent flagella with unilateral mastigonemes have been demonstrated for more genera than those quoted, notably *Phacus* and *Trachelomonas*; colonial euglenoids are known, for example, *Colacium mucronatum*, which forms extensive dendroid colonies; members of the Euglenaceae and Astasiaceae are described as having "simple bilateral symmetry" whereas one of the major taxonomic features of the euglenoid cell is its helical asymmetry; organisms in the Peranemaceae are said to have "complex dorsiventral organization" without the rider that such organization is found in species of most genera and is superimposed on the underlying helical asymmetry; the statement that "*Euglena gracilis* becomes colourless if grown in the dark" is misleading in its context, since permanent apochlorosis equivalent to the condition in *Astasia* is produced only if treatment with high temperature, ultra-violet irradiation, antihistamines or streptomycin is also applied; finally, *Distigma* cannot be said to be "the colourless counterpart of *Eutreptia*" in the way that species of *Astasia* might be for species of *Euglena*, or *Hyalophacus* is for *Phacus*.

Mistakes in the opening section are repeated in the key to the genera of the Euglenaceae (the only family dealt with in the pamphlet) and in the descriptions of genera and species. For example, the erroneous concept of species with only one flagellum appears several times and is carried to greater lengths for *Euglena obtusa* and *E. vermiformis*. *E. obtusa* is described as having "complete absence of a flagellum" when in fact it has two perfectly good flagella. It is true that in this species both flagella terminate within the reservoir at about the level of the eyespot. Dr. Butcher mentions a flagellar "vestige inside the canal" without apparently realizing its significance. As a practical point of distinction in the specific key it would be correct to say for *E. obtusa* "neither flagellum emergent" or, possibly, "no locomotory flagellum".

---

* Ministry of Agriculture, Fisheries and Food. Fishery Investigations, Series IV: An Introductory Account of the Smaller Algae of British Coastal Waters. Part VIII *Euglenophyceae = Euglenineae*. By Dr. R. W. Butcher. Pp. v+17+8 plates. (London H.M. Stationery Office, 1961.) 12*s*. 6*d*. net.

The main text of the pamphlet contains new inaccuracies and misconceptions of which only the most obvious can be noted here.

It is undesirable to re-introduce Schiller's genera *Ottonia* and *Chlorachne* into the Euglenaceae when most authorities now exclude them entirely from the Euglenineae, especially since the descriptions of these organisms are merely repeated from Schiller's original records from the Adriatic.

Secondly, there is confusion in the section on *Eutreptia* where Dr. Butcher describes a new species, *Eutreptia scotica*, from material which I collected at Millport and gave him as a fresh isolation of *Eutreptia viridis*. Re-examination of my cultures of the Millport isolation shows this species to be cytologically identical with Prof. E. G. Pringsheim's isolation of *E. viridis* in the Cambridge Culture Collection, even to the extent of having the same chromosome count of 44. On the other hand, cells of *E. pertyi* supplied from Prof. Pringsheim's Sammlung von Algenkulturen, Göttingen, are considerably larger and cytologically more luxuriant than cells of *E. viridis* and the chromosome number, 90 ± 2, is approximately twice that of the smaller species. Yet Dr. Butcher finds his material of *E. pertyi* almost indistinguishable from the Cambridge *E. viridis*. From all this it seems probable that Dr. Butcher's "*E. pertyi*" is really *E. viridis*, as is also his "*E. scotica*", presumably described from Millport material in poor condition. The new species, *E. scotica*, cannot therefore be accepted.

Thirdly, an important error occurs in the section on *Lepocinclis*, where the reserve material is listed as "leucosin". Since the generic key states for *Lepocinclis* "2 ring-like paramylum grains always present" (itself not a true statement for all species of *Lepocinclis*), the introduction of the reserve material characteristic of the Chrysophyceae is presumably a slip of the pen, though it does occur five times.

Fourthly, descriptions of pyrenoids, particularly important in the classification of species of *Euglena* and *Trachelomonas*, are incorrect. The description of the double-sheathed pyrenoids typical of the Catilliferae group of the genus *Euglena* is inadequate, and there is nothing in Dr. Butcher's description to indicate that this pyrenoid structure occurs also in *Trachelomonas hispida*. The pyrenoids of *T. volvocina* are described as simple when they have, in fact, the taxonomically important structure referred to by Prof. Pringsheim as "inner pyrenoids", and *T. zorensis* is stated to have "pyrenoid absent" whereas it has good double-sheathed pyrenoids. The *Trachelomonas* species listed could certainly not be identified from the key and descriptions given.

Finally, the term "plastidome", strictly meaning the entire chromatophore complex of a cell, is wrongly used for the paramylum centres ("Paramylonherde" of Mainx) in *Eutreptia*, *Euglena viridis* and "*E. schmitzii*" (= *E. geniculata*).

The illustrations consist of a plate of paintings of cells and two plates of poor photographs which show nothing apart from the size and shape of the organisms. Surely what is needed in a taxonomic work provided with keys is a series of large drawings which can be aids to identification. The final photograph, purporting to show mastigonemes on flagella of *Eutreptia pertyi*, is unintelligible.

One appreciates the work involved in producing this taxonomic account of marine and brackish Euglenineae, and its major errors are listed above in the hope that future pamphlets in the series will achieve a higher standard of biological accuracy, especially since they are appearing as official publications of H.M. Stationery Office and will be read with this in mind by marine biologists throughout the world.

GORDON F. LEEDALE

THE ISRAEL SOUTH RED SEA EXPEDITION

By O. H. OREN*

Director, Sea Fisheries Research Station, Haifa, and Deputy Leader of the Expedition

MANY of the waters covering the globe have been extensively explored. One of the less explored and underexploited is the Indian Ocean. This fact and the desire to continue international and co-operative efforts and achievements during the International Geophysical Year led the United Nations to propose an International Indian Ocean Expedition. Many nations accepted the proposal, formed special committees and submitted national programmes for the exploration of this Ocean.

The Red Sea was not specifically included in the original programme. At a meeting of the Special Committee on Oceanic Research held in Copenhagen in summer 1960, the Israel representatives requested the inclusion of the Red Sea, as a part of the Indian Ocean, into the framework of the International Indian Ocean Expedition. This proposal was accepted provided that a National Programme for Red Sea exploration be submitted to the Special Committee on Oceanic Research.

The reason for Israel's request was based on its more than ten years experience in marine biological and fisheries research in the northern Red Sea. Israel has explored its 12-km. coast of the Gulf of Eilat (Gulf of Aqaba). During 1956–57, two parties of marine biologists had the opportunity of exploring the entire western coast of the Gulf of Eilat, Tiran and Sanaphir Islands, and around the Sinai Peninsula to Tor.

During 1957–58 exploratory fishing, leading to commercial fishery in recent years, was conducted from Massawa (Eritrea) in the north and south Massawa Channels and in the vicinity of Kamaran Island by an Israeli fisheries research vessel and scientific personnel. Observations were made and vast material collected, part of which was examined and the results published in a special series entitled "Contributions to the Knowledge of the Red Sea" in the *Bulletin of the Sea Fisheries Research Station, Haifa*.

Considerable interest in the exploration of the Red Sea was also shown by foreign scientists. By the time the Israel South Red Sea Expedition 1962 materialized, the original team of nine Israeli scientists, led by Prof. H. Steinitz, was reinforced by four American, two Dutch and one Ethiopian specialists. The leader of the American team was Dr. E. Clark, and that of the Dutch team, Dr. L. B. Holthuis.

---

* Compiled from notes by the following members of the Expedition: A. Abulafia, A. Ben-Tuvia, E. Clark, L. Fishelsohn, T. F. Goreau, L. B. Holthuis, Ch. Lewinsohn, Y. Nir, O. H. Oren, G. F. Papenfuss, F. D. Por, A. S. Rogers, H. Steinitz, J. H. Stock and S. A. Wainwright.

The members met in Massawa on March 5, 1962, and the Expedition set its camp on Entedebir Island on March 9 to explore this island and its vicinity during five weeks of intensive field work. After a short interval one group of the expeditionary team continued field work in the mangrove swamps of Melita Bay while the other turned inland to make hydrobiological and geological investigations of various freshwater bodies.

The organization of the Expedition was made possible by grants and assistance of the Government of Israel, the Hebrew and Tel Aviv Universities, the U.S. National Science Foundation and the U.S. Office of Naval Research and the Netherlands Organization for Pure Scientific Research.

The Expedition thanks the Imperial Ethiopian Government, and especially the Imperial Ethiopian Navy, its deputy commander, Commander Alexander Desta, for his personal and keen interest in the work of the Expedition; to the naval officer in charge, Captain S. Braathen, who put the naval vessels at the disposition of the Expedition for the preliminary survey of the working area, for carrying the team and equipment to the camping place, for a cruise to Harmil and Romia Islands, for several days of stay in Zula Bay and for the frequent visits of the cutters to the camp site supplying water and provisions to the camp on Entedebir Island.

Physical Features of the Area

Entedebir, an island of an area of 1·5 km.^{2}, is situated 50 km. east of Massawa on the western approach to the island Dahlak Kebir. It is a coral island of irregular shape built mainly of fossil coral reefs having a general east–west trend with steep cliffs on the northern and southern sides. The main rock of these ridges is a rich coralline limestone with a great number of other fossils, most of them in very good condition.

Recent sediments, mainly calcareous white sands, fill the valleys of the island and its five bays. The island was formed probably during the Pleistocene and was uplifted with the entire Dankalic uplift, still taking place. This can be seen all over the archipelago up to Farasan Island off the coast of Yemen.

The submarine investigations included sampling of representative bottom sediments, and sonar sections showing a variety of features to be interpreted at a later stage.

The climate of Entedebir during the stay of the Expedition (March 9–April 9) was more pleasant than that of the nearby coastal town of Massawa, having lower relative humidity, lower air temperature, northern winds starting at noon time, relieving the midday heat, and cool and breezy nights.

The sea surrounding Entedebir and vicinity is already characterized in the early spring by temperatures as high as 29° C. while in the shallow bays they reached more than 37° C. At a depth of 125 m., north-east of Entedebir, the temperature measured was nearly 27° C. The salinities are higher in the enclosed and semi-enclosed basins, delimited by islands, sills and channels, than those in the open Red Sea. A typical enclosed basin is Ghubbet Mus Nefit, enclosed by Dahlak Kebir and Nocra, and connected with the open Red Sea by two shallow channels. The deepest part of this Ghubbet is depleted of oxygen. This is not the case in the semi-enclosed basin north of Entedebir, which is connected with the open sea over a sill 29 fathoms deep on its north-west side. Both these basins were investigated.

Marine Plants

Entedebir proved to be rather poor in algal growth except for encrusting corallines, the brown algae *Pocockiella*, *Padina*, *Dictyota*, *Sargassum*, *Turbinaria* and *Cystoseira*, and the green alga *Valonia*. *Padina* especially forms extensive growth in quiet bays.

Romia, a mangrove island at the north-east extreme of the Dahlak Archipelago west of Harmil, has a typically tropical dense upper sub-littoral and littoral algal flora with the genera *Boergesenia*, *Turbinaria* and *Hydroclathrus* especially abundant.

The usually ubiquitous *Codium* was found only in one restricted locality at Cundabilu, a small island west-north-west of Entedebir. *Galaxaura* was represented sparsely by only one species, and *Liagora* was unexpectedly absent.

Caloglossa, a genus thought to be absent from the Red Sea, was found on the aerial roots of the mangrove trees of Melita Bay.

The area was found to be poor in marine angiosperms, except at Harmil.

About a half of some 200 species of algae known from the Red Sea are at present in the Expedition's herbarium.

Birds

In the area investigated by the Expedition's ornithologist complete records were made of the birds of Entedebir: those having chosen the island as their domicile as well as those visiting and/or passing it. Naturally, those birds living in close relation with the sea were most closely investigated. Observations and collections made on Dahlak Island and on a number of smaller islands of the Dahlak Archipelago supplied important additional material.

Since biological production was very much in the mind of the Expedition, observations regarding feeding and food were carried out regularly: time of feeding and preference for feeding sites were recorded; stomach contents were analysed in order to find out the role of sea birds in the production cycles of this part of the Red Sea. Breeding season, maturity and nesting habits were studied as closely as possible. Salt glands and kidneys of various birds were preserved for microscopic examination at a later stage.

Among the birds observed and collected were pelicans, various gulls and terns, egrets and herons (including the Goliath heron), tropic bird (*Phaethon*), sooty booby (*Sula leucogaster*), stork (*Sphenorhynchus*), spoonbills, crab plover (*Dromas*), and the osprey (*Pandion*).

Internal and external bird parasites were collected for detailed examination later on.

Fish

More than 280 species of fishes, including new species and new records for the Red Sea were collected by 'Rotenone' poisoning, beach seining, trammel net, trolling lines, or obtained from commercial fishermen. Collecting methods were directed towards obtaining larger samples of certain systematic groups for speciation studies. Elasmobranchs, syngnathiform and apodal fishes were collected for biological population studies. In addition, special attention was given to Erythrean species of the genera *Hemiramphus*, *Caranx*, *Siganus*, *Atherina* and *Sphyraena*. The circumtropical *Auxis thazard* will be studied to see whether the Red Sea population is a taxonomic entity by itself.

An attempt to determine the composition of the fish fauna in a specific area covering 2,250 m.^{2} of coral, sand and rock bottom resulted in an estimated population of at least several thousand individuals of more than 100 species.

Species and individual numbers of blennioid and gobioid fishes, scarids, labrids, pomacentrids and apogonid fishes were found to be abundant in the vicinity of Entedebir whereas chætodontids, plectognaths and certain scorpaenid fishes (*Pterois*), and large sharks were poorly represented. The spectacular large forms commonly encountered in the area were *Manta* rays, *Chanos chanos* and *Bolbometopon muricatus*.

Decapods

The decapod and stomatopod crustaceans of the area were closely examined and collected extensively in all accessible habitats, 'Rotenone' poisoning being one of the more important collecting methods. Despite the relatively poor coral fauna a fair number of shrimps, crabs and stomatopods were obtained from corals, care being taken to record species associations. In colonies of coral *Galaxea* two species of shrimps were found which seem to be restricted to this habitat, one characterized by extreme lateral flattening, the other by marked dorso-ventral flattening. Commensal Pontoniinae were found associated with sponges, ascidians, molluscs and starfish. The special faunas of the rocky cover above the waterline, the sand and sandy mud areas were extensively studied by ecologists of the Expedition. Among such algae as *Cystoseira* many interesting Majid crabs were found. Seining in eel grass and algae provided unusual forms; in this way the only Crangonids were obtained.

A most interesting shrimp belonging to the genus *Antecaridina* was found in a land-locked salt-water pool with tidal fluctuations. This genus was previously known only from a similar habitat in Polynesia and near Madagascar.

Colour patterns of decapods and stomatopods were especially noted because it was recognized that natural colours could be used for field determination without resorting to dissections. Many decapods from the Red Sea were described by Forskal in 1775. Forskal's descriptions, apart for the account of the colour, often provided very few morphological details. For this reason some of his species, hitherto unidentified could now with the help of the life colours be determined with certainty.

Copepoda

As very little is known about the meiobenthos of the Red Sea, the extensive collections made by the Expedition are expected to add significantly to the knowledge of the meiobenthic animals. Various biotopes were examined, the algal growth on the corals in shallow water and the muddy bottom of the mangrove swamps were rather poor in species although the fauna of the mangrove mud was composed of *Enhydrosoma* of the Harpacticoida as well as of interesting Amphipoda, Ostracoda and Tanaidacea. The fauna of some level bottoms is, on the contrary, surprisingly rich both quantitatively and qualitatively. This is especially the case in the coralline gravels at depths of 5–16 m., which are also remarkable for the abundance of lancelets. Deep muds from 50 m. downwards, again, are poor. The harpacticoid characterizing the deepest inhabited muds, down to some 100 m., is the genus *Typhlamphiascus* found at similar depths in all the other areas studied. From 100 m. downwards in the deep basins of the Dahlak Archipelago life progressively disappears with oxygen decreasing and hydrogen sulphide content rising.

Very little systematic research of associated copepods was previously carried out in the Red Sea region. At attempt was now made to collect as many hosts as possible. To this end more than 300 potential hosts were thoroughly examined; about 50 per cent of them proved to be infested. Associates were mostly found on invertebrates although several fish parasites were also obtained. A considerable part of the material presumably belongs to new species and/or genera, or will represent new host and distribution records. Especially striking was the abundance of ascidicolous copepods (formerly called Notodelphoida) in the region covered.

Corals

In the area investigated by the Expedition corals occur in patches, not in structural reefs. The coral patches usually have a dominant substrate-forming genus. They occur in water from sub-tidal limit in a broad area surrounding every island visited by the Expedition (depths beyond 7 m. could not be explored). About half the coral species known from the Red Sea have been found: almost all on Entedebir, which is by far the richest site for number of coral species seen. The results proved to be very significant for the geographical distribution of several common Indo-Pacific coral genera.

Cirripedia associated with corals are abundant, and occur in 90 per cent of the coral genera collected.

The fossil coral reefs show every sign of having been very rich indeed.

Physiological Work

Physiological relationship of the calcification process and of the photosynthesis was investigated by calcium-45 and carbon-14 methods in hermatypic scleractinia (9 species of 6 genera), hermatypic algae, (7 species of 6 genera), a hermatypic hydrocoral, a foraminifer, and two species of *Tridacna*. These experiments provided the first opportunity to extend to reef-building organisms of the Indo-Pacific region, physiological observations of a type that hitherto were carried out only on calcareous biota of west Atlantic reefs. Of the species investigated in the Red Sea three species of algae have also been studied in the Caribbean.

The abundance of young *Tridacna* in the immediate neighbourhood of the Expedition's camp at Entedebir provided an unusual opportunity to investigate, by means of isotope labelling technique, the turn-over rate and metabolic pathways of the photosynthetically fixed carbon in this interesting organism.

Similar studies were also carried out on the small scleractinia coral *Fungia*. Both these organisms contain large numbers of zooxanthellæ. It was of interest to compare *Tridacna* and *Fungia* since the former appears to utilize its symbiotic algae as food whereas the latter does not appear to do so.

Intertidal Ecology

Three different intertidal habitats were investigated for littoral biotic associations, two of them situated conveniently for study on Entedebir, but also represented on other islands of the Dahlak Archipelago. The habitat consisting of almost vertical surfaces or rocky shore was very typical, and most widely distributed. Erosion of the intertidal surface of the rocks formed deeply undercut cliffs and mushroom-like formations scattered around the islands. The second habitat was the gradually sloping bottom of sandy bays. These two biotopes showed different communities of algae and animals. Boring cirripeds and molluscs were prominent on vertical rock surfaces, along with small amounts of filamentous algae, and blennies were the principal fishes. Contrary to this, in the shallow sandy bays are found large communities of various decapod crustaceans, digging holothurians and various gobies.

The third intertidal habitat investigated was the monospecific mangrove of Melita Bay (Gulf of Zula). In the area covered by the mangrove two distinct zones were noted; an outer zone of mangrove trees facing the sea, and an inner one facing a swampy lagoon, the two separated from one another by a piled-up sand barrier. This barrier was narrow enough to allow for the tidal oscillations of the lagoon to coincide with those of the open bay. A marked difference of bottom structure was observed on the two fronts, that of the bay front being much more sandy with a certain amount of mud appearing more in the sub-surface layers of the bottom. The bottom of the lagoon front was made up by a deep layer of mud in which decomposing organic substances were predominant. The lagoon front had a population of animals much denser than that of the bay front. Among the various animals, digging crustaceans and polychætes were outstanding. *Periophtalmus* and their nests were also very abundant.

In these investigations measurements were made of exposure times during the tidal cycle; diurnal temperature fluctuations were recorded, bottom samples were taken from various layers, and attention was given to movements of animals during tidal oscillations. Some of these animals, such as large chitons, were marked so that their movements could be analysed.

Limnological Investigations

The limnological party of the Expedition consisted of five members who covered about 2,000 km. on their inland trip. The results of their work have still to be evaluated.

Biological samples were taken at the hot springs of Ailet. about 50 km. west of Massawa.

Collections were made by the group from the artificial lake Balaza, 10 km. north of Asmara, and at the nearby spring of Mai-Mariam. While proceeding to Gondar, the party collected in the Mareb Valley and River Takazze, a rather large tributary of Atbara River (Nile system). At the mountain pass of Walkefit, some 200 km. north of Gondar, springs and small waterfall were investigated.

Of Lake Tana both the northern shore (near Gorgora) and the southern one (near Bahar Dar) were sampled. No proper pelagic plankton could be taken, but both plankton and benthos were collected in the littoral zone. The small River Arno, an eastern affluent of Lake Tana, provided fairly rich samples. Proceeding southward the party investigated several localities on the Blue Nile: (1) near the outflow from Lake Tana; (2) above the small falls; (3) below the latter falls. Lack of time prevented a study of the large falls of the Blue Nile.

Some geological samples were taken in the Lake Tana region, mainly for the examination of pollen and heavy minerals. These samples will be compared with sediments from the Lower Nile Valley, and from the Eastern Mediterranean Sea close to the Nile Delta.

Conclusions

The presence of a number of experts of certain animal and plant groups among the members of the Expedition naturally resulted in more complete information and more extensive collection in their respective fields than in others. This lack of balance has, however, certain advantages. A short-termed expedition of this kind cannot be expected to give a comprehensive, well-balanced and at the same time much-detailed picture of the nature of the area visited. But specialization will certainly pay in that it will enable us, after collections have been worked up, to draw conclusions as to the fish life, to the decapod fauna, to the occurrence on algae, the distribution of corals and whatever additional groups have been particularly investigated. Thus, an important contribution can be made to the knowledge of the region. Faunistic and floristic features will be co-ordinated with hydrographic observations, and also in part with geological results, to render sound background and to strengthen the conclusions reached. Moreover, all this can and, indeed, will be made a stepping-stone towards a scientific comparison of this southern part of the Red Sea with the northern one and particularly with the Gulf of Eilat, which has been made an objective of extensive exploration over several years in the past.

ION WAVES IN A BOUNDED PLASMA

By P. F. LITTLE

Culham Laboratory, Culham, Oxfordshire

EXPERIMENTS have been carried out on the transmission of low-frequency ion waves in the direction of the electron drift along a mercury arc column[1]. Measurements were made with and without an axial magnetic field. The waves were excited by compressing the plasma over a small region with the magnetic field of a short exciter coil wound round the column, or by modulating the ionization-rate locally with the electric field between a pair of grids across the column. The wave-length was observed to

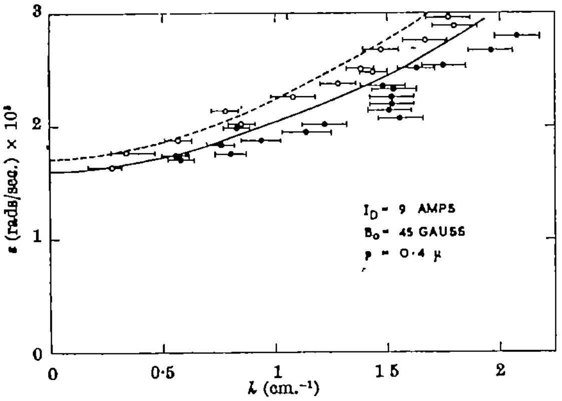

Fig. 1. Observed values of the wave-number $k = 2\pi/\lambda$ for various propagating frequencies ω excited by a short external coil in two different experiments with discharges carrying 9 amp. in a magnetic field of 45 gauss. The theoretical curves are explained in the text

increase strongly as the frequency was reduced, and below a critical frequency no waves appeared. Near this lower limit the phase velocity is greater than the electroacoustic wave velocity in an infinite medium. This is of interest in considering the growth of instabilities when currents flow in a plasma.

The arc was maintained between a mercury pool cathode and a water-cooled anode in a 5-cm. diameter glass tube about 1 m. long. In a fairly narrow range of vapour pressures between 0·1 and 1μ, ion waves could be propagated toward the anode. Under the same discharge and magnetic field conditions there was some weak, irreproducible propagation of cathode-directed waves, critically dependent on the axial position of the exciter coil. The modulation in density was detected by a photomultiplier, the light emission in such a discharge being proportional to the local electron density.

To achieve a tolerable signal-to-noise ratio it was essential to use a phase-sensitive detector[2], which compares the photomultiplier signal v_0 with a reference voltage wave from the c.w. oscillator feeding the exciter. The output from the detector is proportional to $v_0 \cos \varphi$, where φ is the phase difference between the signal and the reference wave-form. A chart recorder displayed the detector output. The photomultiplier assembly was moved steadily along the discharge tube by a synchronous motor, so that the chart record displayed directly changes in amplitude and phase along the column. At the longest wave-length only half a cycle could be traced with certainty, and at the shortest about thirty complete cycles were observed.

Langmuir probe measurements at one point in the tube gave direct confirmation that density modulation was indeed occurring.

Dispersion plots are shown in Fig. 1 for the discharge in a magnetic field, using average wave-lengths measured over about 30 cm. of the column. Two different experiments are shown by the circles and dots. Apparently the discharge conditions were not identical, possibly because in the interval between these measurements (about two months) some contamination had occurred. Below $\omega_0 = 1{\cdot}6 \times 10^5$ rads/sec. no waves propagated, although modulation of the light at the coil still occurred. The theoretical curves are discussed here.

In Fig. 2 the results in zero axial magnetic field are given. The circles represent measurements with a coil exciter, the triangles show results from the grid modulation. The signals were weaker without the axial field and at low frequencies heavily damped, making errors larger there, but both types of excitation give points on a common curve. The approach to a cut-off frequency is not so clear as before. Propagation ceased below 10^5 rads/sec., but the scatter of the points above this frequency is large. It seems possible that with the coil exciter two different modes of propagation can occur, and that these modes have different lower limits for propagation.

From the two-fluid treatment of waves in a plasma[3] such as that examined in these experiments the dispersion relation is:

$$\omega^2 = (k^2 + k_c^2)V_s^2 \tag{1}$$

where

$$V_s^2 = \varkappa T_e/m_i \tag{2}$$

is the electroacoustic velocity predicted by Tonks and Langmuir[4]. For the arc $T_e \sim 3$ eV. and $V_s \sim 10^5$ cm./sec. This treatment holds if $T_i \ll T_e$, $V_s \ll V_a$ the Alfven speed, and if $\omega \gg \Omega_i$, the ion cyclotron frequency. The radial dependence of the density modulation is of the form $J_m(k_c r)$.

For the lowest mode with a pressure node at the plasma boundary[5] R, we have $k_cR = 2{\cdot}40$. Langmuir probe measurements in the discharge conditions of Fig. 1 gave $T_e = 5{\cdot}3 \times 10^4$ ° K., which from equation (2) fixes $V_s = 1{\cdot}5 \times 10^5$ cm./sec. The radius R measured photographically is $2{\cdot}1 \pm 0{\cdot}2$ cm. From equation (1) then the lower bound for:

$$\omega_0 = k_0 V_s$$

is $1{\cdot}7 \times 10^5$ rads/sec., in good agreement with the measurements.

The broken line in Fig. 1 follows from equation (1) with these constants when the drift of the centre of mass of the plasma (6×10^3 cm./sec. approximately, equal to the ion drift velocity) is taken into account. The theoretical dispersion curve would fit better to the experimental points if R were taken as 2·0 cm. and T_e as $4{\cdot}2 \times 10^4$ ° K., 20 per cent lower than the probe temperature. This yields the full line shown.

In Fig. 2, the two lowest modes for $m = 0$ with $k_0R = 2{\cdot}40$ and 5·52 are shown by the broken line, using the tube radius 2·5 cm. as the boundary and $T_e = 2{\cdot}4 \times 10^4$ ° K. from probe characteristics taken in a separate experiment. Again the effect of the plasma's motion has been taken into account. The predicted cut-off frequencies and phase velocities

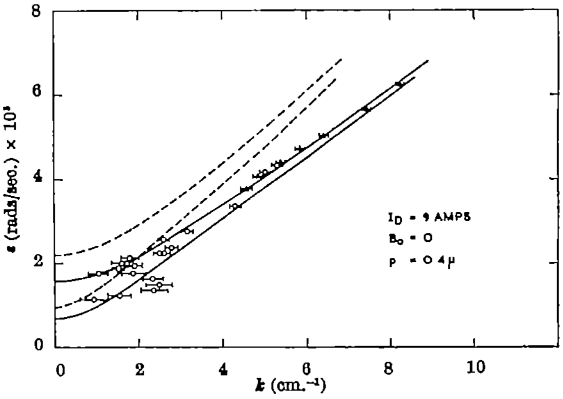

Fig 2. Observed values of the wave-number k for various frequencies ω in discharges carrying 9 amp. in zero magnetic field. The circles show results using a coil exciter; the triangles those obtained with a pair of grids across the column. The theoretical curves are explained in the text

are too high. The electron temperature must be reduced by 40 per cent and the radius R taken as 2·8 cm. to obtain the full-line curves, which give a good fit between experiments and the theoretical dispersion curve for the second mode. The predicted dispersion curve near ω_0 for the lowest mode is in rough agreement with the experimental points, which are subject to large errors in this frequency range because of the strong damping.

The agreement between observed and calculated values of ω_0 and between the electron temperatures measured by the probe and from the dispersion curve when a small axial magnetic field is applied is enough to establish that these are indeed ion waves of higher phase velocities than in an infinite medium. In zero axial field the experimental errors are larger but there is some indication that such waves exist. They may be regarded as the sum of waves moving at an angle to the column and reflected at the boundaries to form a waveguide mode. The existence of this branch of the dispersion relation reduces the maximum electron drift velocity permissible in a plasma where $T_i \sim T_e$ to about ten times the ion thermal velocity if growing waves are not to arise[6].

In my experiments $T_i \ll T_e$ and the electron drift velocity always exceeds the limit for stability so that growing waves would arise in the absence of damping by collisions and by losses to the wall[7]. Since only damped waves propagate with the electrons, the damping must predominate at the frequencies used here. This is consistent with the irreproducible and heavily damped character of cathode-directed waves.

I thank Dr. R. J. Bickerton for much helpful discussion and also Mr. B. E. Avis and Mr. H. G. Jones for their assistance in the experiment.

PARTICIPATION OF DEOXYRIBONUCLEIC ACID IN THE MULTIPLICATION OF INFLUENZA VIRUS

By DR. R. D. BARRY, D. R. IVES and DR. J. G. CRUICKSHANK

Virus Laboratory, Department of Pathology, Cambridge

THIS article is concerned with the effects of actinomycin *D*, an agent which blocks the function of cellular DNA, on the multiplication of two myxoviruses, influenza and Newcastle disease virus.

These viruses are structurally similar, but not identical, RNA viruses[1,2]. Fluorescent antibody investigations indicate that the RNA-containing component, the soluble antigen of influenza or of the closely related fowl plague virus, is produced in the nucleus of infected cells[3–5]. With cells infected with Newcastle disease virus, however, specific fluorescence can only be demonstrated in the cytoplasm; the nucleus does not appear to contain any virus specific antigen[6]. The importance of the nucleus in influenza multiplication suggests that nuclear DNA may play a part in the production of this virus.

The possible participation of cell DNA in the production of some RNA viruses has already been the subject of several papers. Simon[7] has reported that several agents which stop DNA synthesis in cells, namely, aminopterin (4-aminopterolyglutamic acid) and 5-fluorouracil, have no effect on the multiplication of either polio or Newcastle disease virus. Also, aminopterin does not affect the production of fowl plague virus[8]. Consequently, the synthesis of new cell DNA is apparently not required in the production of either Newcastle disease or influenza viruses. Reich *et al.*[9] have shown that the antibiotic actinomycin *D* will prevent the multiplication of the DNA virus, vaccinia, in *L*-cells, but not the multiplication of Mengo, an RNA virus. This substance is known to combine *in vitro* with DNA (ref. 10), and in mammalian cells its effect is to suppress selectively cell RNA synthesis. As it does not apparently interfere with the synthesis of DNA, its mode of action seems to be to prevent the functioning of cell DNA; "to block the expression of the genetic potentialities" of the cell[9]. This agent has been used as a means of blocking cellular DNA function in the work recorded here.

Experiments to test the effect of actinomycin *D* concentration on the yield of influenza or Newcastle disease virus were performed in strips of allantoic cells cut from eleven-day-old de-embryonated eggs[11]. Yields were determined by hæmagglutination 18 hr. after infection of cells with a saturating dose of virus (about 10 ID_{50} per cell). The strains of virus used were the *PR*8 and *MEL* strains of influenza *A*, and the California 11914 strain of Newcastle disease virus. Actinomycin *D* was kindly provided by Prof. E. F. Gale, Department of Biochemistry, Cambridge.

A series of experiments was performed in which a range of concentrations (1–10 μgm./ml.) of actinomycin *D* was added to cells at the same time as virus. Incubation of uninfected allantoic cells in these concentrations of actinomycin results in similar cytological changes to those found with mammalian cells[12]. Preparations of cells stained with acridine orange indicate that there is a loss of nucleoli and an absence of much of the cytoplasmic RNA. In experiments to test the effect of actinomycin concentration, 8–10 replicate strips of cells were used for each concentration. The results of typical experiments are shown in Figs. 1 and 2, for Newcastle disease virus and influenza, respectively. Concentrations as high as 10 μgm./ml. do not affect the production of Newcastle disease virus. With influenza, however, increasing concentrations produce a progressive decrease in yield. Pre-incubation of cell strips in actinomycin for up to 2 hr. before infection does not produce any alteration in the response obtained with either virus. From these results it appears that influenza is a virus which will only multiply in cells in which DNA function is unimpaired.

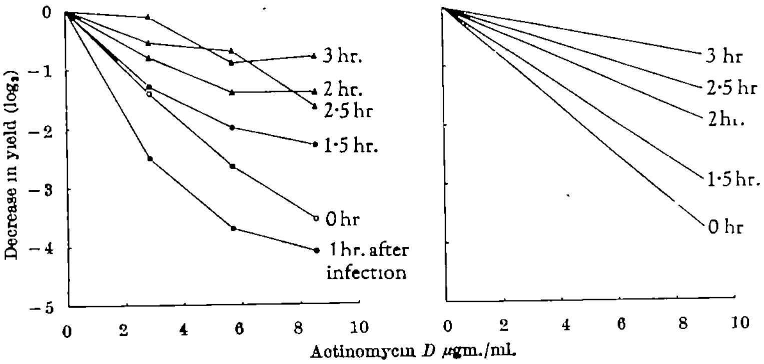

Fig. 3. Effect of time of addition of actinomycin *D* on the yield of influenza, strain *MEL*, from allantoic cells. The left-hand figure indicates the experimental values obtained. The right-hand figure is a diagrammatic representation of the effect of time of addition on virus yield

To investigate the nature of this dependence on DNA, experiments were performed in which actinomycin was added to cells at various times after infection with influenza. The results obtained are shown in Fig. 3. To ensure that virus production was synchronized in all cells, a multiplicity of about 100 ID_{50} per cell was used. Under these conditions, the degree of inhibition produced at 0 hr. was relatively less than found with smaller inputs of virus (Fig. 2). Addition of drug 1 hr. after infection produces rather more inhibition than if given earlier. From this time onwards, however, there is a gradual reduction in the extent of inhibition. This is first noticeable at 1·5 hr. and is virtually complete by 3 hr. The synthesis of virus specific RNA in fowl plague infected chick embryo cells has been shown by Scholtissek and Rott[8] to begin about 1 hr. after infection and to be near maximum at 3 hr. This is the same period of time over which the effects of actinomycin diminish in allantoic cells. Consequently, it appears that in influenza virus infected cells, actinomycin *D* is blocking production of virus specific RNA. This suggests that cell DNA is directly responsible for the production of influenza virus RNA. In the case of Newcastle disease virus, the evidence indicates that virus RNA synthesis is independent of cell DNA function.

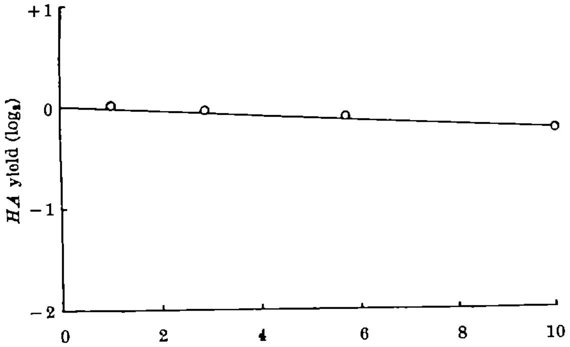

Fig. 1. Effect of increasing actinomycin *D* concentration on the yield of Newcastle disease virus from allantoic cells

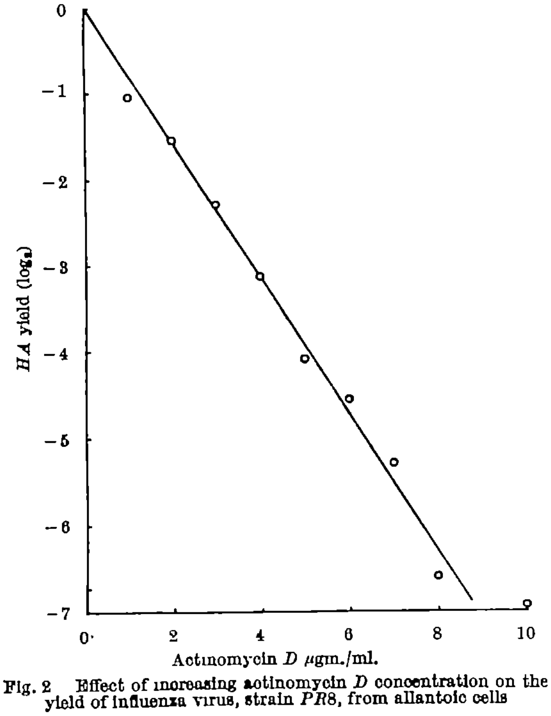

Fig. 2 Effect of increasing actinomycin *D* concentration on the yield of influenza virus, strain *PR*8, from allantoic cells

Concentrations of actinomycin as low as 0·005 μgm./ml. are capable of inhibiting the division of *L* cells, while 0·1 μgm./ml. is sufficient to prevent the production of vaccinia virus in these cells[9]. Compared with these amounts, the concentrations of actinomycin required to block influenza multiplication in allantoic cells are relatively high. On the other hand, the exponential nature of the response curve obtained (Fig. 2) suggests that a particular part only of the total cell DNA is essential in virus production. Taken together, these facts suggest that the effective amount of DNA required for influenza virus production in cells is relatively small. It is known that influenza virus, unlike other RNA viruses, undergoes a number of co-operative phenomena, such as multiplicity reactivation and incomplete virus formation[11,12]. The occurrence of these events suggests that one or a few topographical sites only are responsible for virus production. From the results presented here, it would appear that the site or sites involved are provided by a small part of the DNA of the host cell.

PURIFICATION OF THE MOUSE MAMMARY TUMOUR VIRUS

By Dr. MICHAEL J. LYONS and Prof. DAN H. MOORE

The Rockefeller Institute, New York

IN an earlier communication we discussed the purification of particles believed to represent the milk agent from mouse mammary tumours[1]. Although this procedure yielded pellets that contained areas rich in Bernhard's type *B* particles[2], they were not pure enough to permit chemical analysis nor were the bioassays very impressive. Three different preparations have been inoculated into 73 *C*57 mice. From two of the preparations no tumours have resulted, whereas from the third, where 40 mice were inoculated, only four tumours have developed. These bioassays are in agreement with viral inactivation of other viruses by repeated fluorocarbon extractions. Furthermore, when these fluorocarbon extracted pellets were re-suspended and examined in the electron microscope, either as shadowed or phosphotungstic acid treated dispersions, they revealed a high degree of heterodispersity, and definite identification of *B* particles in them has been difficult. Inasmuch as the negative contrast procedure of Brenner and Horne[3] greatly enhances the amount of detail which can be seen in viral structure, an effort has been made to secure preparations that could be examined by this method. This article describes procedures for obtaining purer and better preserved *B* particles and provides further details on their structure, although bioassay results will not be available for another year.

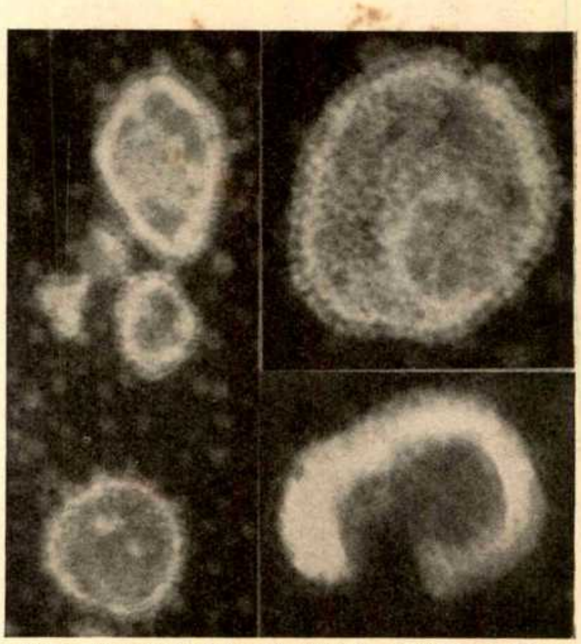

Fig. 1. Dispersions of type *B* particles separated from mouse milk (*R*III strain). The exterior surfaces of the particles are covered with radially extending spines characteristic of myxovirus. Particle at lower right has lost its internal contents by rupture. (Left, × 125,000; upper right, × 250,000; lower right, × 200,000)

Both milk and tumours from the *R*III strain of mice (mammary tumour incidence about 97 per cent) were used. In a typical experiment when milk was used about 4 ml. was centrifuged at 2,000 r.p.m. (1,000*g*) in an International refrigerated centrifuge for 1 hr. The milk, hereafter called skim milk, taken from between the cream and a small pellet was clarified by adding a few drops of 0·15 M ethylenediamine tetraacetic acid (EDTA or versene) which had been adjusted to *p*H 7·2 by the addition of sodium hydroxide. The clarified milk was then spun at 9,000 r.p.m. for 15 min. and the supernatant ultracentrifuged at 39,000 r.p.m. for 1 hr., whereupon the small pellet thus precipitated was re-suspended in a buffer 0·02 M with respect to sodium phosphate and 0·15 M with respect to sodium chloride (buffered saline). The 0·5 ml. of suspension was layered over 4½ ml. of a buffered rubidium chloride solution in the ultracentrifuge tube of a swinging bucket rotor (*SW*39). This solution contained 32 per cent w/v rubidium chloride, 8 per cent magnesium chloride and 0·05 per cent bovine plasma albumin in 0·02 M sodium citrate buffer, *p*H 6·7, and was similar to the solution used by Crawford and Crawford[4] in the isolation of infective Rous sarcoma virus. After centrifugation at 39,000 r.p.m. for 22 hr., the tube was found to contain 4 light-scattering zones. The zone containing the *B* particles lay at the middle of the tube. About 0·5 ml. containing this band was dialysed free of rubidium chloride against a 0·15 M sodium chloride solution containing 0·001 M magnesium chloride.

When tumour was needed a mouse was killed by severing the spine at the neck and the tumorous tissue immediately removed. A typical extraction was as follows: to 5 gm. of tumour was added 50 ml. of the buffered saline and 25 ml. of redistilled (b.p. 47·5°–48·5° C.) 'Freon 113' (Dupont). The mixture was homogenized at 0° C. for 1 min. in a Vertis blender running at full speed. The homogenate was quickly centrifuged in a trunnion cup rotor at 2,000 r.p.m. (1,000*g*) for 2 min. The supernatant was decanted and combined with 25 ml. of fluorocarbon and the process repeated. More *B* particles were obtained if the process was not carried to the point of having a clear supernatant. One or two fluorocarbon extractions are sufficient. The final supernatant was first centrifuged at 9,000 r.p.m. for 15 min. and then ultracentrifuged in 4 tubes of an angle head at 39,000 r.p.m. for 1 hr. The pellets were re-suspended in 1 ml. buffered saline. This opalescent solution was layered over 3 tubes of the buffered rubidium chloride solution and centrifuged at 39,000 r.p.m. in the swinging bucket rotor for 22 hr. Again the band lying at the middle of the tube was found to contain the *B* particles. In extracting *B* particles from tissue, it is important to work very fast at low tem-

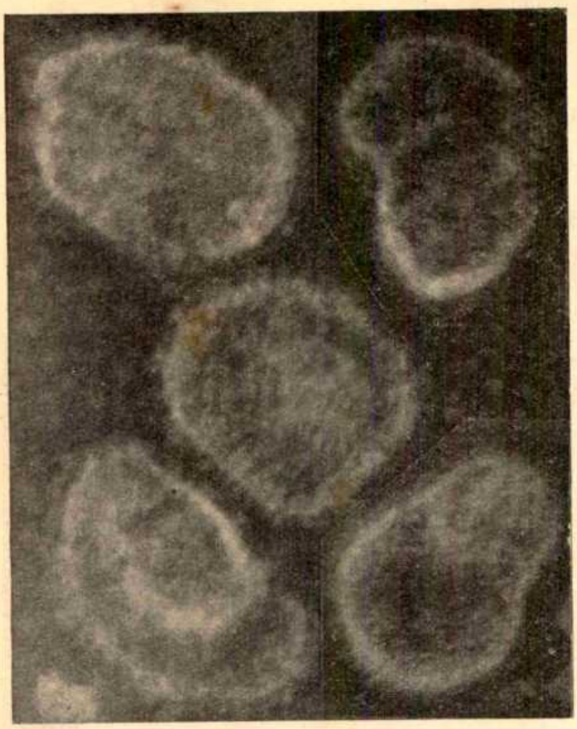

Fig. 2. Negative contrast dispersions of type *B* particles separated from tumours (*R*III strain). Eccentric 'nucleoid' areas are discernible in most of the particles. (× 200,000)

peratures because there is apparently rapid destruction of particles until they are freed of enzymes.

In the equilibrium ultracentrifugation, the density of the zone containing the *B* particles was 1·22. The density of such particles, however, may be influenced by the density of the medium if there is binding of rubidium chloride to the particles. Figs. 1 and 2 show particles, from milk and from tumours respectively, dispersed in buffered neutral phosphotungstate. They vary somewhat in size and shape but are predominantly spherical with an overall diameter of 130–160 mμ. They show two striking features: an outer region—very similar to the outer membrane of influenza virus—consisting of radially orientated spines about 10 mμ in length, somewhat shorter than those on influenza virus, and an internal structure which is quite different from influenza virus. The overall dimension is considerably greater than influenza, which ranges from 80 to 100 mμ. In osmium-fixed methacrylate embedded sections, the *B* particle measures 100–130 mμ (ref. 5), whereas influenza viral particles measure from 60 to 70 mμ (ref. 6). The outline of an eccentric nucleoid is clearly visible in many of the particles. The diameter of the nucleoid is usually a little less than half the diameter of the total virion. In other particles the nucleoid seems to consist of large granules. There is some similarity between the appearance of the nucleoid here and that of herpes simplex virus when studied by the same method[7]. There is little similarity between this *B* particle and the Rous sarcoma virus[8]. Rous sarcoma virions show a thin outer layer which is particulate but does not indicate the presence of distinct spines. Its overall diameter ranges from 70 to 100 mμ and the internal structure of the Rous virus is not as well defined.

The particles were found to disintegrate on treatment of suspensions with ether, and appeared to be resistant to degradation by trypsin, RNase and DNase.

Ultra-violet absorption analysis of dilute suspensions of *B* particles gave characteristic nucleoprotein absorption patterns. A preparation of influenza virus subjected to purification by the rubidium chloride density gradient gave a value of 1·14 for the ratio of optical densities at 260 and 280 mμ, while a *B* particle preparation gave the quotient 1·13.

Following an Ogur and Rosen[9] extraction procedure for nucleic acids, a positive orcinol test for ribose indicated the presence of RNA in the *B* particle preparation. Comparatively low quantities of DNA, representing possibly contaminants, were indicated by the diphenylamine test for deoxyribose. That the RNA was an integral part of the virus was indicated by positive ultra-violet absorption and orcinol tests on extracts obtained following incubation of suspensions for 30 min. at 27° with RNase and DNase (2 μgm. crystalline enzymes per ml.).

The presence of nucleic acid within the core of the particles was indicated by positive staining with uranyl acetate (0·5 per cent solution brought to *p*H 5·0 with 0·1 *N* sodium hydroxide.

IMMUNOLOGICAL ENHANCEMENT OF A LEUKÆMIA

By EDWARD A. BOYSE, LLOYD J. OLD and ELISABETH STOCKERT

New York University School of Medicine and Sloan-Kettering Institute for Cancer Research;
Sloan-Kettering Division, Cornell University Medical College, New York

THE growth of a tumour transplanted into a foreign host may sometimes be enhanced by treatment of the host with immune serum directed against the graft (see review by Kaliss[1]).

Much of the published work refers to sarcoma 1, a mouse ascites tumour which is remarkably susceptible to immunological enhancement. With other tumours it is not so easy to demonstrate this type of enhanced

Table 1. SUMMARY OF EXPERIMENTS ON THE GROWTH OF THE *C57BL* ASCITES LEUKÆMIA *EL4* IN FOREIGN HOSTS TREATED WITH IMMUNE SERUM

Exp.	Host strain	Serum	Titre	Dose-range tested (μl.)	No. of *EL4* cells inoculated ($\times 10^6$)	Result
A	*C3H/An*	$(C3H \times I)F_1$ anti *EL4*	1/512	20–0·02	0·6	See Fig. 1
B	$(C3H \times I)F_1$ and Swiss *Ha/ICR*	$(C3H \times I)F_1$ anti *EL4*	1/512	20–0·002	3	Inhibition at highest serum dose—otherwise no effect
C	*DBA/2*	*DBA/2* anti *EL4*	1/256	100–0·002	16	100 μl.—complete inhibition 20 μl. } 2 μl } moderate enhancement No effect with lower doses of serum
D	*C3H/An*	*C3H* anti *EL4*	1/64	20–0·002	11	No enhancement } No inhibition in this experiment
					2·8	Moderate enhancement with 20 and 2 μl. }
					0·29	No enhancement }
E	*DBA/1*	*DBA/1* anti *EL4*	1/512	100	29 70	See Fig. 2 See Fig. 2
F	*DBA/2*	*DBA/2* anti *EL4*	1/256	100 (single or repeated doses)	45	See Fig. 3

growth, and the opposite effect, suppression of tumour growth, may be seen, particularly if serum dosage is high[2]. In fact, suppression is the only recognized response of leukæmias inoculated into foreign passively immunized mice[3].

This has led to suggestions that transplanted tumours may be divided into two broad classes on the basis of their reactions to isoantisera[4-6]. Accordingly, leukæmias are regarded as highly sensitive to antibody, and for this reason, it has been supposed, they cannot be enhanced by immune sera[6]. In a separate category are the sarcomas and carcinomas which are less sensitive to antibody and are therefore susceptible as a class to the immunological enhancement effect.

This view has received support from the results of cytotoxic studies. These have shown that leukæmic cell populations are uniformly sensitive to the cytotoxic action of *H*-2 isoantibody and complement *in vitro*, whereas populations of sarcoma or carcinoma cells invariably contain a proportion of cells which are not affected under similar conditions[7-10]. Thus, some degree of resistance to antibody, both *in vivo* and *in vitro*, appeared to be a prerequisite of enhancement[3,6]. Naturally, these distinctions, if they can be maintained, favour the acceptance of a specific immune mechanism distinct from antibody formation in order to account adequately for the rejection of homografted carcinomas and sarcomas, and perhaps, by analogy, of their normal tissues of origin also.

Recently, however, we have reported that *BP*8, an ascites sarcoma which has been examined in detail in Gorer's laboratory and which can be enhanced by antibody with relative ease[2], is in fact completely sensitive to cytotoxic antibody *in vitro* provided that the test is carried out with sufficiently dilute cell suspensions[11]. Another sarcoma, a methylcholanthrene-induced fibrosarcoma recently converted to the ascites form, was also found to be completely sensitive under these conditions. Thus, *BP*8 furnishes a clear example of a tumour which can be enhanced by antibody *in vivo* despite the fact that it is completely sensitive to antibody *in vitro* under the proper conditions.

These findings led us to reconsider the possibility of obtaining immunological enhancement of highly sensitive cell populations like leukæmias. To achieve complete destruction of all sarcoma cells *in vitro*, the ratio of total antibody to the number of cells exposed must be higher, perhaps at least ten times higher in the case of *BP*8, than with a typical leukæmia. It seemed possible, therefore, that one might see immunological enhancement of a leukæmia if the ratio of total antibody administered to the number of cells inoculated were greatly reduced.

For this purpose, the ascites leukæmia *EL4* is an appropriate choice since, as a result of repeated tests in several laboratories, there is no doubt whatever as to its complete sensitivity to isoantibody *in vitro*[7,12,13]. Nor is there any doubt concerning its sensitivity to antibody *in vivo* as shown by the ease with which passive immunity can be obtained under the usual conditions of experiment without concomitant active immunization of the host[14]. It is strictly strain-specific, and has never killed an untreated mouse of any foreign strain in our laboratories.

In each of our experiments, with the exception shown in Table 1, the immune serum against *EL4* was prepared in the same strain as that to be used for the particular test. We used the conventional immunization schedule of three or four tumour inoculations over a period of six to eight weeks. Each pool of serum was titrated by the cytotoxic method[7] (against *EL4* in a cell concentration of 1–3 $\times 10^6$/ml.) before use. The titres recorded in Table 1 are 50 per cent end-points: all sera gave 100 per cent 'kill' at higher concentrations of serum.

Male hosts were used because they have been found to show enhancement more readily than females[2]. In every instance there was *H*-2 incompatibility between the host and *EL4*. The hosts were young adults of common inbred stocks from our own breeding nuclei, or, in a few instances, from commercial sources. Immune serum was diluted appropriately in saline to give a standard intraperitoneal injection volume of 0·5 ml. administered from 3 to 16 hr. before inoculation. *EL4* ascites cells were obtained from routine passage in *C57BL/6* mice. They were washed once by slow centrifugation and re-suspended in 'Medium 199'. No suspension contained more than 10 per cent dead cells according to trypan blue staining. After preliminary counting and appropriate dilution, the suspensions were inoculated subcutaneously into the shaved skin of the flank in volumes of 0·1 or 0·2 ml. by means of a tuberculin syringe and a No. 27 needle. The size attained by the grafts has been expressed as the average of two caliper measurements (mm.) at right angles to each other.

The ratio of antibody to the number of cells in the inoculum can be lowered either by reducing the amount of antiserum given or by increasing the size of the cell inoculum. As the summary of our results shows (Table 1) both methods can produce enhancement; but the latter gives more striking effects and serum treatment may then cause such massive growths that the hosts die (Exps. *E* and *F*, Figs. 2 and 3). With a small inoculum of *EL4*, enhancement can be obtained only with minute doses of serum. In Exp. *A* (Fig. 1), with a small inoculum of 6 × 10^5 cells, enhancement was seen with a serum dose of 0·02 µl.; higher doses gave increasing inhibition and apparently complete suppression with 20 µl.

Exp. *F* (Fig. 3) shows that continuous administration of serum over an extended period may be more effective than the usual single injection given before inoculation. It will be interesting to determine whether or not this manœuvre will enable us to secure enhancement of tumours in strains which normally do not show the effect easily. In this respect, our experience emphasizes once again the importance of the host strain in enhancement experiments[15]. Perhaps sufficient attention has not been paid in this connexion to the matter of genetically determined differences in the immune capacity of various strains. Since rejection, or failure to reject, must ultimately depend on this, it seems quite probable that the root of strains differences in the matter of enhancement may lie here. It is worth noting here that in general females respond better than males to certain immune stimuli[16-18] and that they are less favourable hosts for enhancement experiments[2]. *DBA*/2 and *C3H*, which in our hands gave good enhancement, respond poorly to immunization with heterologous red cells[19]. *DBA*/1 also gives good enhancement and is said to be peculiarly receptive to certain foreign tumours[20].

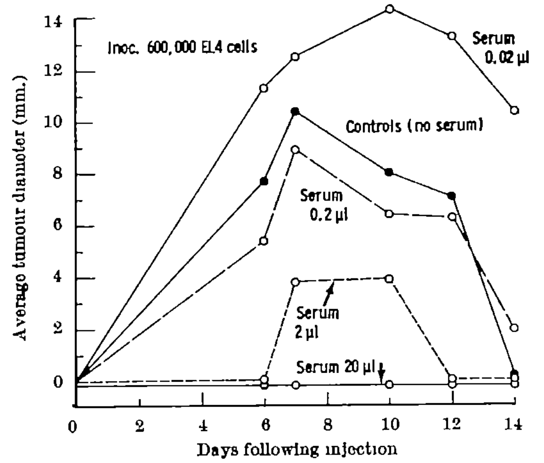

Fig. 1 Growth patterns of *EL4* inoculated subcutaneously into *C3H/An* hosts treated with various doses of immune serum (see Exp. *A*, Table 1): average readings for groups of 4 mice

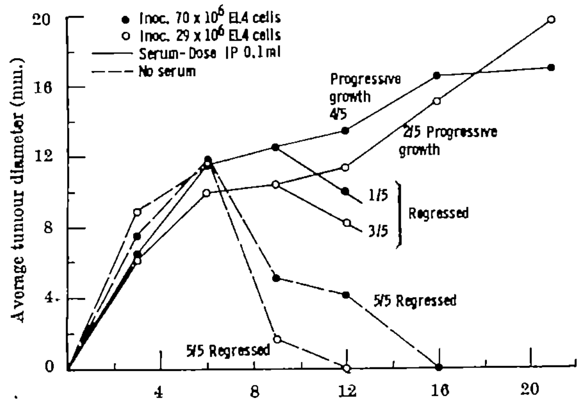

Fig. 2. Growth patterns of large subcutaneous inocula of *EL4* in *DBA*/1 hosts treated with immune serum 'Progressive growth' means that these hosts died with massive enlarging tumours (see Exp. *E*, Table 1)

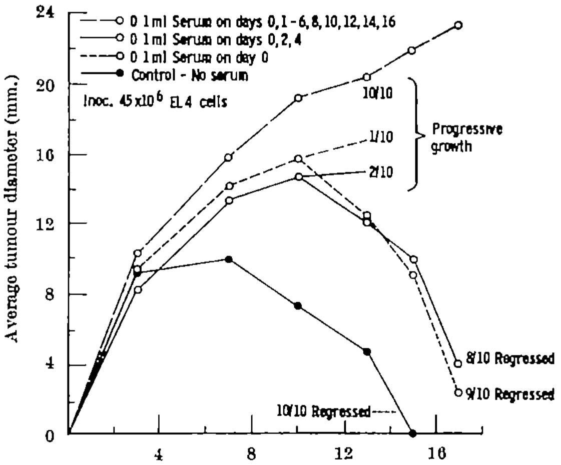

Fig. 3 Growth patterns of *EL4* inoculated subcutaneously into *DBA*/2 hosts treated either once or repeatedly with immune serum

In conclusion, it is clear that at least some sarcomas and leukæmias may not differ significantly in their reactions to isoantibody either *in vitro* or *in vivo* when a sufficiently large range of cell and serum doses is tested. The phenomenon of immunological enhancement therefore cannot be attributed to any inherent quality of resistance to antibody possessed by particular cell populations since one of the most sensitive types, *EL4*, can be enhanced by immune serum, given the proper conditions. Consequently, there is perhaps less need now than formerly to resort to theories of rejection which demand widely divergent immune mechanisms for tumour homografts of various types.

DOSIMETRY OF CÆSIUM-137 IN SHEEP

By R. O. McCLELLAN, J. R. McKENNEY and L. K. BUSTAD

Biology Laboratory, Hanford Laboratories, General Electric Co., Richland, Washington

CÆSIUM-137 is considered one of the most significant constituents of world-wide fall-out because of a long half-life, energetic β- and γ-components and entry into the metabolic processes of plants and animals. Since it resembles potassium chemically, it is distributed quite uniformly in the animal body[1]. For the radionuclides which are rather uniformly distributed in body tissues, the National Committee on Radiation Protection and Measurements[2] has recommended the same occupational exposure limit that applies for external X-ray and γ-sources of radiation, that is, 5 rems per year. In such cases, the whole body is designated as the critical organ.

The estimation of radiation dose to an individual tissue or organ from cæsium-137 is complicated. This isotope emits 0·52 or 1·18 MeV. β-rays. Its daughter, metastable barium-137, emits an 0·66 MeV. γ-ray. For the most part, the β-rays are absorbed within the tissue in which they were emitted. The γ-rays, however, penetrate considerable distances so the dose they produce depends both on the concentration in and the position of other organs around the point in question. The relationship between radiation dose to whole body and gonads from internally deposited cæsium-137 was determined by dose measurements on young male sheep which were fed cæsium-137 (orally) for up to 20 days.

Three male sheep were confined in metabolism cages and fed a normal ration of alfalfa hay. With the morning meal each day for, 5, 10 or 20 days, the rams received a small feed pellet spiked with 1·25, 0·75 or 0·5 mc. of cæsium-137, respectively.

24 hr. after administration of the last dose, the animals were anæsthetized with a sodium pentobarbital solution. The body burdens were then measured by using either model 208 'Victoreen' stray radiation chambers or a scintillation counter with a 2 in. × 3 in. sodium iodide crystal. To compensate for differences in the distribution of cæsium-137 within the animals, measurements were taken with the detectors at various locations relative to the animals, and at least 1 m. from their bodies. Calibration for both methods was done by counting a 'standard' animal of similar size. The 'standard' had been prepared by intravenous injection of 5·5 mc. of cæsium-137 into an anæsthetized animal, which was killed approximately 2 hr. later. This delay before death allowed adequate time for the cæsium-137 to distribute throughout the body, yet not be excreted.

Immediately after whole-body burdens were determined, a number of 'Victoreen' pocket dosimeters were surgically inserted in and/or adjacent to the major organs *in situ*. Measurements were made in the testes after removal from the body and in the scrotum after removal of the testes. The dosimeters were encased in a condom to exclude moisture. The measurements were taken using a special pocket dosimeter reader described by Roesch *et al.*[3]. All readings were within ± 5 per cent and corrected for background radiation. These measurements were considered to represent only γ-radiation since work by Hubbell *et al.*[4] has shown this type of ion chamber to be relatively ineffective in measuring β-radiation in the range of energy emitted by cæsium-137. These measurements are given in Table 1.

Table 1. GAMMA- AND BETA-DOSIMETRY OF DAILY ADMINISTERED CÆSIUM-137 IN THREE RAMS

(Expressed as mrads/hr./mc. in body tissues and gastrointestinal tract at death)

	^{137}Cs regimen					
	1·25 mc./day (5 days)		0·75 mc./day (10 days)		0·50 mc./day (20 days)	
	Radiation					
	γ	$\beta+\gamma$	γ	$\beta+\gamma$	γ	$\beta+\gamma$
Total body	10	17	10	17	10	17
Testes (intact)	9	18	6	19	8	24
Testes (excised)	5	14	3	16	3	19
Scrotum (testes removed)	3		4		5

Body burdens as per cent of daily dose		240		330		280
Per cent of body burden in gastrointestinal tract	40–50		10–20		0–10	

* Approximate location of ovary in female animal.

The animals were killed with an overdose of anæsthetic and the tissue samples were obtained. Samples for radioanalysis were wet-ashed in nitric acid and duplicate aliquots were measured for cæsium-137 concentration using a well-type γ-scintillation counter with a 3-in. sodium iodide crystal. Values obtained are given in Table 2. β-Contribution to total dose was calculated from these values using a factor of 13 mrads/day per μc./kgm. of tissue. This value was estimated from a monogram for β- and γ-dosimetry of internally deposited radioisotopes[5].

Table 2. CONCENTRATION OF CÆSIUM-137 IN TISSUES OF MALE SHEEP

(Expressed as μc./gm. $\times \frac{\text{body-weight (gm.)}}{\text{daily dose } (\mu\text{c.})} \times 100$)

	^{137}Cs regimen		
	1·25 mc./day (5 days)	0·75 mc./day (10 days)	0·50 mc./day (20 days)
Muscle	200	490	550
Heart	470	600	560

Femur head	40	62	50
Rib end	120	170	100
Liver	500	520	420
Spleen	390	560	360
Kidney	640	900	720
Testis	280	610	610
Blood cells	31	56	130
Plasma	24	32	32
Body-weight of animals (kgm.)	67·4	72·4	70·2

Radiation dose-rates obtained for rams fed cæsium-137 for 5, 10, or 20 days are given in Table 1. All dose-rates are expressed as mrads/hr./mc. in the body tissues and gastrointestinal tract at the time of death. This expression allows direct comparisons between the different animals irrespective of body burdens. Thus, differences in dose-rates reflect distribution of cæsium-137 in the body to the number of days fed. Data for the γ-radiation dose-rates are those measured at the time the animals were killed. The combined γ- and β-radiation dose-rates were obtained by adding the γ-radiation dose-rates to the calculated β-dose-rates. A small correction was made for γ-activity of tissue displaced by the dosimeters.

The highest dose-rates were found in the rectum; however, these values only applied to the surface layers of the mucosa and were probably twice that received by most tissues in the rectal region. The highest tissue dose-rates were in the kidneys, where a rate twice that of the total body was measured.

The combined β- and γ-dose-rate to the intact testes were only slightly higher than that received by the total body. A comparison of values for the intact and excised testes reveals that approximately 20 per cent of the radiation dose to the testes originates from surrounding structures, such as the thigh muscle and gastrointestinal tract.

The present policy for establishing the maximum permissible body burdens of radionuclides considers the organ that receives the highest radiation dose relative to its radiosensitivity to be the critical organ. The maximum permissible limits for occupational exposure recommended by the National Committee on Radiation Protection and Measurements[2] were selected for most radionuclides on the basis of an average annual dose to the critical organ of 5 rems for the gonads or total body, 15 rems for most individual organs, and 30 rems for the thyroid or skin. Use of total body as critical organ for γ-emitting nuclides such as zinc-65 or cæsium-137 compensates for the potentially large contribution of the radiation dose to the gonads from concentrations of the radionuclide in surrounding body structures. Although the testis dose was always slightly greater than that of total body, the difference was such that use of total body as critical organ adequately accounted for the radiation dose to testes that originated from contiguous structures. γ-Dose measurements taken at the anatomical location comparable with that of the ovary were quite low. Considering the small size of the ovaries and assuming that they would not have high concentration, it would be expected that the total radiation dose to the ovaries of the ewe would be less than that to the testes of the ram.

Prolonged feeding of cæsium-137 may be expected to increase the gonad dose relative to the total body dose, providing the concentration of cæsium-137 increases in voluntary muscle relative to other tissues. From this brief 20-day study, it was not possible to determine accurately the extent to which this might occur. However, considering that during the period 5–20 days the radiation dose to the testes increased by only one-third, while the concentration of cæsium-137 in voluntary muscle increased nearly threefold, it appears that no great alteration in the relationship between total-body and gonad dose would take place even over extended periods of exposure to cæsium-137.

Obviously the anatomical relationships and metabolic characteristics of the male sheep are not identical to those of man and therefore preclude direct extrapolation to man. However, these results, obtained in a large species comparable to man in size, do help affirm the basic policy of using total body as an estimator of cæsium-137 radiation dose to the gonads.

We thank W. C. Roesch and R. C. Thompson for their advice, F. L. Rising for making the dose measurements and A. C. Case for the radioanalysis.

IMMUNIZING EFFECT OF IRRADIATED CERCARIÆ OF *SCHISTOSOMA MANSONI* IN RHESUS MONKEYS

By Dr. S. R. SMITHERS

National Institute for Medical Research, London, N.W.7

It has recently been reported[1,2] that previous exposure of mice to irradiated cercariæ of *Schistosoma mansoni*, or exposure of monkeys to irradiated cercariæ of *S. japonicum*, afforded protection against a homologous challenge with the unattenuated parasite. Concurrent work has been undertaken in this laboratory on the effect of irradiation on the behaviour of cercariæ of *S. mansoni* in hamsters, and the protective effect of such cercariæ against a homologous challenge in rhesus monkeys.

An Egyptian strain of *S. mansoni* was used and the methods of percutaneous infection, challenge, and worm recovery follow those described previously[3]. Irradiation of cercariæ was effected by X-rays; the cercariæ were collected in 10 mm. depth of filtered rain-water in a glass crystallizing dish 100 mm. in diameter. X-irradiation was delivered by a Newton–Victor *G* × 10 unit, and the radiation factors were 120 kV., 5·5 m.amp. with 1-mm. aluminium filter. The distance from the X-ray tube to the surface of the cercarial suspensions was 190 mm. and the exposure dose-rates ranged from 140 to 160 r./min.

Hamsters were used for estimating the dose of X-irradiation which was necessary to prevent cercariæ from developing to maturity, but which still allowed them to migrate through the lungs and reach the liver. It was found that an X-ray dose of 3,000 r. prevented any cercariæ from surviving for more than six weeks in hamsters; 2,000 r. prevented

48	3,000	3,000	—	—	13 wks.	1,000	440	1 8	Severe

all but about 1 per cent of the worms from surviving beyond this time. Most of the flukes surviving after exposure to 2,000 r. were stunted and the females were sterile. On one occasion, however, two females, each containing an egg *in utero*, were recovered from hamsters exposed to cercariæ irradiated at 2,000 r. although one of these females showed poorly developed vitellaria. On another occasion a few living eggs were found in the liver of a hamster exposed to cercariæ treated at 2,000 r. and one pair of mature worms was recovered; all other worms recovered from the same hamster and from another hamster exposed to cercariæ from the same suspension were stunted and sterile. After exposure to 1,500 r., approximately 5 per cent of cercariæ survived beyond six weeks, and although some of the surviving worms were stunted, others were able to produce live eggs. An X-ray dose of 1,000 r. caused only a slight reduction in the number of cercariæ developing to maturity as compared with a control infection, and live eggs were produced (Fig. 1).

Histological examination of tissues from hamsters exposed to cercariæ irradiated at 2,000 or 3,000 r. revealed that most cercariæ had passed through the lungs uninhibited, but on reaching the liver they died during the second, third or fourth week after exposure. Dead flukes were found in the smaller vessels of the liver, and were surrounded by an intense cellular reaction consisting mainly of mononuclear cells, with a few polymorphs. The dead flukes were gradually absorbed by macrophages. In later stages, fibroblasts were laid down until finally the vessels became completely occluded by fibrotic scars. In contrast with the reaction which occurs around schistosome eggs, giant cells were absent around dead schistosomula and no calcification occurred.

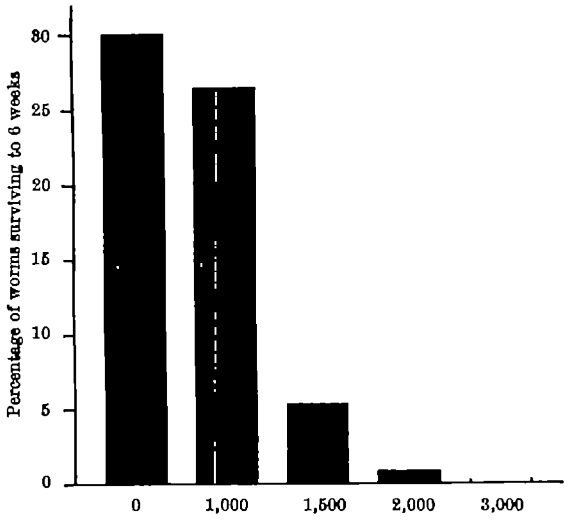

Fig. 1. Percentage of X-irradiated cercariæ surviving to 6 weeks in hamsters· 5 groups of 5 hamsters, each hamster exposed percutaneously to 380 cercariæ

Attempts to protect rhesus monkeys against subsequent challenge with *S. mansoni* were made by exposing them to cercariæ irradiated at 2,000 and 3,000 r. During the period of immunization, 6–9 fæcal examinations per monkey by the *AMS* III method[4] failed to reveal the presence of schistosome eggs as a result of the exposures to irradiated cercariæ. At varying periods after the exposures, each monkey was challenged with 1,000 normal cercariæ taken from a single suspension. The experiment is summarized in Table 1.

It is believed that the monkeys exposed to cercariæ irradiated at 2,000 r. developed a partial resistance to the challenge infection. Although the worm recovery figures from this group were not substantially lower than the worm recovery figures of the control group, the lesions in the liver and gut wall, due to egg deposition, were negligible compared with the severe lesions which occurred in the control monkeys. The reason for this became obvious on examination of stained preparations of the female worms, when it was found that more than half the females recovered from the 2,000 r. group were stunted, their vitellaria and usually their ovaries failed to stain, and their gut contents contained little or no pigment. It is believed that these sterile worms had survived from the immunizing exposures. In the 3,000 r. group, one monkey (No. 40) developed a marked protection against the challenge, but in a second monkey (No. 47) receiving almost identical exposures protection was less marked. The third monkey of this group, which received only one exposure of 3,000 irradiated cercariæ, failed to develop any recognizable signs of resistance against the challenge.

These results generally confirm the work of Villella *et al.*[1] on *S. mansoni* in mice, and Hsu *et al.*[2] on *S. japonicum* in monkeys. It appears, however, that under the conditions used by Hsu *et al.* a slightly lower X-ray dose than that needed to prevent egg formation in *S. mansoni* will sterilize the worms of *S. japonicum*. One fact is clear: large numbers of irradiated cercariæ are necessary to induce an incomplete protection against *Schistosoma* in rhesus monkeys.

I thank Dr. Janet Niven and Mr. M. J. Ashwood-Smith for their advice.

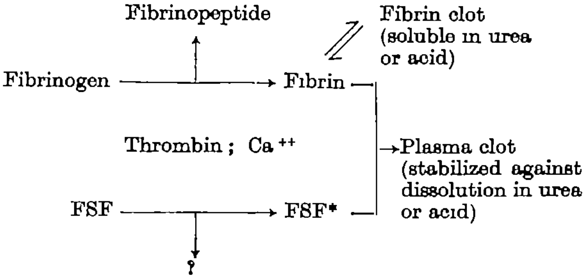
TRANSPEPTIDATION MECHANISM IN BLOOD CLOTTING

By Prof. L. LORAND, Dr. K. KONISHI and Mrs. A. JACOBSEN

Department of Chemistry, Northwestern University, Evanston, Illinois

THE actual clotting phase in blood coagulation is initiated by two parallel sets of reactions catalysed by thrombin. Fibrinogen is converted to fibrin through the scission of fibrinopeptide from the parent molecule[1] and the more recently recognized plasma globulin, fibrin stabilizing factor (FSF), is also activated in some manner[2]. The thrombin-activated form of FSF (designated as FSF*) produces covalent cross-links in the clot polymer which is thus rendered insoluble in solvents such as 30 per cent urea or 1 per cent monochloroacetic acid[3]. Accordingly, physiological clotting may be outlined as follows:



Fibrinopeptide
Fibrin clot (soluble in urea or acid)
Fibrinogen
Fibrin
Thrombin; Ca ++
Plasma clot (stabilized against dissolution in urea or acid)
FSF
FSF*
?

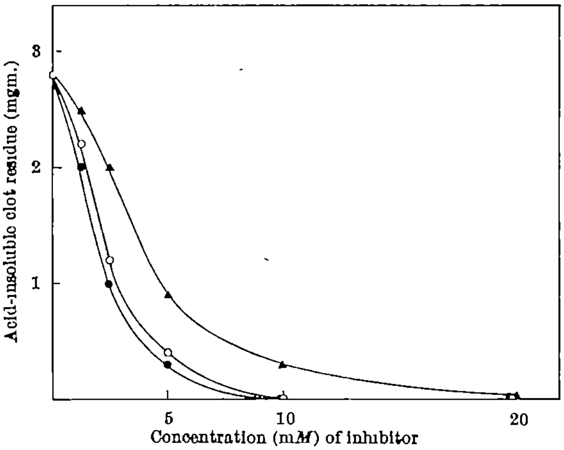


Fig. 1. Effect of inhibitors on the cross-linking of fibrin by the thrombin-activated fibrin-stabilizing factor. Buffer consisted of 0·05 *M* *tris*-HCl of *p*H 7·5 brought to an ionic strength of 0·18 by addition of sodium chloride. (*Tris* itself, probably because of its being an amine, is somewhat inhibitory on the cross-linking reaction studied, but the effect begins to be noticeable only at ten times the concentration used.) ***The activation mixture*** contained 0·4 ml. (65γ) of FSF, 0·1 ml. (2 units) of thrombin (ref. 8), 0·5 ml. each of 1 m*M* calcium chloride and 0·1 *M* neutralized cysteine, all being dissolved in the *tris* buffer. Following incubation for 10 min. at 20°, the action of thrombin was stopped by the addition of 0·2 ml. neutralized 0·25 *M* N$^{\alpha}$-tosylarginine methylester dissolved in *tris*. 2 min. later, 0·5 ml. of the neutralized inhibitor substance, dissolved in the buffer, was added in the concentrations shown on the abscissa. ***The polymerization mixture:*** Clotting was initiated 3 min. later by the addition of 0·8 ml. of purified fibrin, dissolved in 1 *M* sodium bromide containing 0·05 *M* acetate buffer at *p*H 5·3. Gelation occurred in all instances in less than 2 min. 30 min. after clotting, 2·5 ml. of 2 per cent monochloroacetic acid was added to the gel. After 24 hr. in the acid, the insoluble residue was washed and its protein content (shown on the ordinate) estimated. ●, Gly NH$_2$; ○, gly Me; ▲, gly gly Me

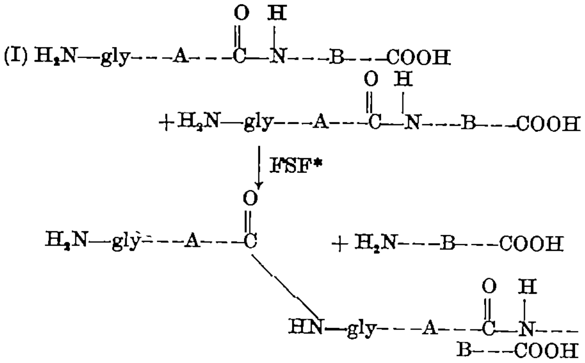
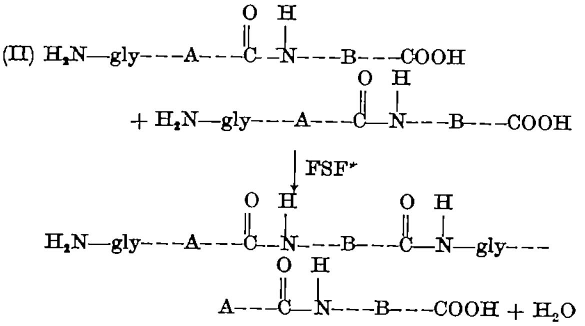
We have obtained some evidences which strongly suggest that the cross-linking of fibrin by FSF* belongs to the class of reactions generally referred to in protein chemistry as 'transpeptidation'[4].

(1) *Reduction in the number of amino end-groups in the cross-linked clot structure.* Bovine fibrin, purified[5] by repeated dissolution in urea and reprecipitation by dilution into a neutral buffer, contains *N*-terminal residues of glycine and tyrosine in amounts of about 1·1 and 0·5 moles per 100,000 gm. of protein respectively. When such purified fibrin is finally taken up in 1 *M* sodium bromide[6] and allowed to gel following an eight-fold dilution with a *p*H 7·5, μ : 0·18 *tris*(hydroxymethyl)aminomethane buffer in the presence of FSF* (prepared as described in the legend to Fig. 1), the clot becomes cross-linked so that it can no longer be dissolved in 30 per cent urea. Examination of the *N*-terminal residues of the urea-insoluble proteins shows only glycine and tyrosine end-groups, but in greatly diminished quantities (about 0·25 moles each per 100,000 gm. of protein) as compared with the starting fibrin material. The ε-NH$_2$ lysine contents of fibrin and stabilized fibrin are identical.

The observed reduction in the number of open peptide chains may be due to one of the following two possibilities, illustrated only for the dimerization of chains with glycine (gly) end-groups:



$$\text{(I) }\mathrm{H_2N{-}gly{-}{-}{-}A{-}{-}{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}{-}\overset{\mathrm{H}}{\overset{|}{\mathrm{N}}}\mathrm{{-}{-}{-}B{-}{-}{-}COOH}$$
$$+\mathrm{H_2N{-}gly{-}{-}{-}A{-}{-}{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}{-}\overset{\mathrm{H}}{\overset{|}{\mathrm{N}}}\mathrm{{-}{-}{-}B{-}{-}{-}COOH}$$
$$\Big\downarrow \mathrm{FSF^*}$$
$$\mathrm{H_2N{-}gly{-}{-}{-}A{-}{-}{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}\qquad+\mathrm{H_2N{-}{-}{-}B{-}{-}{-}COOH}$$
$$\diagdown$$
$$\mathrm{HN{-}gly{-}{-}{-}A{-}{-}{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}{-}\overset{\mathrm{H}}{\overset{|}{\mathrm{N}}}\mathrm{{-}{-}{-}B{-}{-}{-}COOH}$$



$$\text{(II) }\mathrm{H_2N{-}gly{-}{-}{-}A{-}{-}{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}{-}\overset{\mathrm{H}}{\overset{|}{\mathrm{N}}}\mathrm{{-}{-}{-}B{-}{-}{-}COOH}$$
$$+\mathrm{H_2N{-}gly{-}{-}{-}A{-}{-}{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}{-}\overset{\mathrm{H}}{\overset{|}{\mathrm{N}}}\mathrm{{-}{-}{-}B{-}{-}{-}COOH}$$
$$\Big\downarrow \mathrm{FSF^*}$$
$$\mathrm{H_2N{-}gly{-}{-}{-}A{-}{-}{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}{-}\overset{\mathrm{H}}{\overset{|}{\mathrm{N}}}\mathrm{{-}{-}{-}B{-}{-}{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}{-}\overset{\mathrm{H}}{\overset{|}{\mathrm{N}}}\mathrm{{-}gly{-}{-}{-}}$$
$$\mathrm{A{-}{-}{-}}\overset{\mathrm{O}}{\overset{\|}{\mathrm{C}}}{-}\overset{\mathrm{H}}{\overset{|}{\mathrm{N}}}\mathrm{{-}{-}{-}B{-}{-}{-}COOH}+\mathrm{H_2O}$$

Analysis of the clot liquor for the appearance of (H$_2$N---B---COOH) soluble fragments during stabilization of fibrin by FSF* will decide between the two mechanisms.

It should be mentioned that the tendency for reduction in the number of N-terminal glycines was also noticed by Middlebrook during the formation of a clot in whole plasma[7]. His results, concerning the release of end-groups into the supernatant of that system, seem to indicate to us that mechanism I is preferred. However, transamidation between a glutamine side-chain and a terminal amino group must also be considered[8].

(2) *Inhibition of the cross-linking of clot structure by certain amines.* Since the end-group measurements indicated mainly the involvement of α-NH_2 groups of glycine residues in the cross-linking of fibrin units, it was reasoned that the presence of a suitable glycine derivative during the polymerization of fibrin by FSF* might interfere with the cross-linking process. Indeed, as shown in Fig. 1, some simple amines, related to glycine in an N-terminal position, were found to inhibit the development of the acid-insoluble clot structure. At pH 7·5, minute concentrations of glycineamide, glycine methylester, glycylglycine methylester and glycylglycine were effective, whereas glycine, imidazole and aniline showed no appreciable inhibition. It must be emphasized that the inhibitors did not affect the onset of gelation; they appeared only to delay the cross-linking of the protein units of the clot as measured by solubility in 1 per cent monochloroacetic acid. The possibility that the inhibitors may become temporarily incorporated into the clot proteins and act as transient chain terminators in the polymerization processes is now being examined.

It is noteworthy that the inhibitors, when added to oxalated plasma, did not interfere with the onset of clotting after recalcification, but again inhibited the development of the acid-insoluble, stabilized clot structure. A wider survey of inhibitory amines is in progress.

This work was aided by grant H–2212 from the National Heart Institute, U.S. National Institutes of Health.

OCCURRENCE OF CITRULLINE IN PROTEINS

By DR. G. E. ROGERS

Division of Protein Chemistry, Commonwealth Scientific and Industrial Research Organization,
Parkville, N.2, Victoria, Australia

REPORTS in the literature claiming that the amino-acid citrulline is present in many proteins have appeared from time to time[1–3]. These claims have not been substantiated. Furthermore, the application of recent developments in amino-acid analysis has not revealed citrulline in any of the well-characterized proteins.

More recently the presence of citrulline was reported in the red alga, *Chondrus crispus*[4]; but it was later shown to be combined in small peptides and not in protein[5].

In previous work we demonstrated the presence of significant amounts of citrulline in hydrolysates of the hardened inner root sheath cells of the hair follicle[6–8]. The evidence favoured the view that the citrulline was covalently bound by peptide linkage to the proteins of these cells and not simply adsorbed by secondary forces[6,8]. The present results support this view.

In these experiments citrulline-rich polypeptides have been released from the cell proteins by tryptic digestion. However, owing to the small size of the inner root sheath even in large hair follicles and the attendant difficulty of obtaining sufficient material for examination, attention was turned to the medullæ of hairs and related structures, namely, porcupine quills, where the medullary cells had been shown to have proteins which contain citrulline[8]. Both inner root sheath cells and medullary cells give a strong colour in the Fearon test for citrulline which is now shown to be incorporated in the peptide chains of the insoluble proteins in these cells.

Inner Root Sheath Cells

The inner root sheath layers were stripped from vibrissal hairs with 'roots' attached, plucked from rats (Wistar strain), and from the soft 'root' ends of quills plucked from the African porcupine (*Hystrix cristata*).

The sheath layers, which consist mostly of hardened protein-filled cells, were treated with 8 M urea to remove the unhardened cells containing trichohyalin[6], washed and dried, then 1–2 mgm. quantities of each were digested with 50 μgm. crystalline trypsin, pH 8, for 4 hr. The digests were centrifuged to remove cellular debris, lyophilized, and then examined by unidimensional paper electrophoresis. Bands of separated polypeptides were detected by spraying with ninhydrin, and on duplicate strips citrulline-containing peptides were visualized by the yellow colour produced when sprayed with Ehrlich's reagent under mild acid conditions. The patterns obtained are shown in Fig. 1*a* and *b*. Five separate ninhydrin-positive bands were usually distinguishable; one which moved the fastest towards the anode (1) reacted strongly for citrulline whereas another band (4) reacted only faintly. The others (2, 3 and 6), more basic in character than band (1), did not react for citrulline.

From this distribution it follows that in the inner root sheath protein the citrulline is concentrated into regions of the peptide chains where the concentration of dicarboxylic amino-acids is higher than that of the basic amino-acids. The large peptide fragments,

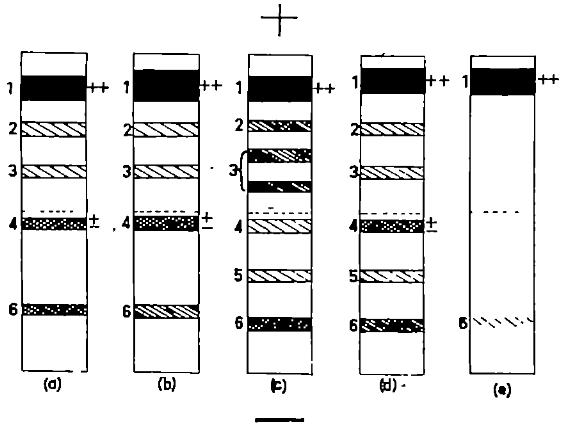

Fig. 1. Paper electrophoresis band patterns of polypeptides obtained from tryptic digests of (*a*), inner root sheath cells from rat hair follicles and from (*b*) African porcupine quill follicles, (*c*) medullary cells of medullated reindeer hair and Lincoln wool, (*d*) medulla from African porcupine quill, (*e*) medulla from African porcupine quill after fractionation according to the scheme in Fig. 2. Relative intensities of ninhydrin colour are indicated by shading. Degree of reaction with Ehrlich reagent for citrulline is signified by ++ (strong) and ± (weak). Run in 0·04 *M* phosphate *p*H 6·8, 7·5 V./cm. for 4 hr. in a Spinco model *R* paper-electrophoresis apparatus.

containing citrulline, glutamic acid (and aspartic acid) and smaller amounts of other amino-acids, are liberated when trypsin hydrolyses lysyl and arginyl linkages of the protein.

It could still be argued that these results do not exclude the possibility of strong adsorption of citrulline to the insoluble protein before trypsin digestion. However, this possibility seems most unlikely when the results obtained with medullary cells are taken into account.

Medullary Cells

Amino-acid composition. Paper chromatograms of acid hydrolysates of medullary cells isolated from rabbit fur by the alkali method[9] and of medullæ dissected from the quills of African, North and South American porcupines (*Hystrix* sp., *Erithizon* sp. and *Coendou* sp. respectively) revealed similarities to inner root sheath cells in their qualitative amino-acid composition, in particular in their high contents of citrulline and glutamic acid. Quantitative amino-acid analysis of rabbit fur by the Moore and Stein procedure[10] (Table 1, col. *A*) revealed the presence of citrulline originating from the medulla, but greatly diluted by the contribution of cortical keratin. Medullary cells isolated from the fur by alkali treatment[9] were richer in citrulline and also glutamic acid (Table 1, col. *B*). The medulla manually dissected from African porcupine quill had a comparable composition (Table 1, col. *C*). Other features of the amino-acid compositions of the medullæ are the relatively high leucine and aspartic acid figures, the low content of tyrosine and the virtual absence of cystine, the total pattern resembling that of the inner root sheath (Table 1, col. *E*).

Identity of citrulline. The identification of the citrulline in medulla proteins does not rest solely on the position of the amino-acid in Moore and Stein amino-acid analyses or paper chromatograms. Citrulline was isolated in quantity from medulla hydrolysates by ion-exchange chromatography and converted to the dinitrophenyl (DNP) derivative. The properties of this derivative, such as melting-point, elemental analysis, infra-red spectrum and R_F values in a variety of solvents, were indistinguishable from those of an authentic sample of DNP-citrulline. Both DNP derivatives were also remarkably stable to hydrolysis by 6 *N* hydrochloric acid at 110° C. for 16 hr. but a trace of α-DNP-ornithine was observed in both cases.

Isolation and composition of citrulline-rich peptides. Although resistant to solution by the usual protein solvents medullary cells are rapidly digested by trypsin[9,12] and unidimensional paper electrophoresis of tryptic digests of medulla material from hairs and porcupine quills gave band patterns (Fig. 1*c* and *d*) similar to those of the inner root sheaths. Usually six or seven ninhydrin-positive bands were obtained, the most prominent again being one which moved rapidly to the anode (1) and gave a strong reaction for citrulline. The citrulline-rich polypeptide material of this band was separated from the more basic polypeptides of the remaining bands according to the scheme shown in Fig. 2. Fraction *A* and fraction *B*, which were obtained in the ratio of about 2 : 1, moved almost identically on paper electrophoresis in a position similar to the fastest migrating anodic band 1, and were only slightly contaminated by the basic material of band 6 (Fig. 1*e*). Both polypeptide fractions did not dialyse through 'Cellophane' and therefore have molecular weights of about 10,000, which is in accord with preliminary ultracentrifuge data. Since they are produced by protein splitting with trypsin, each are mixtures of polypeptides, but their electrophoretic and chromatographic behaviour strongly suggests that although being mixtures they are closely related in molecular size and in composition. Fractionation of them by ion-exchange chromatography on DEAE-cellulose columns has not yet led to the separation of discrete components.

The amino-acid composition of fraction *B* only is given in Table 1 (col. *D*). A striking feature is that citrulline and glutamic acid together constitute

Table 1. QUANTITATIVE AMINO-ACID ANALYSES* OF CITRULLINE-RICH COMPONENTS

Proteins hydrolysed in 6 *N* hydrochloric acid at 110° C.; *A* and *B*, 16 hr.; *C*, *D* and *E*, 10 hr. The lysine figure in each case includes ornithine originating from citrulline breakdown and not separately resolved. Thus the citrulline figure is a minimal one.

FIG. 2. Isolation of citrulline-rich polypeptides from trypsin digest of quill medulla

58 per cent of the total nitrogen and on a weight basis the citrulline content of fraction *B* is 24·7 per cent, but since it was found that 16 per cent of the citrulline was converted to ornithine during hydrolysis of fraction *B* for 10 hr. in 6 *N* hydrochloric acid at 110° C. the corrected value for zero time is 28·6 per cent. An independent determination of citrulline by a colorimetric method[13] gave the same value. This means that 1 residue in 2·8 is glutamic acid and 1 in 5 is citrulline. The next most abundant amino-acids from Table 1 (col. *D*) are leucine and lysine, whereas tyrosine, isoleucine, threonine, cystine and methionine are absent. The composition of fraction *A* was similar, but the glutamic acid and citrulline contents were slightly lower than in *B*.

Peptide bonds involving citrulline. A most significant finding indicative of the citrulline being combined in peptide linkage in medullary proteins was the release of free citrulline from fractions *A* and *B* by both carboxypeptidase and leucine amino-peptidase. Using the 'molecular-sieve' technique[14,15] it was shown that in addition to citrulline these enzymes liberated four or five other amino-acids, including glutamic acid. When pepsin was allowed to act first, about 25 acidic peptides separable by the 'fingerprinting' technique[16] were produced and about 10 of these contained citrulline. Subsequent action of carboxypeptidase and leucine aminopeptidase on the pepsin digests released greatly increased quantities of amino-acids. About twelve liberated amino-acids were detected by paper chromatography, with citrulline and glutamic acid in concentrations relatively much higher than the others. Leucine aminopeptidase was more effective in liberating citrulline and glutamic acid than was carboxypeptidase and the evidence indicates that in the initial digestion of the medulla the trypsin hydrolysed citrullyl bonds only very slowly compared with arginyl and lysyl bonds.

General Conclusions

The present results show that the proteins of medullary cells (within the hair) and inner root sheath cells (external to the hair) are very similar in properties. This is not altogether unexpected on histological grounds for trichohyalin 'droplets' are found in both types of cell[17] during development in the follicle. Consequently some properties of the medulla are likely to apply to the inner root sheath.

The amino-acid compositions are distinctive and the evidence for the identity of citrulline and its occurrence in peptide linkage is now unequivocal for medulla, and almost certainly for the inner root sheath as well. Of particular interest is the release from both cell proteins by trypsin of closely related polypeptides which contain virtually all the citrulline and much glutamic acid. This observation and the action of pepsin and exopeptidases in liberating large amounts of both amino-acids not only rules out the possibility of adsorption of citrulline to the protein but also indicates the frequent occurrence of trypsin-resistant cit-cit, cit-glu and glu-glu sequences gathered together and forming citrulline-rich regions in the medulla proteins.

Earlier investigations of medulla pointed to features which distinguish it from α-keratin; for example, a β-type X-ray diagram[18], avidity for dyes and rapid digestion by trypsin[9,12,19], alkali resistance[9], and low cystine but high glutamic acid content[20]. The present work has demonstrated even more striking dissimilarities from α-keratin in amino-acid composition, including a low content of the aromatic amino-acids contrary to reported high values[9]. Moreover, the majority of the cystine present in the whole medulla analysed in the present work probably arose from the keratinous septæ present in quill of African porcupine[21] and was not detected in the citrulline-rich fraction of medulla.

At the present time it is not known whether during growth citrulline *per se* is incorporated into the medulla and inner root sheath proteins or whether citrullyl residues are derived from arginyl residues. The conversion of arginyl residues to citrullyl while in protein combination has been suggested for the inner root sheath[6-8] and supporting histochemical evidence has been obtained for this mechanism in both the medulla and the inner root sheath[22]. A mechanism of this kind, if it exists, would be unique and could constitute a specialized process in protein biosynthesis in which the imino-nitrogen of the guanidino group might be released (as ammonia or derivative) to nearby cells synthesizing keratin. In addition to introducing difficulties for the 'triple-letter code' of Crick[23] for 20 amino-acids, the direct incorporation of citrulline into proteins would require a specific activating enzyme and *s*-RNA. Nevertheless, a search for such a system in hair follicles is being undertaken as well as investigations into the alternative conversion mechanism.

I thank Mr. A. S. Inglis and Mr. R. J. Rowlands for the amino-acid analyses.

SPORIDESMIN POISONING IN THE RAT

By Prof. C. RIMINGTON, F.R.S., Dr. T. F. SLATER, Dr. W. G. SPECTOR, URSULA STRÄULI, and Dr. D. A. WILLOUGHBY

Departments of Chemical Pathology and Morbid Anatomy, University College Hospital
Medical School, London, W.C.1

SPORIDESMIN is a toxin of as yet unknown chemical structure (empirical formula $C_{18}H_{22}O_6N_3S_2Cl$ (ref. 1)) which is produced by the fungus *Pithomyces chartarum* (formerly *Sporidesmium bakerii*). The toxin is closely associated with the development of facial eczema, an affliction of sheep of great economic importance mainly in New Zealand. Done, Mortimer and Taylor[2] have reported the pathological disturbances in field cases of facial eczema in sheep; similar results have been found by the New Zealand workers to occur with rabbits, guinea pigs and sheep after dosing with sporidesmin (Taylor, A., personal communication). At the request of Dr. Taylor we commenced a study of the effect of sporidesmin on the rat and a comparison of its action with another liver poison, icterogenin[3].

Poisoning was induced in female rats (body-weight approx. 150 gm.) by a single intraperitoneal injection of 1–5 mgm./kgm. sporidesmin. Dosages of the highest level often produced ascites and/or pleural effusions; with such an insult approximately 1 rat in 4 died between the second and eighth days. The rat is apparently more resistant to the toxin than either rabbits or guinea pigs, in which serious liver damage occurs at a much lower dose[1]. The male rat appears more resistant than the female, apparently due to a more rapid detoxication of the toxin. Preliminary experiments in which *SKF*–525 *A* was given to male rats concurrently with sporidesmin indicated that a greater toxicity was obtained than with sporidesmin alone; *SKF*–525 *A* inhibits microsomal detoxication enzyme systems[4].

Animals injected with sporidesmin showed a variety of symptoms associated with tissue damage. Changes in the serum included variable increases in cholesterol, glutamic–pyruvic transaminase and malic dehydrogenase; there were no increases in serum alkaline phosphatase, bilirubin and β-glucuronidase. There were variable decreases in total serum protein; on occasions this was decreased by more than 30 per cent. Serum ribonuclease was also decreased. Serum mucopolysaccharide, as measured by the diphenylamine method[5], was slightly increased (+15 per cent); the increase was of the same order as that found to occur in serum from bronchitic patients[6]. Starch-gel electrophoresis of serum from rats poisoned with sporidesmin showed that in acutely ill animals a new protein band appeared in region *a* (Fig. 1). The position of the new band is similar to the band found to appear after poisoning by certain heavy metals[7] and also to appear in pregnant, immediately post-weaned, and tumour-bearing rats[8]. The electrophoretograms show other differences which will be discussed in more detail at a later date.

Rats treated with sporidesmin developed a proteinuria associated with marked oliguria; the total amount of protein excreted daily was not much affected. Total urinary carbohydrate was virtually unaffected. The urinary amino-acid pattern was normal. There was a moderate increase in the urinary excretion of 17-hydroxy corticosteroids and 11-deoxy-17-hydroxy corticosteroids; the increases were consistent with an ACTH–mimetic effect. Urinary glucuronic acid excretion increased rapidly during the first 24 hr. after injection but had returned to normal by the second day.

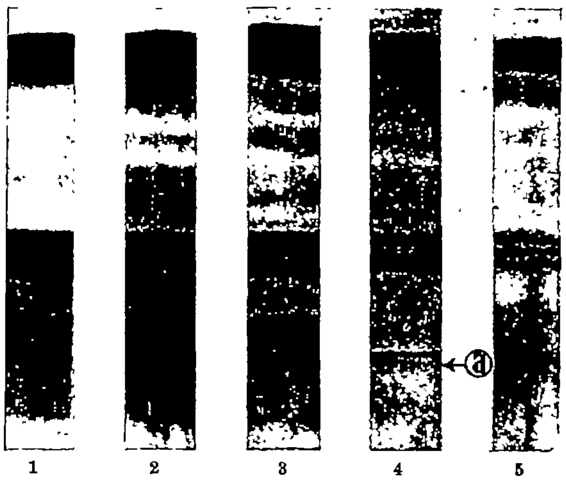

Fig. 1. Starch gel electrophoresis of serum samples from normal and sporidesmin-treated female rats. Electrophoresis was carried out by Poulik's method (ref. 10). Strip 1, normal serum, strips 2–4, sporidesmin-treated animals. The rat corresponding to serum 4 had extensive ascites and the electrophoretic pattern of this fluid is shown in strip 5

Many sporidesmin-treated rats showed decrease in the liver weight although total liver RNAP and DNAP remained in the normal range. Even in animals which were acutely ill there were no noticeable differences in the acid-soluble ribonucleotide pattern; the level of adenosine triphosphate (ATP) was slightly higher in the treated animals than in normal rats. This is possibly a result of the animals entering a state of shock in which the level of liver glycogen is known to fall and that of ATP to rise. In agreement with previous work on the sheep, it was found that treated rats showed adrenal cortical hyperplasia[2]; in the limited number of determinations made, adrenal ascorbic acid and dehydro-ascorbic acid were in the normal range.

Sporidesmin was tested for its effect on several enzyme systems *in vitro*. At concentrations equivalent to 10^{-3}–10^{-5} *M* it had no effect on DPNH–oxidase (with malate or α-ketoglutarate as substrates); on glucose-6-phosphate dehydrogenase; on cytochrome oxidase; on succinate–neotetrazolium reductase; and on the ratio of free/bound ribonuclease in a lysosomal preparation.

Dr. C. H. Gallagher has since informed us that sporidesmin *in vitro* leads to an increased mitochondrial permeability to pyridine nucleotides and, as a consequence, produces a decreased activity in pyridine nucleotide dependent systems. Gallagher has also found that sporidesmin has no effect *in vitro* on succinic oxidase. Although we could find no effect of sporidesmin on DPNH oxidase *in vitro* we did find that the level of DPN in the livers of sporidesmin-poisoned rats was slightly decreased.

In vitro, sporidesmin caused mitochondrial swelling to a limited extent as measured by Tapley's procedure[9]. In addition to this effect on mitochondrial permeability, sporidesmin caused a delayed increase in capillary permeability as measured by the method of Spector[10]. Large amounts of sporidesmin, when injected subcutaneously, produced intense inflammation and abscess formation. It was very active in releasing from rat plasma slow-reacting substances that stimulated the guinea pig ileum and rat uterus preparations. The intense irritant effect of sporidesmin after subcutaneous injection into rabbits had been reported to us previously (Mortimer, P. H., personal communication). Since this manuscript was prepared and sent to Ruakura, New Zealand, for preview, we have learnt that Mortimer, working in Ruakura, has found effects in rats similar to some of those reported here, that is, a delayed increase in capillary permeability and also the production of necrotic zones in the liver.

Pathological lesions produced by sporidesmin in the rat were different from those previously described in the sheep. In almost every instance there was lung damage which took the form of a sustained protein-rich pulmonary œdema with a variable inflammatory or parenchymal reaction. Liver damage was not marked but when it did occur it was in the form of focal necrosis and periportal abscess formation. Biliary hyperplasia was sometimes present but never extensive. The kidney usually showed no abnormalities but in one case there was a necrotizing renal papillitis. Organizing peritonitis and necrotizing inflammation of the subcutaneous and muscular tissues of the injection site were sometimes seen. Tissues routinely examined were liver, lung, kidney, adrenal, ovary, uterus, spleen, heart; and, on occasion, intestine, peritoneal membrane, testis and brain. These results will be described in full elsewhere.

Supplies of sporidesmin were kindly made available to us, through Dr. A. Taylor, by the team working on facial eczema at the Ruakura Animal Research Station, Hamilton, New Zealand. They also gave us much information concerning their own work. We also thank Drs. M. Bulbrook, E. Huehns and D. Y. Wang and Mrs. B. Sawyer for assistance.

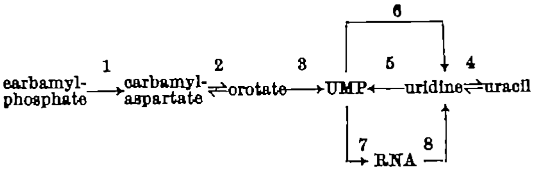
FACTORS INFLUENCING SYNTHESIS OF URIDINE-5′-MONOPHOSPHATE IN RAT LIVER

By Dr. E. REID

Chester Beatty Research Institute, Institute of Cancer Research: Royal Cancer Hospital, London, S.W.3

THE pyrimidine nucleotide moieties of nucleic acids are derived, directly or indirectly, from acid-soluble uridine nucleotides, of which the simplest is uridine-5′-monophosphate (UMP). The latter nucleotide arises from orotate ('*de novo* pathway') or, in some circumstances, from uracil or uridine produced when ribonucleic acid (RNA) or UMP itself is catabolized ('salvage pathway')[1]:



Steps 2, 3, 7 and 8 are actually multi-stage, but can be considered as single steps for the present purpose —which is to survey the overall behaviour of processes for synthesis of UMP in liver, both normally and in certain experimental situations (adrenalectomy, hyperthyroidism and carcinogenesis).

The finding of a change in enzymatic activity *in vitro* does not prove that the rate of the process is correspondingly altered in the animal. In multi-step reaction sequences only one step—perhaps the first step[2]—is likely to be rate-limiting. The limiting step would be expected to have low activity *in vitro* even when assayed under optimal conditions, for example, with respect to *p*H and to substrate concentration. *In vivo*, the conditions may, of course, be less favourable, and there may be other adverse factors: for example, Pardee[2] has shown with a bacterial system that step 1 in the synthesis of UMP is subject to 'feed-back inhibition' by one of the ultimate products (cytidine-5′-monophosphate). With the tissue present at a high concentration in the assay system, as in the present measurements of steps 1, 2, 3 and 5, the observed activity may reflect to some extent any influence of endogenous inhibitors or activators[3].

Steps 1–6 *in normal liver*. In assaying these steps the *p*H was within the range 7·2–8·0, with magnesium ions present in the case of steps 3, 5 and 6, and adenosine triphosphate (ATP) in the case of steps 3 and 5.

Table 1. CHANGES IN ENZYMATIC ACTIVITIES

Changes are expressed on a percentage basis (see text), and are followed by the standard error of the mean (except where there were fewer than 4 observations) and, in parentheses, by the No. of degrees of freedom and by the P value if less than 0·1, where P is the probability that the change could be due to chance. For changes given in bold figures, the P value was $<$0·05

* Excluding old rats (controls for the hepatoma-bearing rats), for which the value was 0·13.

For steps 1, 2, 3 and 5, use was made of substrates labelled with carbon-14, and the reaction product was finally separated by chromatography on 'Dowex-1' resin. The choice of substrate concentration, pH, incubation time, and other variables, was guided by information in the literature[3–10]. Most of the assays were done with whole homogenates (0·25 M sucrose medium) or homogenates freed from nuclei; but for step 3 mitochondria were also removed, to eliminate interference from step 6 (ref. 6). For steps 4 and 5 particle-free supernatant fractions were used.

The enzyme concerned in step 1 is probably located in mitochondria[7] but easily detached[3,4,10]. The observation[8] that nuclear or microsomal fractions can effect step 2 has now been confirmed, but the mitochondrial fraction is more active and may be the true location of the enzymes concerned[7]. It has now been found that two-thirds of this activity is in a latent form which, as for the latent activity of lysosomal enzymes[11], becomes manifest if the tissue preparation is repeatedly frozen and thawed. Assays previously reported[4,5] may well have revealed only the 'free' activity and not the latent activity. Step 6 resembles step 2 in its intracellular location[6] and in its partial latency.

The rate of formation of carbamylphosphate with normal liver *in vitro* is so fast[12] that this process could scarcely be rate-limiting in the *de novo* pathway for the synthesis of UMP. Moreover, it is questionable whether step 1 (formation of carbamylaspartate) is rate-limiting in liver as distinct from bacteria. Step 1 has indeed been reported to have low activity in liver[4,7], of the same order as that of step 2, and the overall conversion of aspartate to UMP was found to be slow in Potter's laboratory (citation in ref. 13). However, in agreement with findings in Cohen's laboratory[3], we have observed the normal activity of step 1 to be as high as 0·5 µmole/gm./min. We have found the normal 'free' activity of step 2 to be only 0·002 µmole/gm./min. (Table 1)—a value of the same order as may be calculated from other reports[4,5]. Although step 3 likewise has low activity (Table 1) and, moreover, is irreversible[1,13], this step is unlikely to be rate-limiting since orotate is undetectable in normal liver[1,13].

Accordingly, the evidence from normal liver argues that in the *de novo* synthesis of UMP it is step 2 (and, in particular, dihydro-orotase[14]) that is rate-limiting —a conclusion which is supported by data discussed below. In the formation of UMP by the salvage pathway, step 5 is presumably limiting; to show even the low activity stated in Table 1, it is necessary to have uridine present in high concentration[9].

Since liver has a high capacity for dephosphorylating nucleotides such as UMP (Table 1, step 6), and a low capacity for the synthesis of UMP, it appears paradoxical that uridine nucleotides are normally present in quite high amount[15,16]. However, the dephosphorylating enzymes are only partly in 'free' form in fresh homogenates and, moreover, can scarcely be saturated with substrate *in vivo*. The concentration of UMP in liver (0·1 µmole/gm. (ref. 16)) is only one-twentieth of that required to achieve saturation when assaying the dephosphorylation of UMP *in vitro*, as in the experiments of Table 1 (step 6).

Enzymatic activities following adrenalectomy, injection of thyroxine, or feeding with a carcinogenic azo-dye. The animals and treatments, and the techniques for homogenization and centrifugation, were as described elsewhere[16–19]. The azo-dye 3′-methyl-4-dimethylaminoazobenzene was fed for 3 months to obtain primary hepatomas (which arose 3–5 months after cessation of dye feeding), and for periods less than the 'critical period'[20] to obtain 'pre-cancerous liver'. Experiments not presented here, with carcinogenic and non-carcinogenic analogues of 3′-methyl-4-dimethylaminoazobenzene[20], have suggested that the biochemical changes observed are specifically associated with carcinogenesis. In the work on adrenalectomized rats, no differences were seen between sham-operated controls and intact controls.

In the work on hepatomas and pre-cancerous liver, enzymatic activities have been calculated per gram of fresh tissue, this basis being considered preferable to a 'per cell' basis[20]. In the hormonal work, activities have been calculated per 100 gm. of body-weight; but the conclusions would be similar if based on tissue weight uncorrected for changes in liver size.

In each group of experimental rats there were certain clear-cut changes in enzymatic activities, as indicated in bold type in Table 1. These changes are best discussed in conjunction with results previously reported from this laboratory, concerning changes in the levels of uridine nucleotides.

Pattern of changes in the hormonal studies. Adrenalectomy produces a biphasic change in the level of UMP: there is an increase at 3 days after the operation, followed by a decline[17]. (An analogous biphasic change has been observed for incorporation of amino-acid into microsomal protein *in vitro*[21].) As predicted[17], it appears that altered availability of orotate accounts for this change in the level of UMP. The 'free' capacity for forming orotate is transiently increased at 3 days, although the 'total' capacity revealed by freezing and thawing the tissue sample is impaired (Table 1, step 2). With the eventual decrease in UMP, the situation becomes more complex. There is an increase in the capacity for the synthesis of UMP by the salvage pathway (step 5); the capacity for synthesis of carbamylphosphate is little altered[22], but there is evidence of impairment of the *de novo* pathway at steps 1 and 2 (Table 1), and also of increased utilization of UMP for the synthesis of RNA (ref. 17)—a process which may be quite fast *in vivo* even with normal liver (say, 0·01 μmole of UMP incorporated/gm./min.).

Thyroxine, even in a single dose of 0·1 mgm., decreases the levels of uridine nucleotides such as uridine triphosphate (UTP), although not of UMP itself[17]. Since ATP is also decreased[17], there may well be impairment both of the synthesis of UMP and of phosphorylation of the UMP to UTP. A single dose of thyroxine does in fact reduce the 'free' capacity for the synthesis of orotate (Table 1, step 2). The activity of step 1, by which carbamylaspartate is formed, can likewise be reduced by thyroxine, but only slightly with a single dose of 0·1 mgm.—which supports the argument that this step is less important than step 2 in governing the *de novo* synthesis of UMP.

It is unlikely that the effects of adrenalectomy and of thyroxine on uridine nucleotide levels are due to altered rates of nucleotide catabolism. There are no changes in the 'free' capacity for dephosphorylation of UMP, in the 'total' capacity as tabulated (Table 1, step 6), or in the capacity for dephosphorylation of UTP.

Pattern of changes in the azo-dye studies. The levels of uridine nucleotides, and particularly of UMP, show a marked rise within 10 days of commencing azo-dye feeding[18,23]. The data in Table 1 for step 5 suggest that this is due to increased activity of the salvage pathway. The rise in uridine kinase is evidently not a sequel to an enzyme 'deletion' in the *de novo* pathway. Step 1 of the latter pathway initially shows variable behaviour and later a decline which, however, is evident only after 3 weeks of dye feeding (Table 1); moreover, as already argued, it is unlikely that this step is rate-limiting. Steps 2 and 3 show no change in activity. It is conceivable that with the rise in UMP there is a depression of some step of the *de novo* pathway *in vivo*, not evident *in vitro*; but such a 'feed-back inhibition' of step 1[10], 2[10] or 3[18] by UMP is demonstrable *in vitro* only with UMP at a concentration much above that found in pre-cancerous liver.

The rise in the level of UMP is, then, not due to increased activity of the *de novo* pathway; nor is it attributable to decreased dephosphorylation of UMP (Table 1, step 6), or to decreased utilization of UMP for the synthesis of RNA (ref. 18). It is, however, not proved that the increased activity of uridine kinase (step 5) found *in vitro* connotes acceleration of the salvage pathway in the animal; one reason for hesitation is that ATP, which is requisite for this step, is diminished in amount in pre-cancerous liver[18,23].

In primary hepatomas the levels of certain uridine nucleotides, including UMP and UTP, tend to rise, but less strikingly than in pre-cancerous liver[18,23]. As is shown in Table 1, the capacity for the *in vitro* synthesis of UMP by the salvage pathway (steps 4 and 5) is greatly increased, in accordance with observations by Rutman *et al.*[24], who injected labelled uracil into hepatoma-bearing rats and found a high uptake by the hepatomas. (Since, however, with the high dose of uracil used in their work the tissue was probably 'flooded' with uracil, it is not proved that there was an increase in the actual, as distinct from potential, rate of synthesis of UMP from endogenous uracil or uridine).

Study of the *de novo* pathway in primary hepatomas (Table 1) has shown that step 3 is impaired, step 1 is enhanced (in agreement with a previous report[3]), and step 2 is usually enhanced at least with respect to 'total' activity. (In transplanted hepatomas, step 1 is undiminished[25]; the capacity for supply of carbamylphosphate is lowered[25], but it is doubtful if this supply is rendered limiting.) If the conversion of orotate to UMP (step 3) were to become rate-limiting in primary hepatomas, orotate would accumulate and, by a mass-action effect[1], damp down its own synthesis. However, we have so far found no evidence of such an accumulation, and conclude that the *de novo* pathway is unimpaired or even enhanced.

If, then, there is a high capacity for the synthesis of UMP in hepatomas, at least by the salvage pathway, why do hepatomas show only a moderate rise in nucleotides such as UMP and UTP? Possibly there is faster incorporation of uridine nucleotides into RNA (step 7)[16]. Another factor may be a higher capacity for the catabolism of uridine nucleotides, as now shown with UMP (Table 1, step 6) and with UTP (not tabulated).

The catabolism of RNA to uridine (step 8) may likewise be accelerated in hepatomas, since there is evidence of increased 'free' activity of acid ribonuclease[20] and of a higher capacity for dephosphorylation of the uridylic acid (3′-isomer of UMP) thus liberated. Evidently primary hepatomas do not show a general suppression of catabolic processes[9], although there may indeed be a slowing of late stages of catabolism such as the oxidation of hypoxanthine[20]. The evidence concerning UMP and RNA points to faster turnover in hepatomas, rather than to a serious imbalance between anabolism and catabolism.

Primary hepatomas as now obtained admittedly show some histological and biochemical variability[20], but they often show little necrosis (except in the 'core', which is routinely rejected) and, moreover, they appear to have arisen from parenchymal cells. It is therefore felt that the present results are a valid contribution to the understanding of neoplasia. In regenerating liver, there is an early rise in uridine kinase[8,9] and in aspartate transcarbamylase[3], and an eventual rise in uridine phosphorylase and (in contrast with hepatomas) in the enzyme system which converts orotate to UMP (ref. 8). Further study is warranted concerning analogies between liver regeneration and azo-dye carcinogenesis.

Conclusions. In the *de novo* pathway for the biosynthesis of uridine nucleotides in rat liver, the rate-limiting step is probably the conversion of carbamylaspartate to orotate. Even with tissue homogenates treated so as to liberate latent activity, this conversion is notably slow. Changes in the rate of this conversion underlie the changes in uridine nucleotide levels observed 3 days after adrenalectomy or in hyperthyroidism.

In pre-cancerous liver, the observed rise in the level of UMP is attributable to enhanced activity of uridine kinase. In primary hepatomas, uridine kinase is likewise increased, and the activity of the *de novo* pathway appears to be increased or at least undiminished. The lack of a marked rise in the level of UMP in hepatomas is attributable to faster turnover; the belief that catabolic processes are suppressed in tumours is an over-simplification.

Controlling factors not disclosed by the present assays may be operating in the animal. Moreover, increased activity of uridine kinase cannot be taken to prove that the salvage pathway is accelerated *in vivo*. Experiments in this laboratory with labelled uracil, injected in low dosage, have shown no increase in uptake when uridine kinase activity is increased[23]; to prove that the salvage pathway is nevertheless accelerated, it would be necessary to show that the endogenous 'pool' of uridine or uracil is enlarged.

INHIBITION OF GLUTAMIC-ASPARTIC TRANSAMINASE BY ANTIBODIES

By Dr. FÉLIX CÓRDOBA, CONCEPCIÓN GONZÁLEZ and AARÓN PÉREZ

Department of Biochemistry, School of Medicine, National University of Mexico

CINADER[1] has reviewed a good deal of the work on the neutralization of enzymes by antibodies but very few of the numerous investigations concerning glutamic-oxaloacetic transaminase (GOT) enzymes are of this nature. The reasons for this may be: transamination involves a shift of amino-groups from one compound to the other rather than the formation of a totally new product. Size of substrate, which as pointed out by Cinader[2] is so important in these reactions, is here comparatively small. The apoenzyme, against which one would like to direct the antibodies, has only recently been described by Banks[3] as purified and, finally, the apparent fact, discovered by Fleisher[4], of a family of 'isoenzymes' in a given tissue does not favour this method of approach.

Córdoba *et al.*[5] have been able to obtain enzymatic inhibition by using sera from GOT-injected rabbits and hens. This article describes some of the serological characteristics of this neutralization.

Human hearts and livers, monkey (*Macacca cynomolgus* hearts and livers and pig hearts were cleaned, minced and homogenized with three volumes of cold water. Fibrous material was removed by gauze filtration and 30 gm. ammonium sulphate added to the supernatant and the precipitate discarded.

Table 1. PERCENTAGE INHIBITION OF CRUDE MONKEY HEART GOT WITH HEN ANTI-MONKEY HEART PLASMA GLOBULINS

Plasma inhibitor (mgm./protein)	Enzyme activity tested 10 units	27 units	30 units	40 units
0·118	10	2	0	0
0 237	21	7	3	0
0 475	43	22	14	2
0·950	73	58	50	38
1 900	94	80	71	60

Table 2. EFFECT OF TIME OF INCUBATION AND DILUTION ON THE INHIBITION OF MONKEY HEART GOT WITH HEN ANTIBODIES

Incubation time (hr.)*	Per cent inhibition of 15 units	Incubation vol.† (ml.)	Per cent inhibition of 9 units
2	75, 73	0·4	83, 86
24	78, 78	0·8	84, 87
48	73, 73	1·3	86, 83
—	—	1·7	86, 83

* All tubes incubated 2 hr. at room temperature and additional time in the refrigerator at 4° C.

† Final volumes of 3 7 ml. Experiment conducted for 2 hr. incubation at room temperature.

Table 3. INHIBITION AND HÆMAGGLUTINATION OF MAMMALIAN TISSUES GOT WITH HEN ANTI-MONKEY HEART GLOBULINS

Bleedings of hen No. 2	Enzymes tissue sources: Monkey heart Inhib. per cent	Monkey heart Hæmgl. titre	Pig heart Inhib. per cent	Pig heart Hæmgl. titre	Monkey liver Inhib. per cent	Monkey liver Hæmgl. titre	Human liver Inhib. per cent	Human liver Hæmgl. titre
Pre-immuniz.	0	0	0	12	0	0	0	12
First week	93	1,536	95	1,536	88	192	50	384
Second week	85	384	58	96	50	192	50	96
Third week	10	48	45	24	16	12	—	12

Inhib., percentage inhibition tested with 10±3 units of enzyme. Hæmgl., inverse of titre in the tannic acid hæmagglutination test.

According to Green *et al.*[6], 40 gm. of the same salt precipitates the bulk of the enzymes. This precipitate was dissolved in 0·9 per cent sodium chloride dialysed extensively and stored in small vials in a freezer.

Immunization was carried out by injecting into the wing veins of adult hens (local strain 500) 1 ml. of the monkey heart preparation containing 18·7 mgm./protein/ml. analysed by the Folin reagent of Kabat and Mayer[7]. Monkey liver preparation, at a concentration of 24 mgm./protein/ml., was similarly injected three times a week. At the end of each week, blood was collected into centrifuge tubes, filled with 0·25 vol. 1·1 per cent sodium citrate, and the plasma fractionated according to Gregory[8], by addition of one-third (v/v) saturated solution of ammonium sulphate at room temperature. The γ-globulin precipitate was dissolved in saline, dialysed and stored in the cold at − 30° C.

The measurement of enzymatic activity and the serological inhibition was obtained by spectrophotometric determinations of the oxalacetic acid produced by the action of the enzymes in a set-up as follows: 0·1 ml. of enzyme dilution, pyridoxal phosphate (20 μgm.), 2 ml. substrate in *tris* buffer at *p*H 8·6 with 200 μmoles aspartic and 2 μmoles α-ketoglutaric acids, 100 μmoles sodium tetraborate and 1 μmole magnesium sulphate. The controls were completed to volume with 0·8 ml. saline and the experimental ones with 0·1–0·3 ml. of the γ-globulin solutions plus the required saline. The oxalacetic acid formed was measured at 1-min. intervals by readings of the optical density at 290 mμ (1 unit: 0·001 *O.D.*/min : 0·0011 μmole oxalacetic acid) in the Beckman *DU* spectrometer. For the evaluation of the antibody in the neutralizing sera Boyden's tannic acid hæmagglutination test, as modified by Stavitsky[9], was used. 0·25 mgm./protein of each tissue enzyme preparation was used to sensitize 1 ml. of a 1 : 40 suspension of absorbed tannic acid-treated normal red cells. The agglutination patterns were examined 18 hr. later.

The inhibition plots using monkey heart enzymes with hen anti-monkey heart γ-globulins presented in Table 1 show a correlation between neutralization and amount of neutralizer on one hand, and degree of inhibition and enzyme concentration on the other. These results are comparable with recent findings of Gregory and Wróblewski[8] in the lactic acid dehydrogenase anti-L.A.D. systems.

Results in Table 2 show that the inhibition is not altered by changing the time of interaction of enzyme (antigen) with antibodies from the usual 2-hr. period up to 48 hr. It is also shown how the neutralization effect is not sensitive to certain changes in volume in that length of time. Variations of volume up to four times did not modify appreciably the observed neutralization. In this respect, the transaminase–anti-transaminase system behaves like most antigen–antibody reactions[7].

In Table 3 are given the serological results obtained using monkey heart anti-transaminase against different tissue enzyme preparations. The activity of the enzyme sources was pre-set at 10 ± 3 units and were tested for antibody neutralization by the usual procedure. The same enzyme extracts were then used for sensitizing 'tanned' erythrocytes and tested against the anti-monkey heart globulins in the hæmagglutination test. The first week's blood shows a titre (inverse of the dilution) of 1,536 and an inhibiting power of 93 per cent when tested with the homologous antigen. The titre in the second week's blood is only 384 and the inhibiting power 85 per cent. By the third week, the titre has dropped to 48 with only 10 per cent of neutralization capacity. The pig heart preparation, when tested against the same antiserum, behaved strikingly similar. Both human and monkey liver enzymes, on the contrary, were agglutinated and inhibited to a much lesser degree.

Absorption on the anti-monkey heart globulins was carried out with the three heterologous extracts during one week in the refrigerator. The supernatant was tested again for neutralization to the monkey heart preparation; but this time no inhibition was demonstrable. This result suggests a combination of the anti-enzyme(s) with heterologous tissue extract components with a consecutive removal of inhibitors from the antibody solution.

The enzyme–anti-enzyme combination produced discrete precipitates. Attempts to locate the missing activities by re-suspending the precipitates in saline with co-factor and substrate failed. The addition of an excess of soluble enzymes, in an attempt to bring the precipitates to antigen excess and liberate the supposedly trapped activity, was also unsuccessful.

The neutralization observed seems compatible with an immunological effect. The plasma globulins from the immunized animals showed inhibitory power subsequent to the injections, and this was reflected in an agglutinating ability roughly parallel to the neutralization of the enzyme(s). The fact that the precipitate was inactive, favours the hypothesis of a close combination of the enzyme(s) with the antibodies. Although this interpretation is attractive, confirmation awaits the purification of the GOT enzymes in these extracts by methods like those used by Córdoba and Ortega[10]. The absorption of the inhibiting activity by heterologous tissue extracts also runs in favour of the immunological nature of the phenomenon, and here again only quantitative immunochemical analyses with homogeneous antigens can prove the validity of this conclusion.

LIPID METABOLISM IN HIGHER PLANTS*

By Prof. P. K. STUMPF†

Department of Biochemistry and Biophysics, University of California,
Davis, California

INFORMATION concerning the anabolic and catabolic fate of lipids in higher plants merits the attention of not only the plant biochemist and the plant physiologist but also the comparative biochemist who is interested in the metabolic mechanisms of a broad spectrum of organisms. As summarized in Fig. 1, during the past ten years we have been examining some of these mechanisms in higher plants; here I shall limit myself to a discussion concerning the degradation and synthesis of straight chain fatty acids. I shall not cover areas involving phospholipids or the glyoxylate bypass.

α-Oxidation. In 1952 Newcomb and Stumpf[1] observed that carbon dioxide labelled with carbon-14 was rapidly released when palmitic-1-^{14}C was added to a homogenate of cotyledons of germinating peanut seeds. Differential centrifugation of the homogenate yielded several fractions of which both the microsomal fraction (obtained by centrifugation at 100,000*g* for 1 hr.) and the supernatant fraction were active. However, while the supernatant fraction only decarboxylated palmitic-1-^{14}C, the microsomal fraction could readily release $^{14}CO_2$ from both internally labelled and carboxyl labelled palmitic acid, providing NAD$^+$ had been added to the reaction mixture. When the supernatant soluble proteins were submitted to ammonium sulphate fractionation, all decarboxylation activity was lost, but this could be restored on addition of boiled crude supernate. Castelfranco *et al.*[2] isolated and identified the unknown co-factor as glycolic acid. Further experimentation readily proved that an α-hydroxy acid in the L-series could substitute for glycolic acid in the decarboxylation of palmitic acid. In 1956 Stumpf[3] demonstrated that glycolic acid functioned as a substrate for glycolic oxidase for the purpose of forming hydrogen peroxide. In addition to carbon dioxide, long-chain aldehydes were also formed. Finally, in 1959, Martin and Stumpf[4] described the interrelationship of two discrete enzymes: (*a*) a specific fatty acid peroxidase which catalysed the decarboxylation of long-chain fatty acids from C_{13} to C_{18} to yield carbon dioxide and a long-chain aldehyde containing one less carbon atom ; (*b*) a long-chain aldehyde dehydrogenase which in the presence of NAD$^+$ oxidized the aldehydic group to the carboxylic group.

This reaction sequence has been named α-oxidation to distinguish it from the more widespread β-oxidation sequence which occurs in plant cells. α-Oxidation is a limited type of degradation but has been found in several plant tissues. The commonly occurring plant peroxidases are totally inactive in this reaction. The role of α-oxidation in plant cells is somewhat puzzling although one can speculate possible functions: (*a*) as a source of long-chain aldehydes and their reduction products, long-chain alcohols, which may then be used as substrates for the formation of waxes; (*b*) for the formation of odd-chain fatty acids which may then enter the β-oxidation sequence and be converted to propionic acid.

β-Oxidation. Although considerable difficulty has been experienced in the past in attempts to demonstrate the occurrence of β-oxidation, in 1956 Stumpf and Barber[5] realized that the success of its demonstration depended on using only trace amounts of fatty acid substrates since amounts greater than 0·5 μmole proved to be toxic and markedly inhibited mitochondrial respiration. Barber was able to prepare mitochondrial particles which, when supplemented with ATP, CoA, Mn^{++}, NAD$^+$, NADP$^+$, and a TCA cycle acid, could readily oxidize a long series of fatty acids to carbon dioxide and water. Mitochondrial preparations from peanut cotyledons, avocado mesocarp, lupine and pine seedlings have been found to contain the system. Of interest is the observation that propionic acid is also readily oxidized.

Modified β-oxidation of propionic acid. The comparative biochemistry of propionic acid is of interest. In 1957, Flavin and Ochoa[6] had shown that the following sequence holds as the major pathway of oxidation in animal tissues:

$$CH_3CH_2COOH + CoA + ATP \rightarrow CH_3CH_2CO - CoA \quad (1)$$

$$CH_3CH.CO - CoA + CO_2 \rightarrow CH_3CH(COOH)CO - CoA \rightarrow \text{succinyl} - CoA \quad (2)$$

Recently it has been shown that biotin is the co-factor for the carboxylation reaction and a cobamide derivative is the co-factor for the subsequent isomerization reaction. Of some interest is the repeated observation made by many workers that vitamin B_{12} or its derivatives do not occur as a functioning unit in the normal plant cell. Plants can passively accumulate vitamin B_{12} from the soil environment; but the vitamin does not appear to participate in any reactions in the plant cell. A notable exception is the observation made recently by Kliewer and Evans[7] that cobamides occur in nodules of roots of legumes and the alder tree and may indeed play an important part in the process of symbiotic nitrogen fixation. Because of the absence of vitamin B_{12} or its derivatives in the normal plant cell, the Flavin–Ochoa mechanism can be dismissed as occurring in plants. Moreover, Hatch and Stumpf[8] have recently shown that methylmalonic acid is inert in plant slice experiments although it can be formed by the carboxylation of propionyl CoA.

On the basis of the kinetics of formation of $^{14}CO_2$ from differently labelled propionic acid, the isolation of β-hydroxypropionic acid from reaction mixtures, and the location of radioactive carbon in succinic acid (formed the reaction mixture) depending on the position of the label in the initial substrate, pro-

---

Since this article is not intended as a review of the subject, only references pertinent to the discussion are cited.

† Senior Postdoctoral Fellow of the U.S. National Science Foundation, 1961; John Simon Guggenheim Fellow, 1962.

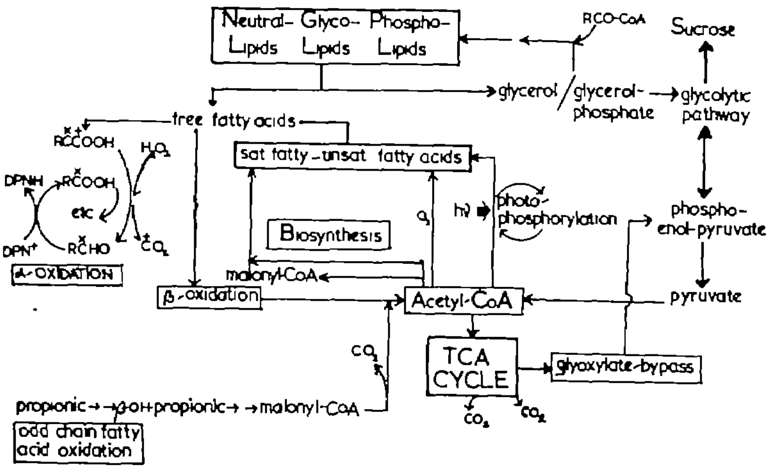

Fig. 1. General summary of lipid metabolic activities in higher plants

pionic acid, Giovanelli and Stumpf[9] have proposed the pathway outlined as follows:

$$\begin{aligned} &CH_3CH_2COOH + CoA + ATP \rightarrow CH_3CH_2CO - CoA \rightarrow \\ &CH_2 = CHCO - CoA \rightarrow CH_2OHCH_2CO - CoA \rightarrow \\ &CH_2OHCH_2COOH \rightarrow CHOCH_2COOH \rightarrow \rightarrow \\ &\quad CoA - COCH_3 + CO_2 \rightarrow \text{TCA cycle acids} \qquad (3) \end{aligned}$$

It should be noted that Vagelos and Stadtman[10] have proposed a slightly different pathway for propionate degradation in several bacteria. Their pathway differs from that which occurs in plants in that β-hydroxypropionyl CoA, formed from propionic acid by similar reactions, is oxidized as a CoA derivative and therefore the carbon dioxide is derived from C-3 of propionic acid rather than from C-1 (as in plants), and acetate is formed from carbons 1 and 2 rather than from carbons 2 and 3, as in plants.

Propionic acid is a rare acid in plant tissues. It is quite possible that by the participation of an effective oxidative pathway, the plant cell can readily remove any newly formed propionic acid and thereby propionic acid-levels never build up to a significant concentration. Moreover, propionic acid may in part act as a precursor of the pyridine ring in the alkaloids nicotine and ricinine. Byerrum *et al.*[11] have recently suggested that carbons 1 and 2 of the pyridine ring may be derived from carbons 3 and 2 of propionic acid. Similar results have been obtained by Waller and Henderson[12] in their studies on the pyridine ring derivative of ricinine. In addition, Hatch *et al.*[8] have shown that β-alanine is formed from propionic acid in a variety of plant tissues. It is also of interest that glycerol, another product of lipid metabolism, contributes its carbon skeleton to carbons 4, 5 and 6 of the pyridine ring[13]. Thus we can implicate two substrates in the area of lipid metabolism, propionic acid and glycerol, as important precursors of pyridine biogenesis and CoA biogenesis (β-alanine).

Table 1. COMPOSITION OF FATTY ACIDS IN AVOCADO MESOCARP AND NEWLY SYNTHESIZED FATTY ACIDS BY PREPARATIONS OF AVOCADO MESOCARP

Type of tissue	Percentage Palmitic	Stearic	Oleic	Linoleic
Avocado mesocarp	20	1	60	18
Mitochondrial lipid	15	1	70	15

Slice	48	10	31	3
Mitochondrial prep.	50	30	20	1
Acetone powder extract	25–40	60–75	0	0
Sonicate prep.	14	59	9(+13)*	—

* 13 per cent includes polar long-chain fatty acid.

Biosynthesis. In 1952 Newcomb and Stumpf[14] fed radioactive substrates to slices of cotyledons of maturing (synthesizing) and germinating (degradative) peanut seeds. In both systems, acetate was the most effective of several tested for incorporation into long-chain fatty acids. In 1957, Stumpf and Barber[15] initiated a series of investigations of the incorporation of acetate into long-chain fatty acids by various preparations obtained from avocado mesocarp. Table 1 summarizes some of the results obtained with various preparations. Note the alteration of the composition of newly synthesized fatty acids from acetate by the different preparations. It would appear as if the unsaturation process is rather unstable and tends to disappear in the various cell-free systems. A more detailed analysis of these preparations will now be undertaken:

Particulate system. Stumpf and Barber[15] prepared a particulate system from ripe avocado mesocarp. This preparation possessed TCA activity, oxidative phosphorylation, and β-oxidation, three typical systems always found associated with mitochondrial particles. The soluble proteins freed from mitochondrial particles had no capacity to synthesize fatty acids, while the particulate system readily incorporates acetate into palmitic, stearic and oleic acids. ATP, CoA, Mn++ and carbon dioxide were essential co-factors. When either stearic or palmitic acid is added as substrate both are incorporated unchanged into triglycerides and phospholipids, providing both ATP and CoA are present. Thus while these acids are readily activated to acyl CoA derivatives, there is no evidence that they are elongated or serve as precursors of oleic acid. Mudd and Stumpf[16] have considerably extended the original observations, particularly with regard to the factors involved in oleate biosynthesis from acetate. The critical factor proved to be the degree of aerobiosis in a given reaction mixture. Thus under strictly anaerobic conditions acetate is incorporated only into palmitic acid (61 per cent) and stearic acid (39 per cent) whereas under aerobic conditions 53 per cent palmitic and 1 per cent stearic are formed as well as 46 per cent oleic. Oleic acid synthesis is not inhibited by cyanide or azide. At first glance it would appear as if stearic acid had a precursor relationship to oleic acid; however, under strongly aerobic conditions, while oleic acid is formed from acetate readily, added palmitic or stearic acid does not affect oleic synthesis. Either stearic acid is not a precursor or if it is it must be enzyme bound and therefore not in equilibrium with exogenous stearic acid.

Acetone-powder extracts of particulate fraction of avocado mesocarp. Barron, Squires and Stumpf[17] have prepared extracts of acetone powders of avocado mesocarp particles which readily incorporate either acetyl CoA or malonyl CoA into long-chain fatty acids with little, if any, formation of oleic acid. These acetone powders are extremely stable in that they can be kept for two or more years at − 10° with little if any loss in activity. The saturated fatty acid synthesizing system is extremely sensitive to avidin with 20γ giving a 78 per cent inhibition when acetyl CoA is the initial substrate; with malonyl CoA as the substrate avidin is ineffective. ATP and carbon dioxide are required with acetyl CoA as substrate whereas with malonyl CoA these co-factors are not required. The properties of this system seem to be very similar if not identical to those described by Lynen[18] for yeast system and by Wakil[19] for chicken liver system. However, in contrast to these two systems, the avocado system is always associated with particles.

Sonicated avocado particles. Since acetone treatment of the particulate system completely destroys the capacity of the particles to synthesize oleic acid, several attempts were made to solubilize the unstable enzymes associated with these particles[20]. An active preparation could be obtained by exposing the particles to a brief sonication under hydrogen with a subsequent high-speed centrifugation. The clear supernatant had the capacity to synthesize long-chain fatty acids. Surprisingly, when malonyl CoA was the initial substrate only palmitic and stearic acids were formed whereas with acetyl CoA 59 per cent of the total radioactivity was associated with stearic acid, 14 per cent with palmitic, 9 per cent with oleic, and the remaining 13 per cent with a long-chain polar acid having properties of a hydroxy acid. Addition of octanoic, decanoic, palmitic and stearic acids or palmityl CoA and stearoyl CoA to the enzyme preparation did not lead to oleic acid synthesis. It would appear as if there are two separate pathways for the synthesis of fatty acids, one for unsaturated and the other for saturated fatty acids. What the nature of these pathways is remains for future exploration.

Light-stimulated chloroplast incorporation of acetate. Chloroplasts[21] are usually considered to be the site of photosynthesis and consequently the site of sugar biogenesis. They are unusually rich in lipids, which presumably maintain the lipo-protein insulating layers in the grana where the photo-excitation process occurs. Smirnov[22] has already reported a biosynthetic system in spinach chloroplasts which requires light, ADP, Mg^{++}, CoA and acetate to form long-chain fatty acids. We have recently examined lettuce chloroplasts[23] for their capacity to synthesize fatty acids from acetate and have described a system which requires ATP or ADP, inorganic phosphate, CO_2, NADPH, and oxygen to synthesize palmitic and oleic acids from acetate. In the dark the system incorporates only small amounts of acetate; but in the light a very marked increase is consistently observed. Light undoubtedly participates by activating a non-cyclic photophosphorylation mechanism which thereby supplies to the lipid-synthesizing system ATP, NADPH, and oxygen, all important components in the incorporation of acetate into long-chain fatty acids. However, there is also evidence to suggest that light has an additional function in the synthesis of fatty acids. Apparently both photophosphorylation and lipid synthesis are tightly coupled and any disturbance in this coupling will disrupt lipid synthesis. Thus, ammonium ions and CMU, both effective inhibitors of photophosphorylation, will greatly decrease acetate incorporation into long-chain fatty acids. Moreover, ATP, NADPH and oxygen, the primary products of non-cyclic photophosphorylation, will not replace the requirement for light.

In summary, an examination into some of the mechanisms in higher plants for the synthesis and degradation of fatty acids has revealed several new and interesting systems as well as systems which are very similar to, if not identical with, those found in other living organisms. The incorporation of this knowledge into such diverse systems as carbohydrate and alkaloid biogenesis and photosynthesis once more demonstrates the interdependence and intermeshing of seemingly unrelated biochemical areas.

METAL DEFICIENCIES IN BANANAS

By C. G. JORDINE

Banana Board Research Department, Kingston, Jamaica

Manganese

THE only record known to me of a minor element deficiency in the banana is that for zinc described by Moity[1] on Dwarf Cavendish bananas in the French Guinea. Recently, a peculiar disorder has been observed on the Lacatan, Robusta and Gros Michel varieties in a few areas; the results of foliar spray treatments and leaf analysis suggest a manganese deficiency.

The earliest visible symptom is a marginal, interveinal chlorosis on the younger leaves. This chlorosis advances towards the mid-rib, and pinhead-sized dark brown and black spots appear on the upper surface of the leaf, mainly within the chlorotic area; spots in the green area of the leaf usually have a pale yellow margin. The spots, mainly confined between the veins, increase in diameter to 1–3 mm. and begin to coalesce until oblong necrotic patches with orange margins are formed. Necrotic areas eventually fuse to form a brown margin often around the entire leaf. The margin appears crinkled, drawn together and gives the leaf a boat-shaped appearance when untorn. Examination of the necrotic band reveals many brown or black, circular and oval spots on the dead tissue. The inner part of the leaf-blade remains green with varying numbers of necrotic areas with orange-yellow margins. Marginal necrosis advances with age of leaf until eventually the whole leaf turns brown and dies (Fig. 1).

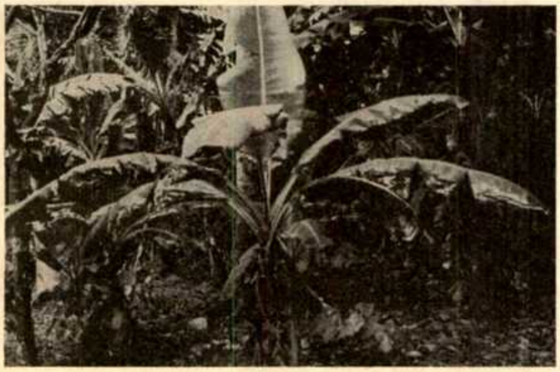

Fig. 1. Banana plant suffering from a deficiency of manganese

Affected plants usually produce bunches of fruit with widely distributed raised spots, dark brown to black in colour. Meredith[2,3] has described this unusual form of fruit spot and has discovered that the fungus *Deightoniella torulosa*, which causes 'speckle' (fruit-spot or 'swamp-spot') of Jamaican bananas also causes the scab-like spots on the fruit. In fact, on affected fingers there is usually a range of spots from the tiniest fruit spot with water-soaked halo to the large scabs up to 6 mm. in diameter (Fig. 2). The fact that the scab-like spots on the fruit were confined to certain areas, and had not spread, strongly suggested that some other factor, possibly a soil or nutritional condition, was associated with the disorder.

Preliminary examination revealed that there were two soil types on which the condition occurred. One known as 'Wait-a-bit clay', a normally acid, highly leached soil, showed up the disorder on any alkaline spot such as roadside ditches with limestone washings from the road. The other soil type, known as 'Killancholly clay', was a rendzina and the condition occurred on areas with very high lime contents.

Foliar spray treatments were carried out on two severely affected plants using the following treatments: 2 per cent magnesium sulphate, 1 per cent manganese sulphate, 1 per cent ferrous sulphate, 1 per cent borax, 1 per cent ammonium molybdate, 1 per cent zinc sulphate, 1 per cent ammonium sulphate. There was also a soil treatment of 16 lb. sulphur/root given once a year. The foliar spray treatments were given once every two months at first, but after four months this was changed to once every month. The manganese sulphate treatment improved the condition of the affected plants. At the time of shooting one of the plants so treated had the four youngest leaves unaffected, the next three leaves slightly affected and the last two leaves severely affected. The other plant had all eight leaves unaffected. The treatment has also considerably reduced the degree of spotting or 'scabbing' on the fruit.

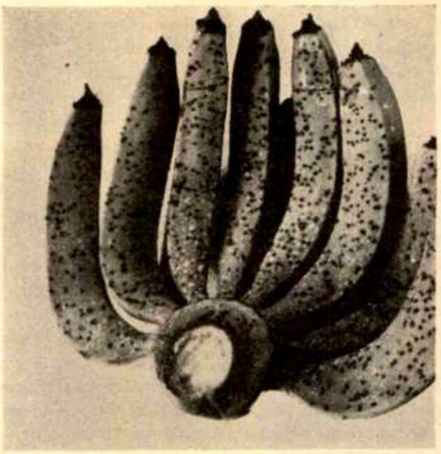

Fig. 2. Hand of fruit from manganese-deficient plant. Note wide distribution of spots

A weekly foliar spraying treatment of a similar nature as the former was carried out and plants sprayed with manganese sulphate gave response within two weeks. Leaves produced after this interval were all unaffected and after fourteen weeks the condition was non-existent. Leaf samples were taken from affected and also unaffected plants in one such area at Hopewell, St. Mary. The method of sampling is that of Boland[4]. The results showed that manganese was very significantly lower ($P < 0{\cdot}001$) in affected leaves.

The relation of soil *p*H on the 'Wait-a-bit clay' and the disorder described are in agreement with the existence of a manganese deficiency, as the main factor which controls the available manganese in the soil is *p*H. The more acid a soil, the greater is the availability, the more alkaline a soil the less is it.

Usually where the black scab occurs on banana fruit there is every gradation in size of spots from the typical 'speckle' to the scabs of varying diameters. Both are caused by the same fungus, but the black spots or scabs only exist in certain areas where, as a result of the lime content of soils, the plants suffer from a manganese deficiency. Stahel[5] describes *D. torulosa* as a powerful parasite, and thus it may be that 'fruit-spot' or 'speckle' may be reduced, though perhaps not prevented, by optimum levels of manganese in the banana plant. It may also be that apart from the factors detailed by Meredith[2] as affecting the incidence and degree of speckling the available manganese in the soil might be operative. Experiments are to be set up to test this.

Zinc

A peculiar chlorosis and narrowing of the leaves of Lacatan bananas has been observed on the St. Catherine plains, Jamaica, for a number of years. Preliminary work[6] showed that the soils and the leaves of plants in such areas were very high in available phosphate ('Truog') and percentage phosphate, respectively. The results of recent foliar spray treatments and the similarity of the foliar symptoms to those described by Moity[1] on Dwarf Cavendish bananas in the French Guinea suggest a zinc deficiency.

Symptoms may appear in 1-month-old plants, but they are more commonly observed in plants 2–5 months old. The foliage may appear bunched and the growth habit stunted; leaves are uniformly narrow, or narrower towards the tip end than the petiolar end, or less often, narrower towards the petiolar end than the tip-end. Length–breadth ratios of leaves of up to 8·6 : 1 have been observed. Affected leaves may be (*a*) apparently wholly green, (*b*) green, but with transverse pale stripes bleached of much of the chlorophyll alternating with transverse greener bands, or (*c*) bleached of the normal green colour thus being creamy white (sometimes the leaves are almost completely bleached at the petiolar end but green with transverse chlorotic bands towards the tip end). In the pale green, bleached areas of the leaves, numerous lighter coloured blemishes, oblong in shape, 1–5 mm. in length, and parallel to the leaf venation develop, and many of these 'dashes' become necrotic on ageing. A number of the chlorotic or whitish areas on affected leaves may develop into necrotic spots, 2 or more inches wide, and with concentric rings. Older leaves sometimes show a general bronzing or chlorophyll deficiency with a brown scorching and rotting along the margin or over the entire leaf-blade.

Leaves described under (*b*) and (*c*) soon become yellowed, particularly in the pale green and bleached areas; this yellowing is usually more pronounced on the side facing the Sun. Leaves described under (*a*) may also show a yellowing, but there are plants which do not have the chlorotic striping or any noticeable narrowing of the leaves but have yellow patches particularly near the midrib on the side of the leaf facing the Sun. These yellow patches are sometimes 'burnt out', leaving dead areas. Affected plants may produce a few normal leaves which, in turn, may be followed by affected ones. Many plants grow out of the condition but it may recur when the plants have fruited. Plants showing symptoms of the deficiency at shooting develop more marked symptoms with yellowing and bronzing during fruit development. On some plants without discernible symptoms before fruiting, as the fruit develops the leaves become bronzed and yellow, particularly near the petiolar ends.

On severely affected plants fruit development is slow, the young bunch remaining horizontal or near horizontal for an unusually prolonged period. The fingers seem twisted and are shorter, smaller, thinner and usually lighter green in colour than those of normal fruits. The distal ends of the fingers of affected fruit are nipple-shaped (Fig. 3) in appearance whereas normal Lacatan fingers possess a blunt distal end. A comparison of fruit from affected plants with that from unaffected plants with a similar number of hands showed a considerable reduction in weight of fruit from affected plants.

The soils in St. Catherine where the condition exists are known as Caymanas sandy loam and Caymanas clay loam. Symptoms are usually more severe on the sandier areas. These soils are alkaline in reaction, usually high in available phosphate and potash, well drained and were originally some of the highest yielding banana soils in the island.

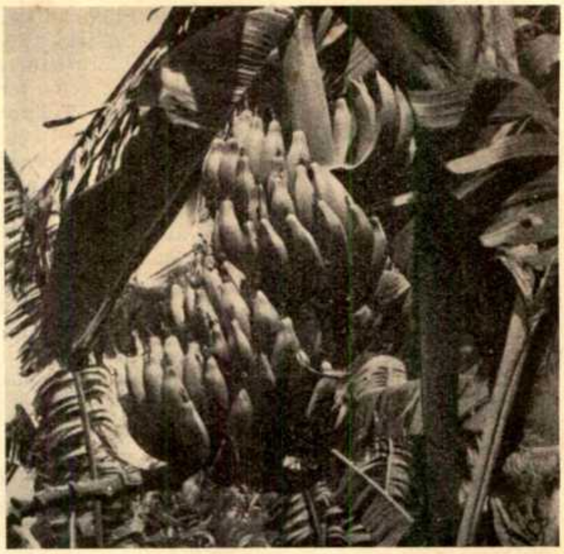

Fig. 3. Fruit from zinc-deficient plant

A weekly foliar spray treatment was carried out on three each severely affected young banana plants using the following treatments: 1 per cent zinc sulphate, 1 per cent manganese sulphate, control (water); 'Triton *X*-114' was added to all solutions. Despite some scorching of the foliage, plants sprayed with zinc sulphate produced greener leaves of normal shape and size. Later, another foliar spray treatment was carried out using weaker concentrations of the salt: 0·5 per cent zinc sulphate, 0·5 zinc sulphate neutralized with calcium hydroxide, control (water), all with 'Triton *X*-114'. Within two weeks there was a response to zinc sulphate; leaves produced after this interval were unaffected and in three months the condition had disappeared.

The foliar symptoms of the disorder, with the exception of the yellowing, closely match the symptoms of zinc deficiency as described by Moity[1]. Sunlight and/or temperature may be partly responsible for yellowing but, since there were plants just as exposed but not showing yellowing, it is possible that soil or nutritional factors predispose plants to become yellow. This may be wholly or partly the zinc deficiency. Zinc-sulphate sprayed plants did not show up marked yellowing but there was still a discernible difference in colour between the sides of some leaves which faced the Sun and the shaded side. It is not known whether this difference is due to sunlight only or to some other factor in combination with it. Many workers have shown that high light-intensities are conducive to the development of zinc-deficiency symptoms.

The soil factors responsible are likely to be alkalinity, sandy texture and high phosphate content. Numerous investigators have observed that zinc deficiency usually occurs on soils of *p*H 6 or higher. Camp[7] concluded ". . . it seems reasonably well established that the availability of zinc declines as the *p*H of the soil rises, the critical point being between the *p*H range of 5·5 and 6·5". Many workers, for example Chandler[8], have noted that the deficiency is most apt to show up on sandy and gravelly soils. Zinc deficiency has frequently been reported in soils containing abnormally high contents of soluble or total phosphates. Some investigators have reported reduced zinc availability when phosphatic fertilizers are added to the soil.

Mention must be made of the similarity of this disorder with many of the symptoms of alkali chlorosis described by Wardlaw[9] as occurring in certain alkaline areas around Delugé in Haiti. It seems that this alkali chlorosis may in fact have been partly if not wholly a zinc deficiency. There is also the possibility of mistaking zinc deficiency for nitrogen deficiency, and virus diseases such as described by Wardlaw and McGuire[10] as occurring in Brazil, Wardlaw[11] as occurring in Trinidad, or infectious chlorosis as described by Magee[12] in Australia as some of the foliar symptoms are close to those of zinc deficiency. Moity[1] has also directed attention to this.

PLANT ANALYSIS BY X-RAY FLUORESCENCE SPECTROGRAPHY: DETERMINATION OF CALCIUM AND POTASSIUM

By D. F. BALL and Dr. D. F. PERKINS

The Nature Conservancy, Bangor Research Station, Penrhos Road,
Bangor, Caernarvonshire

X-RAY fluorescence spectrography[1,2] is a powerful non-destructive analytical technique capable of determining elements above atomic number 12 (magnesium) with speed and accuracy over a wide concentration-range. There is a rapidly developing application of the method in the geological[3–5] and biological[6–10] sciences. Vacuum or helium path instruments now permit quantitative analysis of elements lighter than titanium, among which are many of the major rock-forming and biologically significant elements.

Work of the Nature Conservancy at Bangor[11] is concerned with the ecology of mountain grasslands, and in this work there is a need for a wide range of rock, soil and plant analyses. Many of the analyses of macro- and micro-elements involved appeared likely to be amenable to rapid and accurate determination by the X-ray spectrograph. Accordingly, a Hilger and Watts vacuum spectrograph, the Flurovac, has been installed and the results reported here were obtained with this instrument. Some of the practical details of sample preparation and instrumental technique in X-ray fluorescence spectrography of plant material are discussed and the X-ray data correlated with potassium and calcium determinations by flame photometry.

As an illustration of the preparation of calibration curves we report here results for analyses of mixed herbage grasses, selected from a range of material kindly provided by the Soil Chemistry Department, N.A.A.S., Ministry of Agriculture, Bryn Adda, Bangor. Twenty-five samples covered a range in potassium content of 5·7–25·3 mgm./gm. dry matter and twelve samples a range of calcium content of 4·6–9·6 mgm./gm. dry matter. The selected samples were afterwards analysed by flame photometry after ashing at 520° C., potassium being analysed directly on the diluted ash solution and calcium after an oxalate precipitation procedure.

We have previously reported[12] that potassium, calcium, manganese, iron and zinc are elements present in adequate amount for quantitative work by direct X-ray fluorescence spectrographic analysis of vegetation dried at 80° C. and milled to pass a 0·5-mm. sieve. It is possible to get a rapid and moderately reproducible result for these elements when milled vegetation is loosely tapped down in a sample-holder having a Melinex (Mylar) window through which the primary X-ray beam and the secondary emission both pass. Radiation from light elements such as potassium and calcium is reduced in intensity by the presence of even the thinnest practicable Melinex film (about 0·006 mm.). Additionally, packing and particle size have an important effect on the amount of secondary radiation emitted. Both finer particle size and greater degree of close packing increase the obtained count. Loose packing in a Melinex window holder is not generally precise enough for quantitative work, but can be useful for rapid comparative examination of samples, particularly when the material is required for further destructive analyses.

The simplest and quickest sample preparation should be used for quantitative analysis which is commensurate with adequate radiation emission and with reproducibility of count from replicate samples. To improve the reproducibility over that obtained by packing loosely in a holder, a 2·0-gm. sample is compressed into a disk, of 32 mm. diameter, large enough to cover completely the sample-window of the spectrograph. The disks are made in a tool-steel mould using a hydraulic press (Research and Industrial Instruments, Ltd., London, Type *H* 30–1 *Mk*. II) at an indicated operating pressure of 5,000 lb./in.^{2}, moderate deviations from which do not significantly affect count-rate. Aliquots of a sample milled to pass from 0·5 to 2·5 mm. sieves did not give significantly different counts when compressed into disks, but finer particles bond together more effectively. Disks made in this way are reasonably rigid but can be greatly improved by being given a cellulose backing. A layer of powdered cellulose (Whatman's standard grade) is added above the plant material in the mould and the sample with cellulose backing is then compressed into a disk. The cellulose bonds well with the plant material, increasing the rigidity of the sample.

Table 1

Weight of plant material (gm.)	Mean disk thickness (mm.)	Count (Se $K\alpha$) without Se backing	Count with Se backing
2·0	2·8	528	12,089
2·5	3·4	521	7,891
3·0	4·1	533	4,767
3·5	4·7	536	2,552
4·0	5·5	528	1,634
4·5	6·2	532	1,133
5·0	7·0	520	882
5·5	7·6	536	705
6·0	8·2	523	609
7·0	9·6	525	524

The question of a suitable thickness of disk required some investigation. Mechanical strength of the disks is too low under vacuum when less than 1 gm. of material is compressed into a 32-mm. diameter disk. Tungsten radiation, which is the primary radiation used, has a deep penetration in a very light matrix such as is provided by plant material. The thickness of material through which secondary fluorescent radiation travels to contribute to the analytical count (the effective sampling depth of the material), depends on the nature of the sample matrix and on the element being determined. The lighter the matrix, the deeper the effective thickness for any element; the lighter the element, the less the effective thickness in a similar matrix. The magnitude of this effect is negligible for practical thicknesses of sample of heavy matrix, but is appreciable for heavy elements in a light matrix, such as plant material. The magnitude of this effect was tested by counting radiation emitted by a pure element, used as a backing on increasing thicknesses of sample disk. When emitted secondary radiation from the backing element failed to penetrate the grass, the count-rate for the element remained constant with increasing thickness of the sample disk. In this way curves could be drawn for each element, plotting thickness of sample disk against count-rate.

If the thickness of sample is less than that at which counts with and without backing are identical, then variations in count-rate may be caused by variation in thickness of disk. Thickness of disk can be carefully controlled but preparation is then tedious, and too low a sample-thickness means that the count-rate is not the optimum obtainable from the specimen. Table 1 shows the general form of the relationship of disk thickness to count, when a backing sample of pure selenium is used behind varying thickness of disk (without backing cellulose). Since it is easier to prepare disks from a weighted aliquot, corresponding weights are included in Table 1.

From data of this type, it is possible to say for any particular element in a plant material matrix what is the thickness of sample disk required to ensure that minor thickness variations have no effect on count-rate. Table 2 shows minimum weight of disk required to ensure complete secondary emission within the specimen for a given element, against atomic number of the element.

Tables 1 and 2 show that pure selenium as a backing contributes to the selenium count up to 6·5 gm. (8·9 mm.) of sample disks. However, if a grass matrix containing 5 per cent added selenium is made up in disks of different thicknesses, an increase in counts, of practical significance, is only obtained up to a 3·0 gm. (4·1 mm.) disk. The effect is negligible for the elements we find readily detectable in non-ashed material (up to zinc) at the concentrations in which they are present, if a standard sample of 2 gm. (2·8 mm.) is taken. When ashed material is used for determination of other elements, the depth of penetration in this matrix is much less and a smaller weight in a thinner disk is acceptable on these grounds.

Table 2

Element	Atomic number	Weight of disk (gm.)
Manganese	25	1·5
Nickel	28	1·8
Copper	29	3·3
Zinc	30	3·8
Selenium	34	6·5
Zirconium	40	10·0

The Hilger and Watts instrument uses a reference monitoring system, whereby counts of secondary radiation are accumulated on the analytical channel until a pre-set count has been accumulated on the reference channel. The reference channel monitors a constant, but adjustable, proportion of the primary tungsten radiation. The analytical count is determined against a constant reference of a standard quantity of primary radiation reaching the sample. Counts of different samples for the same element are therefore strictly comparable regardless of slight fluctuations in primary radiation. The X-ray data are recorded as total counts accumulated for a

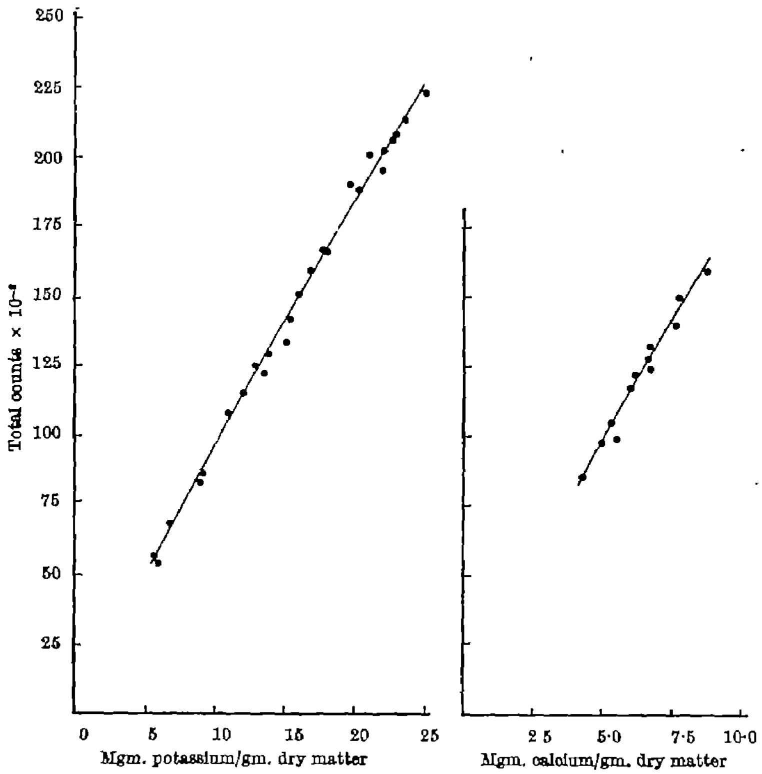

Fig. 1. X-ray fluorescence spectroscopy calibration curves for potassium and calcium determinations in samples of mixed herbage grasses

given reference count, rather than as counts per unit time.

Normally the X-ray generator is operated at 40 kV., 20 m.amp., and the reference monitor adjusted to approximately 4,000 c.p.s. For potassium and calcium determinations, 10^5 reference counts are accumulated, with an $N/4$ scaler in operation. Thus a counting time of approximately 100 sec. is used for each determination. Potassium and calcium are determined under vacuum using an ethylenediamine ditartrate analysing crystal and gas-flow proportional counter. Pulse-height analysis is used, with settings of 15 V. low-level and 33 V. window-width for potassium; 16 V. low-level and 44 V. window-width for calcium.

Fig. 1 gives calibration graphs for potassium and calcium in a series of mixed herbage grass samples. The X-ray counts given on these curves are from the $K\alpha$ lines of the elements and are of single determinations against 10^5 reference counts. The correlation thus shows what is attainable under rapid routine operating procedure for large numbers of samples. For practical purposes the calibrations can be considered to be linear, but they are in fact slight curves of the type to be expected for a moderately light element in a lighter matrix[2]. The speed of manufacture of disks from dried material is approximately 24 per hr. Analytical time, including application and release of vacuum for each sample and change-over of samples, is also 24 per hr. In a normal 8-hr. day, allowing time for the instrument to stabilize, approximately 150 single-element analyses can reasonably be made, which include determinations to check the calibration curve and the stability of the instrument. It is usual to determine one element in a large batch of samples as a continuous run.

Analyses of the same sample disk inserted and removed in the standard fashion throughout a day showed variation of ± 1–2 per cent in counts over the standard length of count of approximately 100 sec. Several disks made from the same bulk material showed errors no greater than this statistical counting error. It was found that the X-ray count on the same disk left under vacuum increased by about 1 per cent over a 1-hr. period. Our standard practice is to count each sample immediately the vacuum gauge indicates < 1 mm. mercury.

PURE MUTANT CLONES INDUCED BY ULTRA-VIOLET LIGHT IN THE GREEN ALGA, *CHLAMYDOMONAS REINHARDI*

By NICHOLAS W. GILLHAM* and PROF. R. P. LEVINE

Biological Laboratories, Harvard University, Cambridge, Mass.

AUXOTROPHIC mutants have been obtained in *Chlamydomonas reinhardi*[1] and other species of *Chlamydomonas*[2,3] by irradiating vegetative cells in liquid medium and plating them on complete agar medium, or else plating the cells to be treated on complete agar medium and then irradiating them. After the irradiated cells have formed distinct colonies they are replica-plated to minimal medium and to complete medium. The colonies which are unable to grow on minimal medium, but which do grow on complete medium, are presumed to be auxotrophs and are then tested for their biochemical requirement. Eversole[4] has varied this method by allowing the irradiated cells to undergo two divisions in liquid complete medium prior to plating them on complete agar medium for growth and replica-plating.

The difference between the method used by Eversole, which allows cellular division prior to the plating of irradiated cells, and the first method which does not, is important for the following reason. If cells are plated to an agar medium immediately following irradiation, two classes of mutants might be expected. The first class would consist of cells which only give rise to mutant progeny and thus to a pure clone of mutant cells. The second class of mutants would be composed of cells which give rise to colonies containing both prototrophic and auxotrophic progeny. Mixed clones of this type would not be evident on replica-plating to minimal medium since the prototrophic cells in the clone would overgrow the auxotrophic cells and the clone would appear to be wild-type. Such clones would be detected only if they were broken up into their component cells at some time prior to replica-plating, and if the clones resulting from these progeny cells were those replica-plated to minimal medium.

In order to determine whether or not mutants of the second class were induced, cells were irradiated and plated immediately following irradiation. After several cell divisions had taken place, the colonies on a portion of the plates were broken up ('spread' series) while on the remaining plates they were left undisturbed ('unspread' series)[5]. On replica-plating the resulting colonies in the two series of plates, one of two results was to be expected. First, if mutants occurred only as pure clones then the ratio of plates bearing mutants to plates lacking mutants would be the same in both 'spread' and 'unspread' series. Second, if mutants occurred in mixed clones as well as in pure clones, the ratio of plates bearing mutants to plates lacking mutants would not be the same in the two series. A larger proportion of the plates in the 'spread' series would have mutant colonies. The possibility that mutants occurred only in mixed clones is eliminated because the first method described in this communication has been used with success in obtaining auxotrophic mutants. The detailed experimental procedure and results of experiments carried out to test for the two classes of mutants are described in the succeeding paragraphs.

---

* Present address: Department of Botany, Yale University, New Haven, Conn.

The mutational system which was adopted in these experiments is one using forward mutations to acetate dependence. When mutations to acetate dependence are sought by the first method mentioned in this article, they are found to occur at a frequency of 0·1 per cent at an ultra-violet dose of 97 ergs/mm.^{2}/sec. given for 30 sec. This dose permits a survival of about 50 per cent. In each of the three experiments discussed here wild-type cells were removed from yeast extract agar medium[6], incubated for two days on minimal agar medium, and then placed in liquid minimal medium and shaken for several hours on a Gyrotary shaker. At the end of this time, an aliquot of cells was fixed and stained by the method of Levine and Folsome[7] to determine the proportion of multinucleate cells in the population. A minimum of 200 cells was counted in determining this proportion. The suspension was adjusted to a density of 5×10^6 cells/ml. by hæmacytometer count. A 4-ml. aliquot was then placed in a small Petri dish and irradiated for 30 sec. with two 15-W. General Electric germicidal lamps at a dosage of 97 ergs/mm.^{2}/sec. The suspension was mechanically agitated during irradiation. At the end of the treatment, the suspension was diluted and aliquots (0·1 or 0·2 ml.) were plated on acetate agar medium. The size of the aliquot plated in both the spread and unspread series was the same in any given experiment and contained between 50 and 100 viable cells. To control photoreactivation all post-irradiation procedures were carried out under the light of a General Electric 'Bugaway' yellow lamp, and the plates were incubated in the dark for 12 hr. prior to returning them to the light.

The colonies on the plates comprising the 'spread' series were broken up with a glass rod after the irradiated cells had been allowed to go through about four divisions (the number of divisions was determined by breaking up at least 30 microcolonies with a glass needle and counting the number of cells per colony under a dissecting microscope). The efficiency of spreading was determined by counting the number of colonies seen on a set of plates before and immediately following spreading. The colonies on both the 'spread' and 'unspread' series of plates were replica-plated to minimal medium and to minimal medium plus acetate after sufficient growth had occurred.

The results of the three experiments are given in Table 1. It can be seen that the number of mutants recovered in the 'spread' and 'unspread' series is about the same in each experiment. The data from all three experiments were combined, and a two-by-two contingency test was performed. In this test the number of plates with and without mutants in the 'spread' series was compared with the number with and without mutants in the 'unspread' series. The test shows that the data ($\chi^2 = 0{\cdot}49$; $P = 0{\cdot}48$) allows the conclusion that the number of plates bearing mutants in both series is not significantly different. Table 1 also shows that multinucleate cells and ineffective spreading have little effect on the results. In addition, the results are not affected by spontaneous mutations since none was observed among 60,450 untreated cells.

*U, unspread; S, spread.

† Plates with mutants in the unspread series bore only a single mutant colony. Since spreading disrupts colonies, plates of the spread series bearing mutants had several mutant colonies.

Although it has been known for some years[1–3] that ultra-violet-induced mutations arise in pure clones in *Chlamydomonas*, it was not known until these experiments were performed whether ultra-violet-induced mutations occurred in clones mixed with prototrophic cells as well. The results reported here are in accord with the hypothesis that the majority of ultra-violet-induced mutations to acetate dependence in *C. reinhardi* arise only in pure clones. This result is of interest because Doudney and Haas[8–10], from their investigations of ultra-violet-induced mutations in *Escherichia coli*, have suggested a mechanism of induced mutation in which ribonucleic acid (RNA) is modified by the incorporation of radiation-altered precursors. The altered RNA causes a corresponding modification in newly synthesized deoxyribonucleic acid (DNA). In brief, their hypothesis predicts that an ultra-violet-induced mutation should appear initially in the first DNA synthesized after irradiation. The results reported here for *Chlamydomonas* are in disagreement with this prediction for the following reason. In *C. reinhardi* the DNA of mitotically dividing cells is replicated semiconservatively[11]. Therefore, if an ultra-violet-induced mutation arose initially in the first DNA synthesized after irradiation, a clone would arise consisting of both mutant and wild-type cells. The absence of a significant number of mutants which occur in mixed clones in the experiments reported here suggests that in *C. reinhardi* ultra-violet light induces mutations by a mechanism that directly affects the parental DNA.

PHYSICS

Production of Continuous High-Current Discharges in Gases

The properties of high-current arcs under stationary conditions have been studied, in general, using low-pressure mercury vapour. Thonemann and Cowhig[1], for example, have made probe measurements in a mercury arc at currents up to 100 amp. Much higher currents are used in technical devices such as rectifiers and inverters.

The reason for the use of mercury is that a cathode spot on a mercury pool can supply virtually unlimited currents. Furthermore, the cathode is indestructible since the mercury which is blasted away from the spot afterwards returns to the pool.

It is possible, however, to utilize the properties of a mercury pool to obtain a high electron current which is then sent into a gas other than mercury. This can be done by introducing the gas into a mercury vapour discharge tube in which a cold trap prevents the mercury from entering the part of the tube which contains the anode.

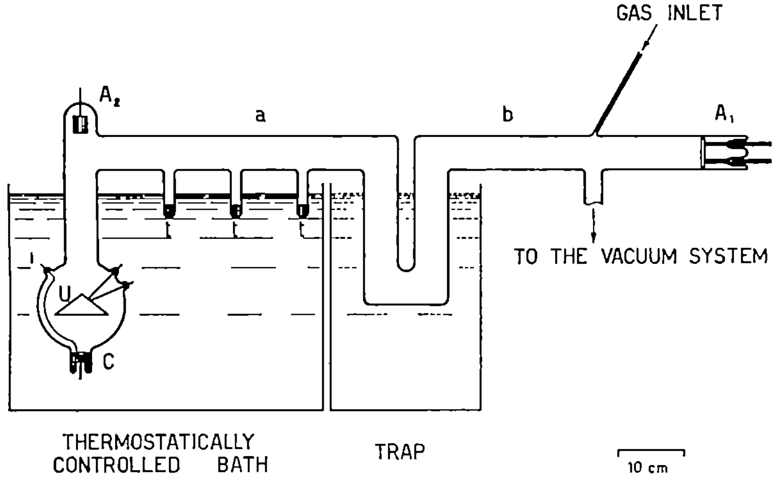

Fig. 1

The experimental tube (Fig. 1) is of 'Pyrex' and has a water-cooled principal anode A_1, a mercury pool cathode C and an auxiliary anode A_2. U is an umbrella which shields the main discharge space from jets of mercury emanating from the cathode spot and i is an electrode which is used to start the discharge. The bulb containing the cathode pool and the three tubes t containing further mercury are submerged in a thermostatically controlled bath. The large U-bend, which is surrounded by a vessel containing dry ice, constitutes the trap. The discharge tube is connected to a two-stage mercury diffusion pump through a liquid nitrogen trap.

Using a suitable optical system, light from regions a and b of the discharge (Fig. 1) illuminates respectively the lower and the upper parts of the entrance slit of a Hilger–Barfit constant deviation spectrometer. Thus the two spectra can be viewed simultaneously through an eyepiece. The measurements presented here were obtained using a photomultiplier which views individual lines through a slit.

Table 1. Intensity of Spectral Lines in Arbitrary Units

Wave-length (Å.)	Light from *a*	Light from *b*	Light from both *a* and *b*
5876 (He)	0·0	2·0	2·0
5770/91 (Hg)	3·5	0·0	3·5
5461 (Hg)	16·0	0·0	16·0
5016 (He)	0·0	8·0	8·0
4922 (He)	1·0	2·0	3·0
4713 (He)	0·0	1·5	1·5
4471 (He)	0·5	0·5	1·0
4358/39 (Hg)	28·0	0·0	28·0

Experiments have been carried out using helium. The pressure of the latter was 10μ mercury, and the mercury vapour pressure was 2·6μ mercury, corresponding to a bath temperature of 30° C. The arc current was 1 amp. and the arc voltage 190 V. Measurements were made of the intensity of the light arriving from region a, from region b and from both regions together. The first two measurements were made by blocking the light beam from part b and part a respectively. Typical results are given in Table 1. These measurements have not been corrected to allow for the variation of the sensitivity of the photomultiplier with the wave-length of the incident light. The figures given are galvanometer readings, which are to the nearest 0·5 division. Successive series of measurements, however, indicate that the error is somewhat greater than this.

It is seen from Table 1 that the light emitted from part a is due almost entirely to excitation of mercury atoms. The essential result, however, is that there is no mercury in part b of the tube, within the limits of experimental error. By analogy with normal vacuum practice it is clear that a discharge tube with a more sophisticated trap system would be even more efficient.

In the present experiment a current of only 1 amp. was used but the method can be extended to much higher currents.

We thank Prof. B. Brunelli for his interest.

Current Distribution in Thin Superconducting Films

The problem of the current distribution in a thin superconducting film has recently been discussed by several authors[1,2]. Although the solution of the London equations for a thin rectangular strip carrying a current cannot be given in a simple analytical form, W. A. Bowers (unpublished, quoted by Glover[3]) has given an approximate solution for the case in which the film thickness d is comparable with the superconducting penetration depth λ, and the width w is greater than λ so that $wd \gg \lambda^2$. Assuming the current density to be constant through the thickness of the film, Bowers finds that the current density at a distance x from the centre of the strip is given by $J(x) = J(0)\{1 - (2x/w)^2\}^{-\frac{1}{2}}$ provided x is not too near $w/2$, while near the edge the solution has the form.

$$J(x) = J\left(\frac{w}{2}\right) \exp - \left\{\mathrm{d}\left(\frac{w}{2} - x\right)\Big/ a\lambda^2\right\}$$

where a is a constant of the order of unity. The two solutions are joined at a point distant $a\lambda^2/2d$ from the edge of the film, so that:

$$J\left(\frac{w}{2}\right) = \exp\left(\frac{1}{2}\right)\sqrt{wd}\, J(0)/\lambda\sqrt{2a}$$

The solution for the central region is the same as the charge distribution on the surface of a thin conducting strip in the analogous electrostatic problem.

A simple test of the validity of this solution can be made by comparing the external magnetic field which would be produced by such a current distribution with that measured experimentally. An experimental study of the perpendicular component of the magnetic field produced by a current in a superconducting lead film 2000 Å. thick × 1·5 mm. wide has already been made by Broom and Rhoderick[4], and we give here a comparison of their results with the magnetic field distribution to be expected from Bowers's expression for the current density. In calculating this field we shall assume that the current density is given by $J(x) = J(0)\{1 - (2x/w)^2\}^{-\frac{1}{2}}$ right up to the edge of the strip; although this gives an infinite density at $x = w/2$ it does not give an infinite magnetic field outside the strip, and the error caused by ignoring the edge solution is negligible for any practicable separation between the film and the magnetic field detector. Let the y-axis be perpendicular to the plane of the strip and introduce new variables $\xi = 2x/w$, $\eta = 2y/w$; then the component in the y-direction of the magnetic field set up by the current distribution will, at an external point (ξ, η) relative to the centre of the film, be proportional to:

$$\int_{-1}^{1} \frac{(\xi - t)\mathrm{d}t}{(1 - t^2)^{\frac{1}{2}}[(\xi - t)^2 + \eta^2]}$$

that is, to the real part of

$$\int_{-1}^{1} \frac{\mathrm{d}t}{(1 - t^2)^{\frac{1}{2}}(\zeta - t)}$$

where $\zeta = \xi + i\eta$. The complex integral is equal to $\pi(\zeta^2 - 1)^{-1/2}$. The real part of this integral is plotted in Fig. 1 for the case $\eta = 0{\cdot}08$, which corresponds to the separation between detector and film used in the experiments, together with measurements of the perpendicular component of the magnetic field. To make comparison possible, the horizontal co-ordinates of the experimental points have been scaled to make the positions of the theoretical and experimental maxima coincide, while the vertical scale has been adjusted to give agreement for $\xi > 2$. This procedure was adopted because neither the calibration of the mechanical drive for the detector nor the sensitivity of the latter was known to better than 10 per cent. The significance of the comparison therefore lies in the shape of the curve, and in this respect the agreement with the experimental results is remarkably good. As an indication of the extent to which the shape of the curve is sensitive to the current distribution, we show in Fig. 1 the magnetic field variation which would be obtained if the current were distributed uniformly across the strip. There is a marked difference between this curve and the experimental results.

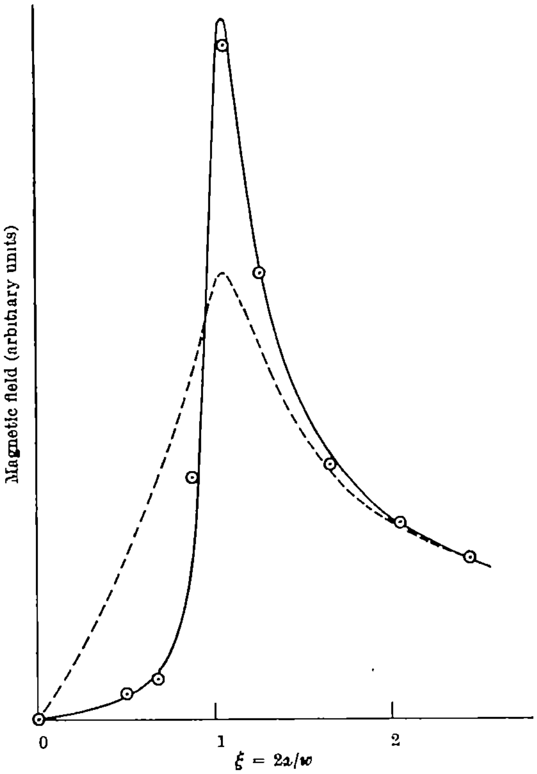

Fig. 1. Comparison of the perpendicular component of the magnetic field due to a current through a superconducting lead strip 2000 Å. thick × 1·5 mm. wide with that to be expected theoretically. ○, Experimental points; —, theoretical for current distribution of the form $J(\xi) = J(0)\ \{1-\xi^2\}^{-1/2}$; ‐ ‐ ‐, theoretical for uniform current distribution

Packing of Liquids for Irradiation in Nuclear Reactors

The 'packing' of liquids for irradiation in nuclear reactors is still in many cases a problem. In our case we had to make use of the self-service channel of the *BR*1 reactor at Mol (Belgium), with a flux of 10^9 neutrons/cm.^{2} sec.—a channel in which irradiation is usually carried out with the samples packed in a 'Perspex' ball, the dimensions of which are shown in Fig. 1.

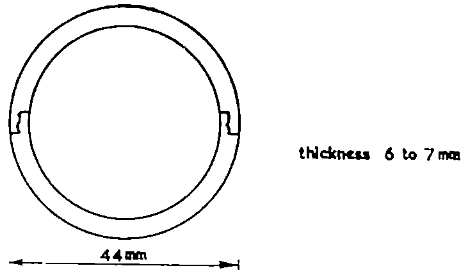

Fig. 1

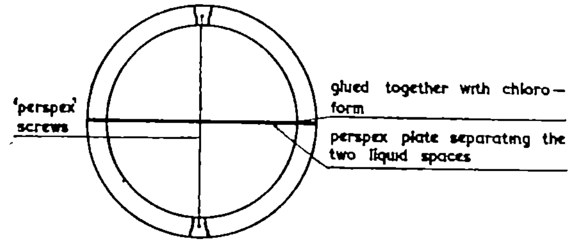
In this ball the samples are present in the solid state, usually pressed to disks. Because our experiments had to be performed with liquids, we tried to find another way. Two possibilities were at hand.

At first we used a 'Perspex' ball as shown in Fig. 2. The advantage of this method is the irradiation of sample and standard at the same time. However, the disadvantages are: (*a*) the difficulty of cleaning the two spaces; and (*b*) the costly construction of the apparatus.



'perspex' screws
glued together with chloroform
perspex plate separating the two liquid spaces

Fig. 2

Therefore, a simple and cheap method was tried out which makes use of table-tennis balls. For this purpose two tiny holes are drilled in the balls at a short distance from each other, and the ball is filled with liquid by means of a funnel with an injection needle, connected with the stem by a piece of plastic tube (Fig. 3). The holes are closed with a plastic glue, and, in order to avoid contamination of the reactor in the event of leakage, the ball is packed in closely fitting polythene shells, tied together with adhesive tape (Fig. 4).

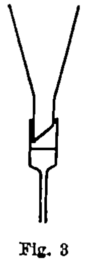


Fig. 3

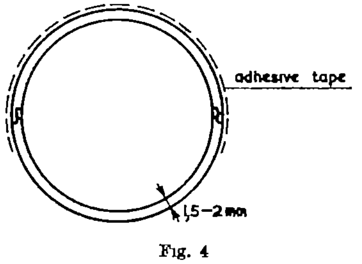

Fig. 4

The standard material is packed in a separate table-tennis ball and irradiated simultaneously with the sample. If it is not possible to bring them together on a spot in the reactor with sufficiently constant neutron flux, sample and standard must contain an internal standard in order to compare the flux that each receives. Afterwards the balls are cut open and 10 ml. of the liquid is pipetted into a bottle to be counted.

The advantages of the use of table-tennis balls are: (1) They are remarkably strong, even after being filled with water, and can stand falls of 8 ft., a temperature of 80° C. and dilute mineral acids for a long time. (The first mentioned was necessary because the ball had to be dropped into the reactor from the height of 8 ft. on to a steel plate.)

(2) They do not contaminate the sample; for example, dilute nitric acid, irradiated in a ball for half an hour and counted 15 min. in a thallium-activated NaI-well crystal detector connected with a multichannel energy spectrometer, showed no trace of activity, either γ-peaks or bremsstrahlung, caused by dissolved impurities of the ball.

(3) They are cheap and easy to obtain in quantity. For these experiments 'Halex' two and three star balls were chosen.

GEOPHYSICS

Effect of Magnetic Disturbances on the Equatorial Ionospheric Jet Current

The existence of an anomalously large diurnal variation of the horizontal components of the Earth's magnetic field near the equator was first noticed at Huancayo[1]. Later, to explain this, Egedal[2,3] and Chapman[4] postulated the existence of an equatorial jet current flowing around the Earth. Several studies of this jet current have been made[5], and naturally the first attempts have concentrated on the days which were magnetically quiet. I have been interested in ionospheric effects near the equator on magnetically quiet days and on magnetically disturbed days, and have found that many of the anomalous phenomena which occur near the equator seem to be markedly reduced under magnetically disturbed conditions. These phenomena include: (*a*) intensity of day-time sporadic *E* of equatorial type; (*b*) amount of night-time spread-*F*; (*c*) the large values of the semi-

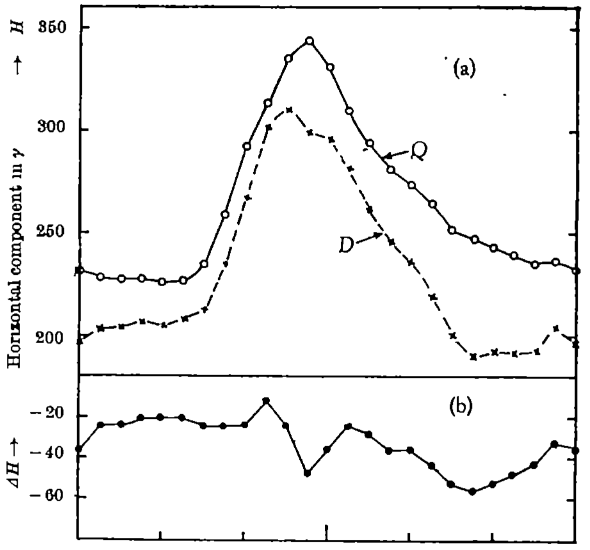

Fig. 1. *a*, Variation of horizontal component of Earth's magnetic field *H* on magnetically quiet days *Q* and magnetically disturbed days *D*; *b*, difference between variation of *H* on quiet and disturbed days $H_D - H_Q = \Delta H$

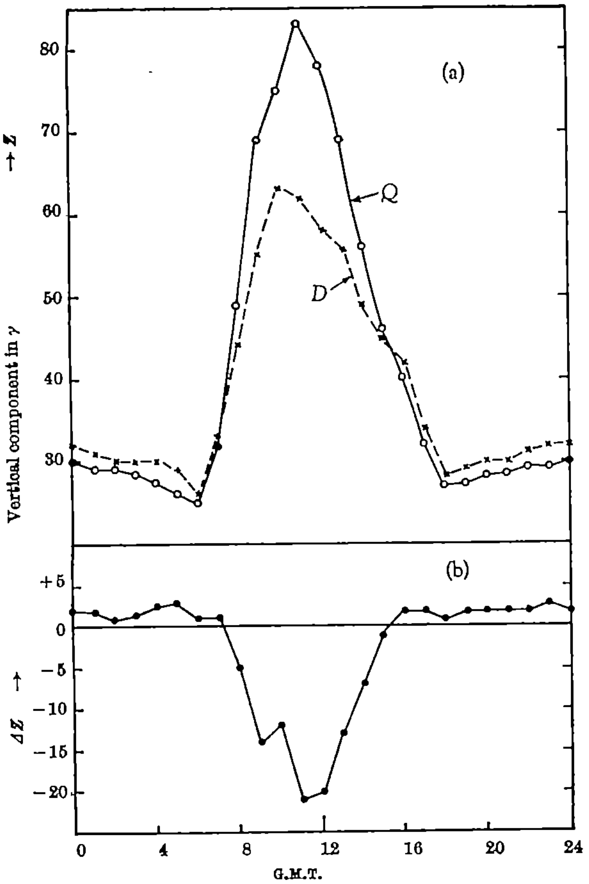

Fig. 2. *a*, Variation of vertical component of Earth's magnetic field Z on magnetically quiet days Q and magnetically disturbed days D; *b*, difference between variation of Z on quiet and disturbed days $Z_D - Z_Q = \Delta Z$

thickness, Ym, of the F-layer in the day-time; (*d*) the mid-day bite-out of the F_2-layer, and (*e*) the separation of the F_2-layer from the F_1-layer.

I have therefore examined the magnetic data obtained during the International Geophysical Year at Ibadan, Nigeria, 3° south of the magnetic equator, to see what effect magnetic disturbance has on the ionospheric jet current. Ibadan is just at the edge of this equatorial jet current, and has therefore a large diurnal range of both H, the horizontal magnetic component, and Z, the vertical magnetic component.

The hourly values of H and Z components of the Earth's magnetic field for the five magnetically quiet days from each month were taken and the mean diurnal variation calculated. The data for the five disturbed days in each month were treated in the same way. The results averaged over the whole 18 months of the International Geophysical Year are shown in Fig. 1 for H and in Fig. 2 for Z. In the case of H for disturbed days, a non-cyclic variation of about 36γ has been removed in the usual way.

There are two points of interest to be noted from the graphs: (1) The reduction in range of diurnal variation of Z of about 40 per cent on magnetically disturbed days. The diurnal range of H is almost unaffected. (2) The overall depression of H by about 30γ with no corresponding change in Z.

The latter effect is well known and indicates currents flowing in regions where the conductivity is independent of time of day, and either a current sheet or a current at a great distance from the Earth. This is explained in a general way by the ring-current theory which is developing from the suggestions of Chapman and Ferraro[6].

The former effect does not appear to have been noted before. The only previous similar investigation is that of Johnston and Bartels[7], who examined the data from Huancayo. The marked change of Z observed here at Ibadan was not observed, but the change in the diurnal variation of H was similar to that found here. This is probably due to the fact that Huancayo is right under the equatorial jet current, and thus the current produces negligible diurnal variation of Z.

The jet current is thought to be about 4° of latitude wide, at about 100 km. height, and in Nigeria centred on 10° N. geographic latitude (see Onwumechilli[5]). One explanation of the behaviour shown in Figs. 1 and 2 would seem to be that on magnetically disturbed days the anomalous behaviour leading to the belt of high conductivity is reduced, so that the current is much less channelled into a jet. The overall diurnal range of H would then be about the same, but the diurnal range of Z at Ibadan would be much reduced. However, the jet current has been ascribed by Martin[8] to polarization inhibiting the Hall currents in the ionosphere. It would suggest, then, that this polarization is reduced on magnetically disturbed days. This would, however, lead to a reduction of the conductivity and hence of the current, and this should be evident from a reduction in the diurnal range of H which is not observed.

An alternative explanation is based on the fact that Ibadan is very close to the region where the diurnal range of Z is a maximum[5]. Therefore, if the exact position of the jet current moves erratically and is most affected on D-days, then the effect will be to give rise to a reduction in the average diurnal variation of Z. There is some evidence for considerable day-to-day changes in the position of the jet current (Rivers, D., private communication). More work is required to examine the suitability of such an explanation.

The results of this analysis will be published in more detail elsewhere. I am grateful to Prof. N. S. Alexander and Dr. C. A. Onwumechilli for making data available.

METEOROLOGY

Some Amino-Acids as Ice Nucleators

THE occurrence of organic nitrogen in snow has been known for many years[1]. More recently amino-acids have been identified in rain[2], and in free air and snow[3].

We have examined amino-acids for possible activity as ice nucleators. At first sight, it did not seem likely that they would be active as a class, since most of them are soluble in water, and water insolubility has generally been conceded to be a pre-requisite for ice-forming nuclei. However, some amino-acids are soluble only with difficulty in cold water.

The following substances were tested: glycine, *l*-leucine, *dl*-leucine, *dl*-isoleucine, *dl*-alanine, *dl*-serine, *dl*-aspartic acid, *l*-glutamic acid, *dl*-phenylalanine, *l*-tyrosine, *l*-tryptophan, *dl*-tryptophan, *dl*-valine.

Nucleating ability was tested in a 4·5 cu. ft. cold box using both soap films and supercooled sugar solutions as detectors of ice nuclei. When using the sugar solution detector the relevant temperature was taken as that of the solution, care being taken that the ambient temperature was maintained at that same value, and that contamination from colder parts of the chamber did not occur. Those substances which cannot be finely powdered and so do not form a stable aerosol when blown into the chamber were tested by dusting a small quantity directly on to the detecting surfaces and watching for the appearance of small ice crystals in the usual fashion.

The threshold temperatures for ice nucleation of those amino-acids found to be active above −10° C. are shown in Table 1.

Table 1

Substance	Threshold temperature (deg. C.)
dl-Alanine	−7
l-Leucine	−4·5
l-Tryptophan	−5·5
dl-Aspartic acid	−6

It has recently been found[4] that nucleating ability with some other organic substances occurs with those possessing —OH, =O, or—NH_2 groups, so that the activity of amino-acids fits into this pattern. The recent suggestion[5] that good ice nucleators such as silver iodide act because of hydrophilic sites on the crystals would also be compatible with the hydrogen bonding properties of the —NH_2 group. It is also interesting that proteins (that is, complex groupings of amino-acids) are stated by V. J. Schaefer to be good ice nucleators[6].

The amino-acids found in the atmosphere have been identified[3] as glycine, alanine, valine, leucine, and (less certainly) glutamic acid, aspartic acid, and proline. Thus, among the naturally occurring amino-acids in the atmosphere are two with excellent nucleating power.

The origin of the amino-acids in the atmosphere and in precipitation is not known with certainty. It has been suggested that they may be synthesized in the atmosphere from simpler compounds[3,6], that they may be formed during combustion processes[2], or that they may arise during decomposition of organic matter[3]. It has been suggested that the surface of the ocean is the source of the organic nitrogen in precipitation[7,8], the organic material being released by the bursting of foam bubbles in surf and in storm waves.

It appears to us that a world-wide class of atmospheric ice nuclei may therefore be certain amino-acids. If this is so, their origin is a matter of some importance.

Amino-acid nuclei if released from the sea or the soil would almost certainly be associated with other substances. We have mixed 1 per cent leucine with a 30 per cent saline solution. When this was sprayed into the cold chamber, it was inactive in producing ice crystals at temperatures above − 15° C. When the same solution was evaporated to dryness, the crystalline powder gave ice nuclei active at − 4 to − 5° C. Natural ocean water[9] and sea salt[10] both give ice nuclei active at about − 15° C.

Some mineral dusts are good ice nucleators; kaolinite is the most active of these with a threshold temperature of − 9° C.[11]. When 1 per cent leucine was added to a slurry of kaolin, the powder resulting from evaporation to dryness was active as an ice nucleator at − 6·5° C. Neither diatomaceous earth nor sand (mainly quartz) showed any noticeable increase in nucleating power under similar treatment.

CHEMISTRY

Iodine as a 'Non-Destructive' Colour Reagent in Paper- and Thin-layer Chromatography

IODINE has been used as a colour reagent for paper chromatography of amino-acids and their derivatives[1,2], imidazoles[3], and other nitrogen-containing compounds[1,4]. Steroids are also revealed by this technique, which is sufficiently sensitive to enable location of 0·5 µgm. oestrone[5]. The method has not gained wide acceptance possibly only because it cannot be relied on to yield a colour diagnostic of a class of compounds—some nitrogen-containing compounds are not revealed—but its application is simple, and if unsuccessful, other colour reagents can be applied to the same chromatogram. In the most convenient procedure, the dried paper is exposed to iodine vapour (supplied by a few iodine crystals in a closed battery jar) for 10–30 sec.; or the paper may be sprayed with a solution of iodine in carbon tetrachloride[3], or may be dipped into a saturated solution of iodine in petroleum ether (b.p. 60°–80°)[5]. Compounds are revealed usually as brown spots, which fade rapidly.

The method is applicable also to 'thin-layer' chromatography[6], in which the stationary phase is a water-moist layer of a powdered silica gel–calcium sulphate mixture ('Kieselgel *G*') supported on a glass plate. Larger quantities of material can be eluted on this phase, in comparison with paper chromatography, and more compact spots are obtained, and this has enabled me to demonstrate that compounds are revealed by the iodine vapour procedure as loose addition compounds, as suggested by Brante[1]. DL-Serine methyl ester hydrochloride was eluted on 'Kieselgel *G*' with butanol/acetic acid/water (6 : 2 : 2) and was located by exposure of the dried plate to iodine vapour; the powder supporting the spot was collected, and was extracted with ethanol. The concentrated extract was shown by comparative paper chromatography in several solvent systems to contain only unchanged DL-serine methyl ester. γ-Benzyl-DL-glutamic acid and benzyloxycarbonyl-DL-methionine were similarly recovered unchanged.

The only alternative 'non-destructive' method for revealing positions of components of a mixture separated by chromatography depends on possible fluorescence in ultra-violet light; in the special case of bacteriostatic compounds a further alternative is available[7]. The iodine technique applied to 'thin-layer' chromatographic separations of mixtures may make possible the isolation of valuable components for further examination.

Heat of Reaction of Polyriboadenylic Acid and Polyribouridylic Acid

POLYRIBOADENYLIC acid (poly A) and polyribouridylic acid (poly U) have been shown by sedimentation[1], light-scattering[2], X-ray[3] and ultra-violet absorption[1,4] investigations to interact in solution to form, depending on external conditions and the mole ratio of reactants, either a two-stranded (A + U) or a three-stranded (A + 2U) helical complex[3,4]. At 25° C., *p*H's between 6 and 9, and ionic strengths of 0·1 or greater, analysis of ultra-violet spectral mixing curves has shown that the formation of the complex species attains completion[5]. At U : A ratios greater than 1·0 the A + U species can, depending on external conditions and the molecular weights of the reactants, add a second poly U strand to form the A + 2 U triple-stranded helix[1,4]. It is not possible to ascertain by spectral analysis the extent to which formation of the A + 2 U species can occur at U : A ratios less than 1·0 under these conditions, as the absorbancy changes for the two steps appear to be equal[1,5].

The A + U complex has been shown to have a conformation which is remarkably similar to that of natural deoxyribonucleic acid (DNA)[3]. It has, moreover, been postulated to be stabilized by inter-base hydrogen bonding similar to that believed to exist between adenine and thymine in DNA[3]. The degree of molecular organization is very high, the evidence from ultra-violet hypochromism indicating that virtually all possible adenine-uracil linkages are formed[5].

The molecular conformations of the two reactants are not entirely equivalent. While both are believed to be single-stranded, poly A, but not poly U, appears to possess some degree of internal hydrogen bonding which results in a fractional helical content[6].

The current concept of the conformation of the (A + U) species represents it as stabilized by hydrogen bonds between the N_{10} nitrogen of adenine and the C_6 carbonyl of uracil and between the N_1 of adenine and the N_1 of uracil[3]. In addition, van der Waals interactions between adjacent pairs of planar purine and pyrimidine rings, which are stacked in a parallel array in the (A + U) complex, are probably of major, although imperfectly understood, importance.

The purpose of the present communication is to report the enthalpy of reaction for this important process in the region of poly A excess.

All the poly A and poly U preparations which were used in the course of this investigation were prepared by the action of the polynucleotide phosphorylase of *M. lysodeikticus* on the corresponding nucleoside diphosphate[7]. The sedimentation coefficients ($S_{0,20}$) of the poly U samples ranged from 4·5 to 10·0 svedbergs; those of poly A (unless otherwise specified) ranged from 8·0 to 12·0. No systematic variation with molecular size was observed and the results for different preparations were averaged without regard for this parameter (Table 1). The A : U ratio was always > 1·0. No variation of the heat with ratio was observed in this range. The question of the distribution of the complex species between the A + U and A + 2U forms in this region of poly A excess must be left open at present. The number of adenine : uracil linkages is, of course, independent of this.

Table 1. HEATS EVOLVED PER MOLE URACIL FOR THE INTERACTION OF POLY A AND POLY U

Effect of ionic strength (average of determinations for 14 preparations)

Molarity potassium chloride	$-\Delta H$ (calories)
0·10	5,900 ± 200
0 50	5,250 ± 200
1·00	4,750 ± 300

Effect of varying size of poly A* (in 0 1 *M* potassium chloride)

$S_{0,20}$ (svedbergs)	$-\Delta H$ (calories)
12·2	5,870 ± 100
4·3	6,050 ± 100
3 2	6,020 ± 100
2·1	5,850 ± 100

In each case 0 01 *M* sodium cacodylate, *p*H 6·6, was present. The temperature was close to 25° C. Poly A was in excess.

* These samples were obtained by stepwise alkaline hydrolysis of a single poly A preparation.

Measurements of evolved heat were made with the heatburst calorimeter developed by Benzinger and Kitzinger[8]. This has been amply described in other publications[8,9]. A 'Teflon' reaction vessel, containing two compartments of 7 ml. each, was used. Reaction was initiated by rolling the vessel and thereby mixing the reactants which were initially separated by an air bubble.

The molarity in nucleotide of the reactants varied from 2 × 10^{-4} to 5 × 10^{-5}. Concentration was determined by removing an aliquot, hydrolysing it quantitatively to mononucleotide (1 hr. at 100° in 0·1 *M* potassium hydroxide), and measuring the absorbancy at 260 mμ after suitable dilution.

Prior to measurement the poly A and poly U solutions were dialysed versus several changes of buffer in the same container. This served to eliminate any gradient of *p*H or electrolyte concentration.

Table 1 cites the average values of the heats obtained for 14 different preparations at three ionic strengths. A slight decrease in heat occurs with increasing ionic strength between 0·1 *M* and 1·0 *M* potassium chloride.

Table 1 includes the heats evolved with a single poly U preparation with a series of poly A preparations obtained by stepwise alkaline hydrolysis of a single poly A sample. No significant variation in heat was obtained for preparations of $S_{0,20}$ ranging from 12·3 to 2·1, corresponding to molecular weights ranging from 10^6 to 10^4 (ref. 10).

It is clear that the enthalpy of reaction of poly A and poly U to form a helical species is a well-defined quantity which is independent of the molecular weight of the interacting species for a considerable span of values of the latter However, it is not yet possible to equate the observed heat of reaction with the intrinsic heat of formation of the adenine–uracil linkage, in view of the uncertain contribution of any internal hydrogen bonding of poly A itself[6] This would necessarily be broken up by formation of the helix and might contribute to the observed heat.

This work was supported by the National Aeronautic and Space Administration under contracts *SC–R*–8 and *R*–38. We thank Dr. T. H. Benzinger for useful discussions.

Sedimentation of β-Lactoglobulin A under Aggregating Conditions

IN a previous paper[1] we compared the experimental results of Townend, Weinberger and Timasheff[2] for the sedimentation of the genetic species β-lactoglobulin *A* and *B* (ref 3) under dissociating conditions with theoretical estimates based on the corresponding light scattering data by the same authors. There appeared to be a good correlation between the two types of data.

Perhaps more important than dissociation in acid solution of the two species, *A* and *B*, is the association[4] which occurs maximally at *p*H 4·40–4·65 for β-lactoglobulin *A* but not for *B*, since this allows the species to be distinguished readily by physico-chemical means.

Timasheff and Townend[5] have shown by light-scattering experiments that in the range of *p*H 3·7–5·2 at low temperatures and ionic strength 0·1, β-lactoglobulin *A*, which exists at room temperature in the form of particles corresponding to dimers of molecular weight 36,000, aggregates reversibly to octomers of molecular weight 144,000. In this *p*H-range the dimer is sufficiently stable for its dissociation to be discounted[2] and for it to be taken as the basic aggregating species. For the present purpose, therefore, the system will be likened to a model in which monomer aggregates to tetramer, the monomer and the tetramer in the model being equivalent to the dimer and octomer of the actual system.

It is now proposed to repeat the procedure adopted in the previous paper[1] and to compare the dependence on concentration of the sedimentation velocity of β-lactoglobulin *A* with that calculated using the light-scattering data[5] of Timasheff and Townend for the extent of association of the molecule The method of calculation is the same as described earlier[6,7], and eliminates the need for the empirical correction for hydrodynamic effects used by Timasheff and Townend[4,8]. The main weakness of this type of calculation lies in the neglect of diffusion, but this does not usually seem to be as serious a defect as might be expected.

The following assumptions are made: (1) A rapidly reversible equilibrium exists between monomer, dimer, trimer and tetramer species formed by polymerization through identical bonds. Equilibrium is governed by the mass-action equations $a_2 = ka^2$, $a_3 = k^2 a^3$, and $a_4 = \gamma k^3 a^4$, where concentrations are in moles of the species per litre. The equilibrium constant for monomer–tetramer equilibrium has been represented by the compound term γk^3 to indicate that two bonds instead of one are formed during the addition of the fourth molecule to the trimer according to the model of Timasheff and Townend[5], and that this accentuates the stability of the tetramer γ times. From light-scattering data[2] $\gamma k^3 = 5 \times 10^{11}$ l^3/mole^3 at 2° C., *p*H 4·65, ionic strength 0·1. The value of k is not known, but has been fixed by *arbitrarily* choosing $\gamma = 100$, whence k becomes 1,710 l/mole. With a value of γ as high as this, k is sufficiently small for the amounts of dimer and trimer to be relatively insignificant, in conformity with the light-scattering data[2], and for the precise value of k to be therefore rather unimportant. (2) The limiting sedimentation coefficient $(s_1)_0$ of the monomeric species (molecular weight 36,000) is taken as in the previous paper[1] to be 2·87 svedbergs. Polymers of degree n are assumed to have sedimentation coefficients equal to $(s_1)_0 n^{2/3}$, that is, they are assumed to sediment as if they all had the same frictional coefficient and had volumes proportional to n. Thus the tetramer, for example, has a limiting sedimentation coefficient of 7·23 svedbergs. (3) The sedimentation coefficient of each species obeys the usual relation applicable to proteins near their isoelectric point, that is, $s_n = (s_n)_0\,(1 - gc)$, where g is a constant and c is the concentration of protein. The value of g is assessed from the experimental results for the dependence of s on c at high concentration. In the present instance a value of $g = 0{\cdot}058$ (gm./100 ml.)$^{-1}$ has been adopted, and this lies within the range to be expected for a protein near its isoelectric point.

These assumptions are sufficient for the evaluation of s as a function of c (refs. 6 and 7). The schlieren pattern breaks into two peaks[6], in agreement with the experimental patterns[4,5]. Two sedimentation coefficients can therefore be calculated, one for the trailing and one for the leading peak, and each of these sedimentation coefficients can be found by taking either the weight average or the median of the peak as the representative velocity. Weight average values

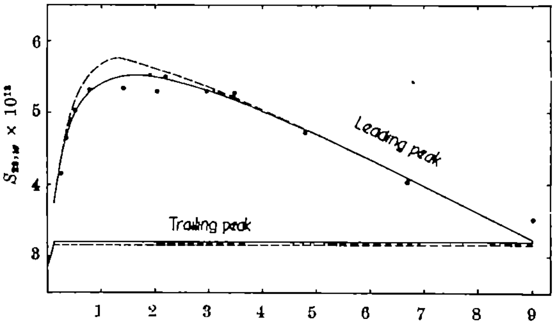

Fig. 1. Sedimentation of β-lactoglobulin *A* under aggregating conditions, *p*H 4 65, 2° C. ——, Weight average (theory); – – –, median (theory), ○, experiment (Timasheff and Townend, ref. 5)

have the advantage that they are less sensitive to the effect of neglecting diffusion, and are therefore likely to correspond more closely to experimental values.

In Fig. 1 theoretical weight average and median velocities for the trailing and leading peaks are shown and experimental points for the leading peak taken from the paper of Timasheff and Townend (ref. 5, Fig. 7) are added for comparison. It will be seen that there is a reasonable degree of correlation between the theoretical sedimentation curves based on data from light scattering, and the sedimentation velocities actually observed.

It is desirable to prepare families of curves in order to determine the sensitivity of the curves to adjustment in the parameters γ and g. This is now being undertaken with the aid of a digital computer.

A comparison of the theoretical and experimental velocity of the slow peak is not possible in the present instance because some 10 per cent of non-aggregating impurity in the lactoglobulin *A* masks the slow peak in the experimental schlieren patterns[5].

We thank the Agricultural Research Service, U.S. Department of Agriculture, for a research grant.

Determination of Parathion

IN chemical determination of parathion (*O*,*O*-diethyl-*O*-*p*-nitrophenyl phosphorothioate) and closely related compounds according to Averell and Norris[1], the nitro-group is reduced by zinc and hydrochloric acid, followed by diazotization and coupling of the primary aromatic amine thus produced. The method has become extensively used[2], but, to our knowledge, the descriptions available comprise only reduction with zinc and hydrochloric acid or similar heterogeneous systems.

p-Nitrophenol can be determined by an indophenol test after reduction to *p*-aminophenol with titan-III-chloride[3]. As a determination, according to the method of Averell and Norris, could be carried through with titan-III-chloride as reducing agent in a homogeneous system, the following procedure was elaborated.

The test solution is presupposed to be a neutral alcohol-containing solution, to 5 ml. of which are added: 50 µl. of titan reagent (2 min.); 200 µl. of about 8 *N* hydrochloric acid (2 min.); 100 µl. of about 3·2 per cent sodium nitrite (4 min.); 500 µl. of about 2 per cent sulphamic acid (3 min.); 500 µl. of about 1 per cent *N*-1-naphthyl ethylenediamine dihydrochloride; alcohol and water to make 10 ml.

The details of the procedure are such that semi-automatic Lang–Levy constriction pipettes could be used. These permit addition of reagents at intervals of 10 sec., so that a series of twelve analyses can be dealt with in 2 min. The reagents and reaction times (stated above in brackets) followed the methods of Averell and Norris[1,2] as well as Terp[4] (determination of procaine). The procedure has been tested to such an extent as to allow a convenient and reproducible technique to be established; but the reagents and reaction times make no claim to be optimal.

The titan reagent consists of 1 vol. of a 15 per cent solution of titan-III-chloride, 1 vol. of 2 *M* acetic acid and 2 vol. of 2 *M* sodium acetate; the amount mixed is such as to correspond with only one or two sets of analyses. In the circumstances, the reduction is performed in a weak acid solution, which is intensely greyish so long as the reducing titan is present in excess. (An old titan solution can be regenerated by adding a piece of zinc a few minutes before the dilution with acetate buffer; deposits of titanic compounds can be removed with hydrochloric acid and hydrogen peroxide.)

The amount of nitrite is somewhat larger than usual as some of it serves to remove the excess of titan. The hydrochloric acid should be added before the nitrite solution in order to avoid precipitation of titan compounds.

If the analysis is performed in a purely aqueous system, the colour develops fairly slowly, with absorption maximum at 555 mµ. Alcohol accelerates the colour development, but at alcohol concentrations of about 80 per cent and higher in the test solution, a different red colour is produced (a single observation implies the hydrochloric acid concentration to be too low in such cases). Usually the test solution should contain 20–70 per cent alcohol, and the final dye solution 30–50 per cent. The absorption maximum is now at 560 mµ. The colour seems to have become fully developed in the course of 10–20 min. and remains constant at least until the next day. The molar absorptivity is of the order of 46,000 M^{-1}cm.$^{-1}$. This is higher than the value found by Blinn *et al.*[5], possibly due to the presence of alcohol. Highly coloured solutions can be diluted with 50 per cent alcohol containing hydrochloric acid to prevent the dye from changing to yellow[5]. The stated quantities of reagents allow total amounts of up to 300 µgm. parathion being determined. In these cases the dye solution was made up to 100 ml. with the alcohol–acid–water mixture.

Using the method described here, the reduction time has been reduced from 10–20 min. (on boiling water bath) to 2 min. (at room temperature). Furthermore, the reduction with titan is performed in a homogeneous system, so that removal of the reducing agent by filtration or otherwise is avoided. Both processes contribute towards a considerable shortening of the process of analysis. Moreover, the somewhat simpler titan procedure opens up possibilities of performing the analysis on very small volumes.

BIOCHEMISTRY

Partial Synthesis of Vitamin B_{12} Coenzyme and Analogues

The structure of the vitamin B_{12} coenzyme[1] has been determined recently by X-ray crystallography[2]. It seemed possible (cf. ref. 3) that a synthesis of this compound, which contains a 5′-deoxyadenosyl group attached direct to the cobalt atom by a cobalt–carbon bond, could be achieved from reduced hydroxocobalamin and a suitably 5′-substituted adenosine derivative. 5′-Tosyladenosine is known[4] to cyclize easily to the tosylate of *cyclo*adenosine but the 5′-tosyl-2′,3′-isopropylidene derivative of adenosine can be prepared without difficulty[4]. Hydroxocobalamin was reduced in aqueous or ethanolic solution with sodium borohydride and reacted with this adenosine derivative. A product which had the properties expected of an isopropylidene derivative of the coenzyme was isolated from the reaction mixture in poor to moderate yield. Following a suggestion from Dr. V. M. Clark, whom we thank for his interest, we then attempted to reduce the cobalamin not just to the brown vitamin B_{12r} (ref. 5), believed to be a cobalt II derivative, but to the grey-green compound containing cobalt in a lower oxidation state[6]. This compound can be prepared under anaerobic conditions from hydroxocobalamin with sodium borohydride, chromous acetate in ethylenediamine tetra-acetic acid buffer at *p*H 9·5, or with zinc dust and dilute acetic acid. Under acid or alkaline conditions it reacts rapidly with a range of alkylating agents to give good yields of coenzyme analogues. In contrast, vitamin B_{12r}, the exclusive product obtained from hydroxocobalamin and chromous acetate at *p*H 5, is quite unreactive.

The reaction product from fully reduced hydroxocobalamin and 5′-tosyl-2′,3′-isopropylideneadenosine was purified via phenol extraction and passage of an aqueous solution through columns of DEAE-cellulose and CM-cellulose in series. The product passed rapidly through the former and more slowly through the latter as an orange zone which emerged as a red effluent. This was concentrated and crystallized from aqueous acetone. Mild acid hydrolysis (0·1 *N* hydrochloric acid for 16 hr. at room temperature or 15 min. at 90°) gave the vitamin B_{12} coenzyme as the main product. It was fully active in the enzyme assay of Abeles and Lee[7]; the absorption spectra in neutral and acid solution and the R_F value on paper chromatography with wet *sec.*-butanol were the same as those of the natural B_{12} coenzyme. On treatment with cyanide it yielded adenine and dicyanocobalamin.

Analogous experiments using 5′-tosylinosine or 5′-tosyluridine yielded crystalline products with absorption spectra and other properties similar to those of the coenzyme. In the enzyme assay, however, these analogues behaved as powerful competitive inhibitors of the coenzyme. Furthermore, alkyl halides and sulphates, for example, ethyl iodide and dimethyl sulphate, react with fully reduced cobalamin in aqueous or alcoholic solutions, the colour changing almost instantly from greenish-black to red or orange. Crystalline products have been isolated which presumably contain the alkyl group linked to cobalt. $^{14}CH_3I$ yielded the methyl analogue of the coenzyme, which had the same specific activity as the methyl iodide. Similar products have been obtained from reactions with ethylene bromhydrin, chloracetic acid, acetyl chloride and benzyl chloride. Some of these products also inhibit the natural coenzyme in the enzyme system.

Work is in progress to characterize these and related compounds and their degradation products, to measure their inhibition indices and to study their effects in biological systems.

Acetylcholinesterase Activity in *Nitella*

It is generally accepted that the process of excitation starts with a localized depolarization of the conducting cell membrane. The adjacent region is then depolarized by the resultant current flow. This process repeats itself at successive points and thereby the impulse is propagated. These electrical phenomena have been widely investigated, but the underlying mechanism is still under discussion. Nachmansohn[1] has suggested a theory according to which the acetylcholine system plays an essential part in bioelectrogenesis. Much evidence has been accumulated in favour of this theory during recent years. The evidence is based on experiments with animal cells, mostly nerve and muscle fibres of vertebrates and invertebrates. However, there are plants which resemble nerve and muscle in being able to propagate impulses by electric currents. There is an excitable membrane separating the cell from its environment, in which a sharp decrease in electrical impedance occurs during the passage of an impulse.

Nitella flexilis is a freshwater alga with large single cells. When an internode is stimulated, an action current is generated and conducts the impulse[2]. It appeared of interest to investigate whether the acetylcholine system is present in *Nitella*. There is a considerable number of difficulties to be overcome for testing this problem. But it appeared possible to test whether acetylcholinesterase is present. If the presence of this enzyme were established, this would be an indication that the substrate may also be present and may be hydrolysed there. It has been found that *Nitella* indeed is capable of hydrolysing acetylcholine. This communication is a preliminary report on the properties and concentration of the cholinesterase in *Nitella*.

The branches were dissected in small particles, dried on filter paper and pre-soaked in the incubation fluid for 1 hr. In previous experiments with other tissues it had been observed that in the first hour the rate of hydrolysis seemed to be much higher than in the following hours. Apparently some substrate is taken up by the tissue. After the pre-incubation the tissue was dried, weighed, homogenized, and then placed into the incubation fluid. Following such treatment the rate of hydrolysis was always linear. The substrates tested were acetylcholine bromide and acetyl β-methylcholine bromide. The latter substrate was selected because it is considered to be specific for acetylcholinesterase. The esterase activity was tested by Hestrin's colorimetric method[2,3] in which the disappearance of the substrate is followed.

Nitella hydrolysed 6·5 μmoles/gm./hr. of acetylcholine, while acetyl β-methylcholine was hydrolysed at a rate of 3·8 μmoles/gm./hr. The hydrolysis of the latter substrate indicates that the enzyme present is essentially the specific acetylcholinesterase. The rate of hydrolysis of acetylcholine in the giant axon of squid is in the order of 40–60 μmoles/gm./hr. It has to be kept in mind that the speed of propagation in *Nitella* is about 1,000 times slower than in nerve fibres. In control solutions without the substrate present some substance was released, presumably an ester. The nature of this substance is still unknown. The finding requires much more investigation before any final conclusions can be drawn about its significance. However, the presence of acetylcholinesterase in a plant cell capable of propagating electric currents suggests the possibility of a fundamental similarity of the mechanism of bioelectrogenesis in plant and animal cells.

I thank Prof. David Nachmansohn for his interest and valuable discussions.

In vitro Examination of the Ribonucleic Acid–Deoxyribonucleic Acid–Deoxyribonuclease System in Mammals

THERE is a considerable number of substances which inhibit the activities of deoxyribonuclease (DNase). Some of the natural inhibitors appear to have a relative specificity of action; these are substances of protein nature active against the DNase of yeast[1] or against the DNase of the bovine pancreas[2,3], or ribonucleic acids (RNA) extracted from certain species of micro-organisms and specifically active against a very small number of bacterial DNases[4–6].

The inhibitory effect of the RNA of yeast on pancreatic DNase is rather slight[7].

We thought it of interest to carry out similar investigations on an isologous enzymatic system, that is, one in which use is made of an enzyme and the substrate from the same animal species. We have therefore examined the effect of calf-liver RNA on the degradation of calf-thymus DNA brought about by neutral crystallized DNase of Kunitz[8], obtained from pancreas of the same species of animal.

The DNase (Worthington Co.) was re-crystallized three times.

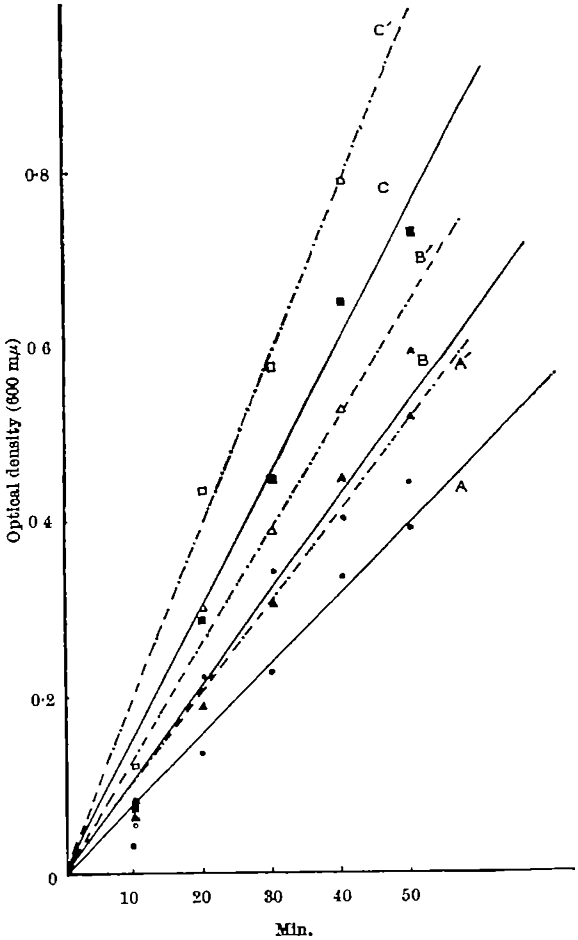

Fig. 1. Influence of calf liver RNA on calf-thymus DNA–Kunitz pancreatic DNase system. Determination of DNase activity was by spectrophotometry. The solutions contained 0·125, 0·166, 0·250 mgm./ml. DNA in *tris*-buffer medium 0 066 *M* at *p*H 7·5, magnesium chloride 0 025 *M* either in the presence of 0·833 mgm./ml. RNA in EDTA 10^{-4} *M* (curves *A'*, *B'* and *C'*) or EDTA 10^{-4} *M* without RNA (curves *A*, *B* and *C*). The concentration of DNase was 0·083 μgm./ml.

The DNA was prepared by the method of Kay *et al.*[9]. It contained less than 0·3 per cent protein. Its molecular weight was 6 × 10^6 (light-scattering data). Its intrinsic viscosity was 5·300 c.g.s. units. $E_{(P)}$ was 6·600.

The RNA was prepared by the method of Laskov *et al.*[10], by precipitation with 3 *M* sodium chloride, and preserved in 10^{-4} *M* ethylenediamine tetraacetic acid. Its molecular weight was 9 × 10^5 (light-scattering data). It contained only traces of protein.

The RNA contained no DNA, showed no DNase activity and was completely precipitable by acid under the experimental conditions used.

The DNA contained less than 0·9 per cent RNA and showed no RNase activity.

The principle of these experiments consisted in the comparison of the degradation-rates of increasing quantities of substrate (DNA) in the presence of an unchanged quantity of enzyme (DNase) with and without RNA. Several experiments were carried out with different RNA/DNA weight ratios. The activity of deoxyribonuclease was determined under optimal conditions as regards *p*H (7·5) and magnesium concentration (0·025 *M*) either by a spectrophotometric method derived from that of Kunitz[8]—determination

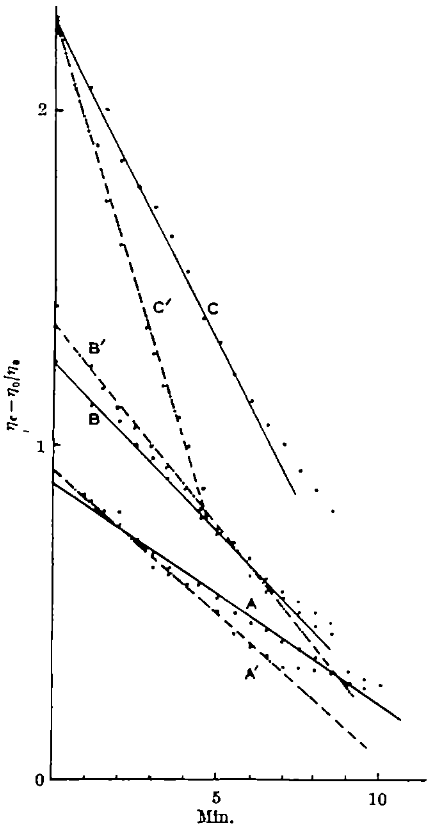

Fig. 2 Determination of DNase activity by viscosimetry. Conditions as for Fig. 1

of the acid-soluble derivatives by quantitative determination of deoxyribose—or by a viscosimetric method at a constant rate of shear.

The results with either method were practically the same (Figs. 1 and 2). The calf-liver RNA definitely had not the same effect as that obtained with bacterial compounds; on the contrary, it slightly enhanced the degradation-rate of the calf-thymus DNA under the influence of crystallized DNase obtained from pancreas of the same species of animal. Preliminary findings (substitution to the RNA of hydrolysates by ribonuclease, or of its calcination residue) suggest that this non-specific activation is due to the presence of mineral substances accompanying the RNA.

Borate Inhibition of Chymotryptic Proteolysis

In attempts to duplicate the experiments on the rate of hydrolysis of bovine growth hormone by α-chymotrypsin[1] a pronounced inhibitory effect of borate ion on chymotryptic proteolysis was observed.

The bovine growth hormone, isolated in this laboratory, was of high purity and comparable with that reported in the literature[2,3] in regard to both biological activity and physicochemical properties. The human serum albumin had been isolated here some years ago by one of E. C. Cohn's alcoholic fractionation procedures. The α-chymotrypsin was a three-times crystallized product obtained from Worthington and was further characterized by the determination of its specific activity against acetyl-tyrosine ethyl ester and benzoylarginine ethyl ester. The protein substrate was dissolved at *p*H 9·5 in a buffer containing either glycine or 2-amino-2-methylpropane-1,3-diol; the ionic strength ($\Gamma/2$) was 0·1. The chymotrypsin was dissolved in $M/10$ sodium chloride containing 10^{-3} M hydrochloric acid. One ml. of the protein solution was added to 5·9 ml. of each of various buffers of *p*H 9·5 containing different concentrations of borate and sodium chloride to make $\Gamma/2 = 0{\cdot}1$. To this mixture 0·1 ml. of enzyme solution was added from a calibrated microsyringe. The final concentration of substrate was 1 per cent; the enzyme to substrate ratio (E/S) was 1/300 for the digestions of growth hormone and 1/100 for those of serum albumin. The buffer compositions were appropriately modified when ionic strength rather than borate concentration was the variable examined. In every case the *p*H of the reaction mixture was found to be 9·5 at the start of the digestion. Aliquots of the digests were removed at 30-min. intervals and precipitated with an equal volume of freshly prepared 10 per cent trichloroacetic acid. The precipitate and supernatant were separated by centrifugation for 10 min. at 2,000*g*. The colour developed in each fraction with Folin's phenol reagent by the procedure of Lowry *et al.*[4] was measured in the Beckman *DU* spectrophotometer and converted to 'protein' by using charts calibrated with the appropriate protein substrate. The percentage digestion was calculated as 100 times (protein in supernatant)/(sum of protein in supernatant and precipitate). All curves are free-hand constructions.

Since the colour intensity developed in this procedure does not follow the Lambert–Beer law and, moreover, varies with the protein used, and since the protein digests are no longer the native protein, an appreciable error is introduced. For a given sample of digest the specific colour yield varies non-linearly and inversely with the concentration of protein used in the determination. This was especially true for the 'protein' soluble in 5 per cent trichloroacetic acid in contrast to the insoluble protein. To minimize this error each sample was analysed at three low levels of concentration and the curve visually constructed on these values was extrapolated to zero concentration. The degree of inhibition of the chymotryptic hydro-

Curve 1, Γ/2 of 0·04 and borate 0 025 *M*. Curves 6 and 7, digestion-rate in glycine buffer of Γ/2 0 1 (▽) and 0 05 (△) with no borate. The *p*H in all cases was 9·5, the substrate concentration 1 per cent and the ratio of enzyme to substrate 1 : 800

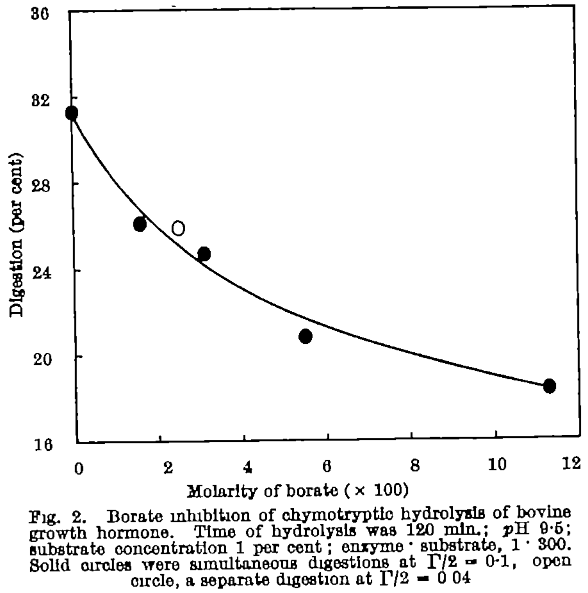

Fig. 2. Borate inhibition of chymotryptic hydrolysis of bovine growth hormone. Time of hydrolysis was 120 min.; *p*H 9·5; substrate concentration 1 per cent; enzyme · substrate, 1 · 300. Solid circles were simultaneous digestions at Γ/2 = 0·1, open circle, a separate digestion at Γ/2 = 0 04

lysis of bovine growth hormone varied from 16 per cent at a borate concentration of 0·016 *M* to 42 per cent at a concentration of 0·113 *M* (Fig. 1). The inhibition is not a linear function of borate concentration (Fig. 2). The adverse effect of borate is not dependent on some peculiarity of bovine growth hormone. Thus Table 1 illustrates the inhibition of chymotryptic hydrolysis of human serum albumin. Since the two protein substrates are quite different in most respects, the inhibition by borate would seem to be a general property of this ion in chymotryptic proteolyses.

Variations of ionic strength independent of borate ion are without effect, within the limits studied, as shown in Figs. 1 and 2. In the latter the digestion carried out at Γ/2 of 0·04 (open circle) falls in line with the curve of borate inhibition at Γ/2 of 0·1. Curves 6 and 7 of Fig. 1 show that the digestion-rate in glycine buffer with no added borate was essentially identical at Γ/2 of 0·1 and of 0·05. A series of four digestions at ionic strengths varying from 0·04 to 0·24 was carried out in borate-free buffers of 2-amino-2-methylpropane-1,3-diol and yielded results which did not differ significantly from those shown for glycine in Fig. 1. Whether or not borate is inhibitory to other hydrolases and whether the inhibition is produced by a complexing with the substrate, the enzyme or both is not known. Osaki[5] has very recently reported on the borate inhibition of the oxidase activity of ceruloplasmin, and proposed the likelihood that the borate combined with one of the carbohydrate residues of that enzyme.

Hofstee[6] recently has reported that salts reverse the inhibition produced by serum albumin on the chymotryptic hydrolysis of synthetic substrates. Schlamowitz and Peterson[7] have shown that ionic strength markedly affects the course of proteolysis by pepsin. The entirely different experimental conditions in both these reports, however, preclude any comparison with the lack of effect of ionic strength described here.

I thank Drs. C. H. Li and H. Papkoff for their co-operation, Mrs. Jessie Ozmun for her assistance, and Dr. H. V. Anderson and Mr. C. Vander-Kolk for the bovine growth hormone.

In vitro Synthesis of Phosphoarginine by Blowfly Muscle

IN a recent review dealing with respiratory metabolism in insect flight-muscle Sacktor[1] directed attention to the fact that the synthesis of phosphoarginine has not been demonstrated *in vitro* in any insect tissue.

While investigating the conditions necessary *in vitro* for the demonstration of respiratory control in flight-muscle of *Calliphora erythrocephala* we have examined the effect of arginine on the oxygen uptake by suspensions of thoracic muscle. These were prepared at 0° C. by crushing thoraces from 50 flies in 3 ml. of a medium containing 0·32 *M* sucrose, 10^{-2} *M* *tris*/hydrochloric acid buffer (*p*H 7·3), 10^{-2} *M* ethylenediaminetetra-acetate, and squeezing the muscle pulp through six layers of muslin. The oxygen uptake was measured with a vibrating platinum electrode after the addition of 0·1 ml. of the suspension to 2·1 ml. of the following medium: 0·18 *M* sucrose; 2·1 × 10^{-2} *M* potassium dihydrogen phosphate/*tris* buffer (*p*H 7·0); 10^{-3} *M* ethylenediamine tetraacetate; $6{\cdot}3 \times 10^{-3}$ *M* magnesium chloride; $4{\cdot}8 \times 10^{-4}$ *M* adenosine triphosphate; $1{\cdot}3 \times 10^{-2}$ *M* pyruvate; $1{\cdot}3 \times 10^{-3}$ *M* fumarate. Under these conditions the addition of adenosine diphosphate caused a six-fold increase in the rate of oxygen uptake. Similarly the addition of arginine hydrochloride (20 µl. 1 *M*) was followed by a three-fold increase in the rate of oxygen uptake, and it seemed likely that this increase could be attributed to the formation of adenosine diphosphate through the arginine phosphokinase reaction. Since this would result in the simultaneous formation of phosphoarginine, the demonstration of this substance in the incubated suspension was attempted. The reaction mixture was deproteinized with 2 ml. of ethanol 5 min. after the addition of the muscle suspension. For the zero-time control 2 ml. of ethanol was added to the reaction medium before the muscle suspension. The deproteinized mixtures were centrifuged at 0° C. for 10 min. at 2,000*g*, and 50 µl. samples of the supernatants were chromatographed on strips of Whatman No. 1 paper either in water-saturated phenol in an atmosphere of ammonia or in propanol/ammonia (sp. gr. 0·88)/water (60 : 30 : 10).

Duplicate chromatograms were tested either with ninhydrin or with the Sakaguchi reagent. Both tests showed that the supernatant from the reaction mixture contained, in addition to arginine, a compound running with the same R_F as phosphoarginine in both solvent systems (0·3 in the phenol solvent, 0·17 in the propanol solvent), and that this compound was not present in the zero-time control. A sample of the supernatant from the reaction mixture was brought to 0·1 *N* with respect to hydrochloric acid and kept for 1 min. at 100° C. The sample was then neutralized with 3 *N* ammonia and 50 µl. aliquots were chromatographed in the phenol solvent. Treatment of the chromatograms with ninhydrin showed that the slower running compound (R_F 0·3) was no longer present, a finding which supports the supposition that this compound is phosphoarginine.

In further experiments muscle suspensions were incubated in Warburg flasks, 0·1 ml. of suspension being added to 0·9 ml. of the following medium: 0·18 *M* sucrose; $5{\cdot}6 \times 10^{-3}$ *M* potassium dihydrogen phosphate/*tris* buffer (*p*H 8·0); 10^{-3} *M* ethylenediaminetetraacetate; $7{\cdot}3 \times 10^{-3}$ *M* magnesium chloride; $5{\cdot}5 \times 10^{-4}$ *M* adenosine triphosphate; $1{\cdot}3 \times 10^{-2}$ *M* pyruvate; $1{\cdot}3 \times 10^{-3}$ *M* fumarate; $5{\cdot}5 \times 10^{-2}$ *M* arginine hydrochloride. Each flask also contained 25 µc. of [^{32}P]orthophosphate. Suspensions treated similarly except for the omission of arginine were used as controls. After incubation at 25° C. for 30 min. 1 ml. of ethanol was added to each flask and the contents were centrifuged at 0° C. The supernatants were chromatographed in the phenol solvent and phosphorus-32 located by scanning the chromatograms radiometrically[2]. About 67 per cent of the phosphorus-32 from the suspension incubated with arginine appeared at R_F 0·3, where a positive reaction was obtained both with ninhydrin and with the Sakaguchi reagent. On chromatograms from suspensions incubated in the absence of arginine only about 10 per cent of the phosphorus-32 was found at this R_F and the ninhydrin and Sakaguchi tests were negative. The orthophosphate in the supernatants was estimated[3] both before and after hydrolysis for 1 min. at 100° C. in 0·1 *N* sulphuric acid. The suspensions incubated with and without arginine contained 4·3 and 0·6 µmoles of '1-minute-hydrolysable' phosphate respectively.

The supernatant from the suspension incubated with arginine was chromatographed, admixed with phosphoarginine, in the phenol solvent, the amount of supernatant being such that compounds labelled with phosphorus-32 were below the threshold for chemical detection. The labelled compound running at R_F 0·3, detected radiometrically, was found to coincide with the phosphoarginine detected chemically. These compounds on the corresponding area of a parallel chromatogram were eluted and chromatographed in the propanol solvent, when again there was coincidence between the labelled compound and the phosphoarginine.

Finally the phosphorus-32-labelled compound in question, isolated chromatographically in the phenol solvent, was hydrolysed *in situ* (1 min. at 100° C. after spraying paper with 0·1 *N* hydrochloric acid) and the hydrolysis products were eluted and rechromatographed. Both ninhydrin and Sakaguchi tests showed a single compound running with the R_F of arginine in the phenol solvent (0·9) and in the propanol solvent (0·39), and the phosphorus-32 ran with the R_F of inorganic phosphate. Thus it appears that the compound produced on incubating the muscle suspensions with arginine is in fact phosphoarginine.

Sacktor's failure to demonstrate the formation of phosphoarginine by isolated sarcosomes[4] may have been due, as he suggested, to the fact that arginine phosphokinase is associated with some other fraction of the insect muscle. A preliminary examination of the sarcosomal and 'soluble' fractions from suspensions of thoracic muscle has shown that on incubation with arginine and adenosine triphosphate the amount of phosphoarginine produced by the 'soluble' fraction is about ten times that produced by the sarcosomes. Thus, although phosphagens other than phosphoarginine may be present in insect muscle, our findings are in keeping with the accepted view that phosphoarginine is of prime importance.

We thank Dr. P. C. Caldwell for a gift of phosphoarginine.

Binding Site of Flavin Adenine Dinucleotide combining with Sulphydryl Group of D-Amino-acid Oxidase Apo-enzyme

In previous papers[1,2] it was demonstrated, by a kinetic method using indicators, that the adenylic acid part of flavin adenine dinucleotide combines with the sulphydryl group of the apo-enzyme of D-amino-acid oxidase. The changes of the absorption spectra of flavin adenine dinucleotide, riboflavin-5′-monosulphate and adenosine-5′-monosulphate, observed on adding the apo-enzyme of D-amino-acid oxidase and/or benzoate as a substrate-substitute, revealed that the adenylic acid part of flavin adenine dinucleotide readily combines with the apo-enzyme, whereas the isoalloxazine nucleus of flavin adenine dinucleotide combines with both the apo-enzyme and the substrate-substitute[3,4]. Thus, the combination between adenylic acid part of flavin adenine dinucleotide and sulphydryl group of the apo-enzyme was considered to be important for reconstruction of the holo-enzyme. We wished to determine which group of the adenylic acid part of flavin adenine dinucleotide can actually combine with the sulphydryl group of D-amino-acid oxidase apo-enzyme.

As already mentioned previously[1,2], the NH_2-group in adenine nucleus of flavin adenine dinucleotide was first noticed. To investigate the meaning of the NH_2-group, we examined flavin hypoxanthine dinucleotide, which possesses an OH-group instead of an NH_2-group in adenine nucleus of flavin adenine dinucleotide.

Flavin hypoxanthine dinucleotide was prepared from flavin adenine dinucleotide by the method of Fujisawa[5]. Flavin adenine dinucleotide was diazonized with sodium nitrite in cold 2 *N* acetic acid and the flavin hypoxanthine dinucleotide that resulted was separated by paper chromatography using 5 per cent sodium phosphate as a mobile phase, eluted from the paper with water, saturated with ammonium sulphate, and transferred to phenol. The yellow phenol layer was collected, dried with sodium sulphate and flavin hypoxanthine dinucleotide was extracted with a small amount of water, washed with ethyl ether several times and then precipitated with 95 per cent ethyl alcohol. The absorption spectrum of the solution of this powder has a shoulder at 255 mμ, the ratio E_{260}/E_{450} being 2·8.

D-Amino-acid oxidase apo-enzyme was prepared by a method that we have described elsewhere[4]. Flavin adenine dinucleotide was prepared by the method of Yagi *et al.*[6]. The coenzyme action of flavin hypoxanthine dinucleotide was tested by a conventional manometric method using a reaction mixture of apo-enzyme 1×10^{-7} mole/l., flavin hypoxanthine dinucleotide 3×10^{-6} mole/l. and an excess of D-alanine in pyrophosphate buffer (*p*H 8·3, *M*/10). The reaction mixture showed no uptake of oxygen. It was also observed that flavin hypoxanthine dinucleotide has no inhibitory action on D-amino-acid oxidase at concentrations of 3×10^{-5} mole/l. and 8×10^{-8} mole/l., of flavin hypoxanthine dinucleotide and flavin adenine dinucleotide respectively. These results indicate that flavin hypoxanthine dinucleotide has neither coenzyme activity nor inhibitory action for D-amino-acid oxidase.

The absorption spectrum at visual wave-length region of flavin hypoxanthine dinucleotide was measured, and was found to be similar to that of flavin adenine dinucleotide. It was not changed on adding the apo-enzyme. The influence of both the apo-enzyme and benzoate, a substrate-substitute of this enzyme, on the absorption spectrum of flavin hypoxanthine dinucleotide was investigated. The absorption spectrum at wave-lengths in the visual region of flavin hypoxanthine dinucleotide was not changed at all.

It has been noted[3,4] that the absorption spectrum of flavin adenine dinucleotide at wave-lengths in the visual region was slightly modified by the apo-enzyme and markedly changed on adding both the apo-enzyme and benzoate.

Comparing these data on flavin hypoxanthine dinucleotide with those of flavin adenine dinucleotide, it can be concluded that the NH_2-group of adenine part of flavin adenine dinucleotide is essential for the reconstruction of the holo-enzyme and is one of the most important binding sites of the coenzyme in D-amino-acid oxidase activity.

PHYSIOLOGY

Sodium–Potassium-activated Adenosine Triphosphatase in the Squid Giant Axon

OUR understanding of the recovery mechanism involved in the active transfer of sodium out of, and of potassium into, the nerve cell has been increased considerably in recent years through the examination of giant axons like those of the squid. Hodgkin and Keynes[1] showed that the efflux of sodium-22 and the influx of potassium-42 were both markedly reduced by exposing the nerves to 0·2 m.mol./l. dinitrophenol, 2 m.moles/l cyanide or 3 m.moles/l. azide. The passive movements of the ions down their concentration gradients were little affected, as was also the electrical activity of the nerves, which involves the latter movements. The inhibition of the active cation transport was largely reversed when the inhibitors were washed away.

Caldwell[2,3] was able to show a parallelism between the axoplasmic levels of adenosine triphosphate (ATP) and related compounds and the sodium-22 efflux from squid axons on exposure to cyanide and during recovery after removal of the inhibitor. Injection of ATP, and also of arginine phosphate (AP) and phosphoenolpyruvate (PEP), into the axoplasm of a squid axon exhausted of endogenous ATP through prior exposure to cyanide caused a transient increase of the sodium-22 efflux[4,5], but external application of ATP and AP had no effect. Injections of creatine phosphate, arginine, adenosine monophosphate, inorganic orthophosphate and pyrophosphate did not change the sodium-22 efflux. It was also shown that within minutes after injection of AP and PEP into a cyanide-poisoned squid axon the internal ATP level had returned to normal[6]. This indicates that the active cation transport is driven by ATP or a related high-energy phosphate compound. In a potassium-free medium the sodium efflux was reduced by 70 per cent[1,6].

These findings assume particular importance in the light of the discovery of a cardiac glycoside-sensitive sodium–potassium-activated ATPase in crab nerve by Skou[7,8], and the subsequent demonstration by Post *et al.*[9] and Dunham and Glynn[10,11] that this enzyme is an integral part of the active sodium–potassium transport mechanism in erythrocyte membranes. Caldwell and Keynes[12] showed that the cardiac glycoside ouabain (10^{-5} mole/l.) applied externally to a squid axon reduced the sodium-22 efflux by 82 per cent, with the remaining sodium-22 efflux being insensitive to cyanide or to injection of ATP. Unlike cyanide. dinitrophenol and azide, ouabain had no effect when injected into the axon[12], nor did it significantly reduce the levels of ATP and AP in the axoplasm[3]. It has now been possible to demonstrate the presence of a cardiac glycoside-sensitive sodium–potassium-activated ATPase in the squid axon and to compare its activity in the sheath on a surface area basis with the ion flux data obtained by Caldwell and Keynes[13].

The giant axons were obtained from the squid *Loligo pealii*, caught at the Marine Biological Laboratory, Woods Hole (Mass.). After dissecting the axon free from the animal and measuring its length and diameter, the axoplasm was separated from the sheath[14]. Sheath and axoplasm were placed on a glass slide, and immediately frozen and stored in dry ice until lyophilization. The material was collected over a 30-hr. period, flown to the laboratory in Bethesda, and frozen-dried within 18 hr. after collection. The length of the sheath was measured again to allow correction for shrinkage during freeze-drying. Sections, approximately 0·7 mm. long, were cut from the sheath, their length was measured microscopically, and the dry weight (1·8–3·3 μgm.) was determined on a quartz fibre ultramicro balance[15]. Samples were taken from the dried axoplasm and weighed in similar fashion (3·0–5·0 μgm. dry weight). Each sample was inserted into a 5 μl. aliquot of each of two substrate media by means of a glass needle under stereomicroscopic observation. The rest of the assay procedure was as described previously[16] except 30 μl. (instead of 50 μl.) 10 per cent w/v trichloroacetic acid was added after incubation. The substrate media used were the complete medium *A* (for total ATPase activity) and the inhibiting medium *B* (containing 0·1 m.mole/l. ouabain for complete inhibition of sodium–potassium ATPase). Six samples of each of five sheaths and two axoplasm specimens were assayed in each medium.

The results, expressed in m.moles/kgm. dry wt./hr., in percentage of total ATPase activity and in moles/cm.^{2}/sec., are shown in Table 1. It will be noticed that the sodium–potassium ATPase activity is present in both structures, representing about 24 per cent of the total ATPase activity. On a dry weight basis, the average sodium–potassium ATPase activity in the axoplasm is only about half as large as in the sheath or really only about one-third as high as in sheaths Nos. 1 and 2, from which the axoplasm specimens were extruded. On a surface area basis, the average sodium–potassium ATPase activity in the sheath amounts to 9·6 (± 1·9 *S.E.*) × 10^{-12} mole/cm.^{2}/sec. Caldwell and Keynes[13] have recently determined that the total resting influx of potassium-42 in the cleaned squid axon is 16·3 (± 2·2 *S.E.*) × 10^{-12} mole/cm.^{2}/sec. Poisoning by 2 m.moles/l. cyanide reduced the potassium-42 influx to 4·3 (± 0·3 *S.E.*) × 10^{-12} mole/cm.^{2}/sec. (ref. 6), indicating that the active potassium-42 influx is 12·0 × 10^{-12} mole/cm.^{2}/sec. The molar ratio of active potassium-42 influx to sodium–potassium ATPase activity is then 1·25 (± 0·34 *S.E.*). This is in good agreement with the ratio of 1·46 moles sodium-22 extruded per mole of ATP injected, determined by Caldwell *et al.*[6]. This approximate equivalence of action flux and sodium–potassium ATPase activity has been found to hold over a 30,000-fold range in cation flux in six different tissues[17].

Table 1. ATPase Activity in Squid Axon Sheath and Axoplasm

Specimen	Ratio area/dry wt. 10^{3} cm.^{2}/gm.	Total ATPase m.mol./kgm. dry wt./hr.	Na–K m.mol./kgm. dry wt./hr.	ATPase activity Percentage of total	ATPase activity 10^{-12} mol./cm.^{2}/sec.
Sheath 1	5·96	857	286	33	13·3
Sheath 2	6·43	854	319	37	18·8
Sheath 3	8·51	664	124	19	4·1
Sheath 4	5·51	824	126	15	6·2
Sheath 5	5·24	1,421	200	14	10·6
Average	—	924	211	23·6	9 6
Axoplasm 1	—	498	109	22	—
Axoplasm 2	—	400	107	27	—
Average	—	449	108	24 1	—

The similarity between the properties of the sodium–potassium ATPase and the active sodium–potassium transport mechanism in the squid axon (ATP requirement, inhibition by ouabain in medium, requirement for potassium in medium, location in sheath), as well as the equivalence of the enzyme activity and the active potassium-influx, seem to indicate that this enzyme is an integral part of the active sodium–potassium transport mechanism in the squid axon[18].

Inhibitory Effect of Some Mucopolysaccharides on the Lipolytic Activity of the Aorta of Animals

THE acid mucopolysaccharides (MPS) as macroanions form complexes with proteins and thus they change the isoelectric point of the latter. Based on this property some MPS's are able to inhibit or activate many enzyme systems[1].

We previously reported[2,3] on the interaction between MPS's isolated from human aortic intimas and β-lipoprotein fraction as well as fibrinogen of human plasma. The fact was established that one group of the aortic intimal MPS's formed specific complexes with these plasma constituents. Zemplényi *et al.*[4,5] demonstrated the lipolytic activity of the aorta of various species and recently established the inhibitory effect of a raised calcium concentration on the lipoprotein–lipase activity.

We have now demonstrated that some intimal MPS's may be of importance in the mechanism of lipid deposition by their inhibitory effect on the lipolytic activity of the vessel wall.

The lipolytic activity of the aortas of 10 rabbits, 6 dogs and 4 rats was investigated by incubating the aortic homogenates with human lipæmic serum according to the method of Zemplényi *et al.*[4]. The effect of an MPS mixture isolated from the intimas of pooled atherosclerotic human aortas on the lipolytic activity of the vessel wall of the animals was examined. The method of isolation was based on that of Dyrbye and Kirk[6]. Our preparations contained, besides the acid-MPS's, sialic acid and other glycoprotein components.

Fig. 1 shows a typical pattern of the inhibitory effect of increasing concentrations of human aortic MPS mixture on the lipolytic activity of rabbit-aortas. With an increasing concentration of the MPS mixture the lipolytic activity decreased and by 5 mgm. previously incubated mixture the grade of inhibition was complete in all cases investigated.

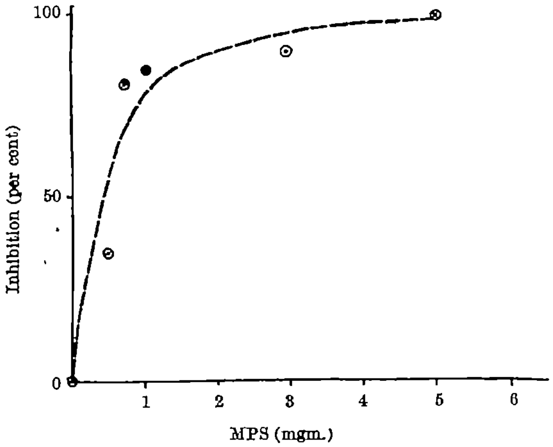

Fig 1. Inhibitory effect of human aortic MPS mixture on the lipolytic activity of rabbit aorta

Next we compared the inhibitory effect of 5 mgm. crystalline hyaluronic acid and that of 5 mgm. chondroitin sulphuric acid (L. Light and Co., Ltd., Colnbrook) with the same quantity of human aortic MPS mixture (which completely inhibited the lipolytic activity of the aortic tissues). Fig. 2 demonstrates that under the same experimental conditions the inhibition of the lipolytic activity of chondroitin sulphuric acid and hyaluronic acid was definitely lower than that of the aortic MPS preparation used by us.

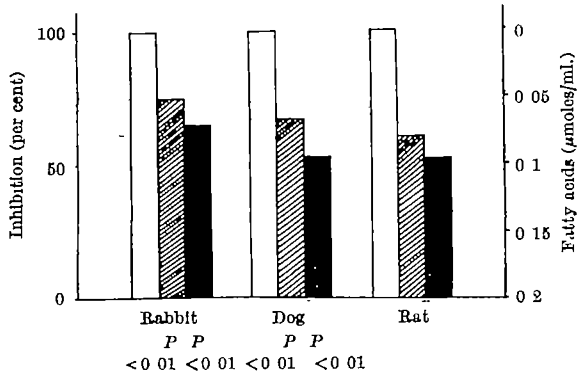

Fig. 2 Inhibitory effect of 5 mgm. aortic MPS, hyaluronic acid and chondroitin sulphuric acid on the lipolytic activity of the aorta. White, human aortic MPS mixture; shaded, hyaluronic acid; black, chondroitin sulphuric acid

Results were similar with all species investigated, differences being significant with rabbits and dogs.

These findings concerning the lower inhibitory activity of chondroitin sulphuric acid and hyaluronic acid support the view that some other MPS components of the vessel wall, even more the interaction of the different components, may be significant.

Based on our previous[2,3] and present investigations —which reflect a part of the possible biochemical processes in the arterial wall—we can assume that the deposition of lipids in the intima may be explained by some chemical or physicochemical changes in the MPS composition of the intimal ground substance. These changes may partly facilitate the formation of MPS-β-lipoprotein complexes and partly inhibit the lipolytic activity of the vessel wall. Both processes may be important in the chain of events which leads to atheromatosis.

Inhibition of Anaphylactic Histamine Release by 2-Deoxyglucose

The inhibition of anaphylactic histamine release by lack of oxygen[1-3] suggested the possibility that the metabolism of glucose by the oxidative pathway might be involved in the process. However, glucose itself caused no stimulation of histamine release in my experiments[4], although such stimulation has been reported by others[5,6]. It is possible that the stimulant effect of glucose is observed only when the tissue is depleted of endogenous substrate during its preparation It should then be possible to inhibit histamine release even in the presence of endogenous substrate with 2-deoxyglucose, which blocks glucose utilization beyond glucose-6-phosphate stage[7]. Moreover, it has been shown that the inhibition of histamine release by anoxia can be partially reversed by glucose[6,8]. If this reversal depends on the glycolytic breakdown of glucose, 2-deoxyglucose would be expected to block it. In the present investigation, therefore, the effect of 2-deoxyglucose on anaphylactic histamine release was studied both under aerobic and anaerobic conditions.

Anaphylactic reaction was produced *in vitro* using minced and washed lungs from guinea pigs sensitized to egg albumin. The histamine release and oxygen uptake during 20-min. periods after the addition of antigen were determined as described elsewhere[4]. The inhibitor, 2-deoxyglucose, was added 30–50 min. before contact with antigen. The incubation medium routinely used (modified Krebs–Ringer solution[9] at

Table 1. Reversal by Pyruvate and Acetate of 2-Deoxyglucose induced Inhibition of Anaphylactic Histamine Release

Exp.	Substrate	2-Deoxy-glucose (m.mol.)	Oxygen uptake (Q_{O_2})	Histamine release (μgm./gm. dry wt.)

	Acetate, 13 m mol.	10	5·2 ± 0·05	5·2 ± 0·34	(4)
				($P < 0·01$)	

Mean histamine release (as base) and standard error of the mean shown. Number of samples in parentheses in the last column. P relates to the two immediately overlying values.

pH 7·3–7·4) was free from substrate. When a substrate was used, the tissue fragments were placed in this medium, in aerobic experiments, about 30 min. before the addition of the inhibitor. In anaerobic experiments the substrate (glucose) and the inhibitor were added at the same time. Anaerobiosis was produced with helium.

In the absence of added substrate 2-deoxyglucose causes pronounced inhibition of histamine release as shown in Fig. 1. The respiration was, however, very little affected—the oxygen uptake corresponding to the histamine values shown in Fig. 1 varying from 86 to 97 per cent of normal. Indeed, the inhibition of histamine release may be associated with an unchanged ($P > 0·5$) uptake of oxygen (Exp. 2, Table 1).

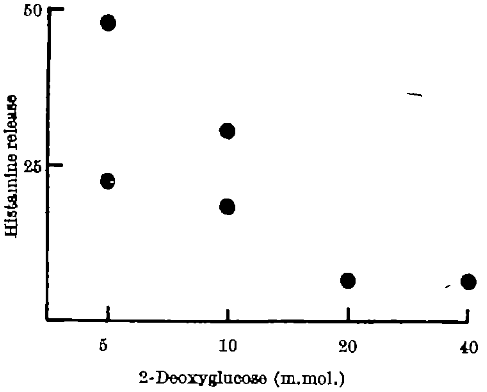

Fig. 1. Inhibition of anaphylactic histamine release by 2-deoxyglucose. Histamine release with inhibitor is expressed as a percentage of the release without inhibitor (control). The points—showing the mean values from 2–4 samples with the inhibitor and an equal number of controls—represent separate experiments except for the two highest concentrations

If the dependence of anaphylactic histamine release on oxygen is due to the oxidative metabolism of glucose, it may be assumed that the blocking effect of 2-deoxyglucose would be reversed by supplying a substrate distal to the block. As shown in Table 1 pyruvate and acetate were indeed effective in reversing the inhibition caused by 2-deoxyglucose. However, the reversal was incomplete even when eight times higher molar concentration of one of the substrates (pyruvate) was used. The penetration of the cell membrane could be a limiting factor, although enough substrate entered the cell to cause a stimulation of respiration.

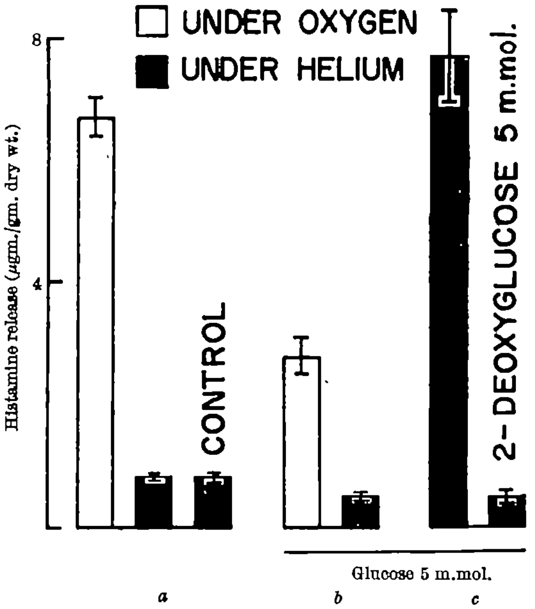

Fig. 2. Effect of 2-deoxyglucose on anaphylactic histamine release (expressed as base) in anoxia. All samples were incubated with antigen except the control of experiment a. Spontaneous histamine release is included in the values of a and deducted from those of b and c. Mean and $S.E.$ of three samples for a and four samples for b and c. a shows that anoxia completely inhibits histamine release in a substrate-free medium; b, glucose partially restores histamine release blocked by anoxia; c, the glucose-effect is inhibited by 2-deoxyglucose

The experiments shown in Fig. 2 were performed to explore the effect of 2-deoxyglucose on histamine release in anaerobic condition. Histamine release was completely inhibited by lack of oxygen in a substrate-free medium (Fig. 2a), and the inhibition was partially restored by supplying glucose (Fig. 2b). As shown in Fig. 2c the reversing effect of glucose could be blocked by equimolar amount of 2-deoxyglucose (5 m.mol.); when 10 m.mol. of 2-deoxyglucose was used in the same experiment histamine release was completely inhibited.

2-Deoxyglucose is phosphorylated by hexokinase but the product, 2-deoxyglucose-6-phosphate, accumulates inside the cell and causes a block in the glycolytic pathway. In rat diaphragm the phosphorylated glucose analogue reaches a concentration of 0·02 M and inhibits the penetration of glucose[10]. This seems to be the mechanism by which the restoring effect of glucose on anaphylactic histamine release in anoxia is blocked by the analogue: 2-deoxyglucose-6-phosphate, formed from the analogue by inhibiting glycolytic utilization of glucose, blocks histamine release in the presence of glucose under anoxia. In case of *in vitro* anaphylaxis under oxygen, where no external substrate was used, the breakdown of glycogen in the cell was apparently blocked by the accumulated 2-deoxyglucose-6-phosphate.

The inhibition of histamine release by 2-deoxyglucose under oxygen was not associated with a remarkable effect on respiration, although only one-third of the oxygen uptake is sufficient for the optimal anaphylactic histamine release[4]. This suggests the possibility that some specific reaction in the metabolic pathway of glucose may be concerned with the histamine releasing process.

It is of interest to note that 2-deoxyglucose has been found to inhibit anaphylactoid œdema of rats caused by dextran and ovomucoid, but the reactions to compound 48/80 were unaffected[11]. The latter observation fits in with the finding[12] that 2-deoxyglucose does not inhibit histamine release from minced rat lung incubated under oxygen with compound 48/80.

PHARMACOLOGY

Analysis of the Vasodilator Effect of Adrenaline on the Skeletal Muscle Vessels of Man

INTRA-ARTERIAL infusions of small amounts of adrenaline cause a marked but transient increase in the flow of blood in the calf of the leg; this is followed by a return to the base-line or even by a decrease in flow of blood, although the infusion continues[1]. The biphasic effect of adrenaline may be explained by interaction with the different adrenergic receptors[2], the primary vasodilatation being mediated by the β-receptors and the secondary vasoconstriction being brought about by action on the α-receptors. Supporting such an explanation is the observation that the decrease in flow of blood in the muscles of the fore-arm due to adrenaline can be abolished by an intra-arterial infusion of dibenyline which is known to inhibit the action of adrenaline on the α-receptors[3]. Proof of the existence of β-receptors in blood vessels of man has so far not been reported.

In order to elucidate the increase in flow of blood in muscle due to intra-arterially administered adrenaline in man, we used the dichloro analogue of isoproterenol (*DCI*, Lilly Compound 20522) which in experiments on animals was found to abolish almost exclusively the action of adrenaline on the β-receptors[4]. This compound, therefore, can be considered a useful tool for the qualitative separation of α- and β-adrenergic receptors. Measurements of flow of blood were made in the calves of healthy male volunteers, 20–25 years of age, using the venous occlusion plethysmography[5]. All substances were subjected to infusions in the femoral artery by means of an electrically driven infusion pump. The transient vasodilatation in the calf caused by a 3 min. infusion of 1·76 μgm./min. 1(–)adrenaline, which is easily reproducible in intervals of 3–8 min., could be abolished by a preceding infusion of *DCI*.

Fig. 1 shows a typical experiment. After a dose of 22 mgm. *DCI* within 5½ min., which produced some vasodilatation, the increase in flow of blood due to adrenaline was not diminished, but modified so that a secondary vasoconstriction followed (cf. A_1 and A_2, Fig. 1). After a further dose of 20 mgm. *DCI* within 2 min., however, no increase in flow of blood was observed during the following infusion of adrenaline (A_3); a decrease appeared instead. A small vasodilator effect was produced by adrenaline again 9 min. later, which was followed by a vasoconstrictor action (A_4).

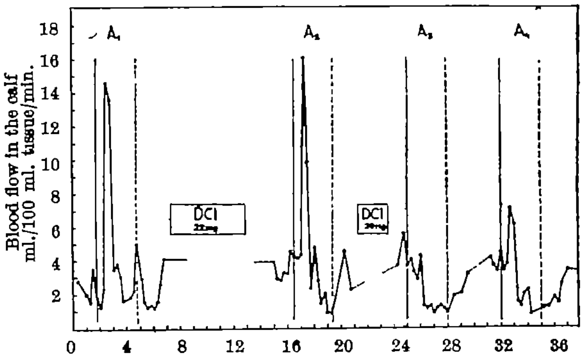

Fig. 1. A_1, A_2, A_3 and A_4, intra-arterial infusion of 1·76 μgm./min. 1(–)adrenaline. *DCI*, 22 mgm.; intra-arterial infusion of 4 mgm. *DCI*/min. for 5·5 min. *DCI*, 20 mgm.: intra-arterial infusion of 10 mgm. *DCI*/min. for 2 min.

The transient vasodilator effect of 0·8 μgm./min. isoproterenol (isopropyl-noradrenaline) (3 min. infusion time) on skeletal muscle vessels, which is similar to that of adrenaline[6], was also blocked by 37·5–62·5 mgm. *DCI*. The increase of flow of blood in the calf due to synthetic bradykinin[7], however, was not influenced by *DCI*.

It can be concluded from these experiments that the transient increase in flow of blood in the skeletal muscle vessels of man caused by adrenaline (and isoproterenol) is mediated by an interaction with the adrenergic β-receptors. If these are blocked by *DCI*, an increase in flow of blood does not occur, and sometimes even a decrease could be observed during the infusion of adrenaline. This vasoconstrictor effect may be explained by unmasking the action of adrenaline on the adrenergic alpha receptors.

Note added in proof. Similar findings have been reported by U. R. Bharadwaj and R. G. Shanks (*J. Physiol.*, 160, 5*P*; 1961) on the human fore-arm.

Effect of 'Busulphan' ('Myleran') on the Spermatogenic Cell Population of the Rat Testis

THE ability of alkylating agents to produce selective effects on spermatogenesis and sperm in rodents has been reported in several publications[1-3]. A comparison of the timing of sterile periods after treatment with the accepted duration of spermatogenic events in the testis has enabled the phase of spermatogenesis affected by particular compounds to be located.

Following the intraperitoneal administration of 'Busulphan' (10 mgm./kgm. in arachis oil) normal fertility is retained for about 50 days, after which sterility soon develops associated with oligo- or

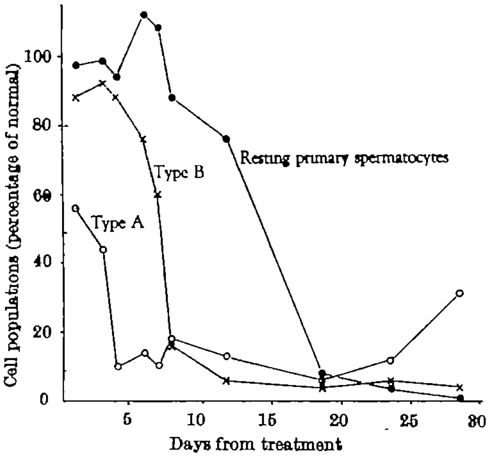

Fig. 1. Consecutive disappearance of spermatogonia (types *A* and *B*) and resting spermatocytes from the seminiferous epithelium of the rat after treatment with 'Myleran' (10 mgm./kgm.)

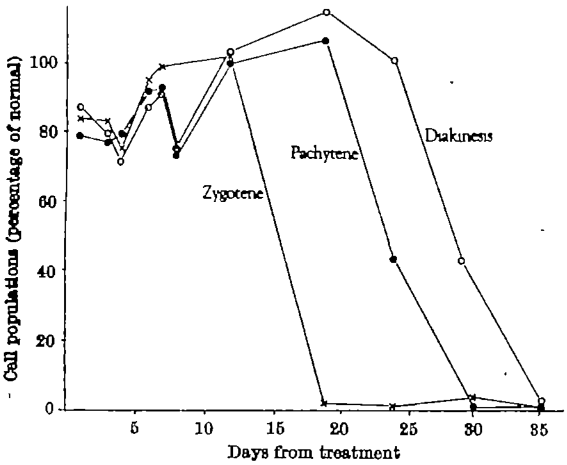

Fig. 2. Progressive depletion by maturation of zygotene, pachytene and diakinesis spermatocytes following treatment with 'Myleran'

aspermia[1,2]. An analysis of the cell population of the testis in animals so treated was undertaken in order to obtain more precise information concerning the identity of susceptible cells. In the rat, any seminiferous tubule section contains up to four successive generations of developing cells, and those in stages V, VIII and XIII[4,5] were selected for counting. Adult male rats were treated and killed at intervals of time from 24 hr. to 35 days. Sections of the testes were examined histologically, and the number of cells of various types counted in the stages referred to here.

The result confirms our earlier belief that this substance acts in a specific manner at a very early phase of spermatogenesis. A block is imposed resulting in the progressive depopulation of the spermatogenic epithelium due to continued maturation of the remainder of the cells into spermatozoa which are shed normally. Thus the number of type *A* spermatogonia falls within 4 days to a low level and remains so for about 24 days, after which slow recovery follows (Fig. 1). The majority of type *A* spermatogonia present at the time of treatment apparently continue to develop but are not replaced. Hence the level of type *B* spermatogonia remains normal for about 6 days before declining. Type *B* cells present at the time of treatment also appear to be unaffected and continue to transform into resting primary spermatocytes. However, the maturation depletion process duly affects these cells after a further lapse of time (Fig. 1). The same applies successively to the various stages of spermatocyte development (Fig. 2) until, about 34 days after the dose, the epithelium is virtually denuded of spermatocytes by conversion to spermatids.

It has been estimated that the testicular phases of spermatogenesis in the rat require exactly 48 days[5], of which 27 days are required for the conversion of type *A* spermatogonia into spermatocytes in diakinesis (calculated from results published by Leblond and Clermont[4], see Jackson, Fox and Craig[3]). From our present results, 26 days elapse between reduction of the number of type *A* spermatogonia and spermatocytes in diakinesis, respectively, to 50 per cent of normal. This is in good agreement with the duration of spermatogenesis from early spermatogonial development to the end of spermatocytic divisions.

It may be concluded, therefore, that 'Busulphan' suppresses spermatogenesis at the earliest phase of the process. A few sperm mother cells remain in a state of arrest for about 30 days, after which spermatogenesis is resumed with progressive repopulation of the seminiferous tubules and ultimate restoration of normal fertility. The evidence suggests that treatment with 'Myleran' selectively inhibits in some way the development of early type *A* spermatogonia, but does not significantly modify the overall time relationships of spermatogenesis. It appears not to interfere with the progressive development of other cell stages present at the time of treatment or with the function of the spermatozoa into which they ultimately differentiate.

PATHOLOGY

Tumour-promoting Action of 4-Ethylsulphonylnaphthalene-1-Sulphonamide

A two-stage mechanism in carcinogenesis in the skin of the mouse was described by Berenblum[1] and termed initiation and promotion. Added evidence for this mechanism has been supplied by Salaman and Roe[2] for mouse skin, by Jull[3] for mouse breast, and by Peirce[4] for mouse fore-stomach.

It was observed that 4-ethylsulphonylnaphthalene-1-sulphonamide (HPA) and two of its analogues caused hyperplasia of urinary tract epithelium in the mouse and rat[5]. The hyperplasia persisted so long as the administration of the chemicals was continued, but quickly regressed on discontinuation of the chemicals. It was, therefore, decided to test whether HPA would act as a promoter in combination with a known weak carcinogen (initiator). In this experiment the bladders of female stock mice 12 weeks old

Table 1. Incidence of Bladder Tumours

	No of mice at start	Mice dead during experiment	Duration of experiment (weeks)	Tumours of urinary bladder					
				Adenoma	Papilloma		Carcinoma		Carcinomas in survivors to 40 weeks (per cent)
					Single	Multiple	Gd. I	Gd. II	
2-amino-1-naphthol hydrochloride + normal diet	39	9	40	4	–	–	4	1	16·7
2-amino-1-naphthol hydrochloride + HPA in diet	49	10	40	2	2	6	15	5	51·3

were implanted with paraffin pellets containing 2-amino-1-naphthol hydrochloride by the method of Jull[6] as modified by Allen *et al.*[7]. Then the animals were divided into two groups, one receiving normal diet and the other a diet containing HPA in a concentration of 0·01 per cent. The results of the experiments are summarized in Table 1.

The tumours were usually transitional cell in type, either adenoma, papilloma or carcinoma. The latter were divided into grades I and II, according to whether the musculature was invaded or not. Only one squamous cell carcinoma was found in the group with HPA in the diet, while one hæmangiosarcoma was observed in the dome in the other group.

The yield of bladder cancers in the group implanted with 2-amino-1-naphthol hydrochloride was 5 out of 30 animals at 40 weeks (16·7 per cent), an incidence similar to that observed by Bonser *et al.*[8]. In the group fed with HPA there were 20 tumours in 39 animals at 40 weeks (51·3 per cent). In this latter group there was also a greater number of papillomas. HPA, therefore, significantly enhances the yield of cancers in the bladder when combined with a weak carcinogen and thus acts as a promoter.

Oral administration of HPA to 79 mice for periods of up to 40 weeks resulted in urinary tract epithelial hyperplasia but no tumours[5]. It is thus clear that further work is needed to determine whether oral HPA is carcinogenic if the treatment is continued for a longer period and whether pellets of paraffin wax without a carcinogen could act as the initiator.

Preservation of Living Metacyclic Forms of the *Trypanosoma brucei* Sub-group

Although it has been known for some time that it was possible to preserve alive blood forms of the African trypanosomes at the temperature of sublimation of carbon dioxide (approximately – 79° C.[1,2]), no reports have appeared on the preservation of the metacyclic forms. This report indicates that it is possible to preserve live metacyclic forms of the *T. brucei* sub-group at a similar temperature.

Metacyclic trypanosomes were obtained in the following manner. 158 wild *G. pallidipes* were caught near Lugala on the North-east shore of Lake Victoria. They were brought to the laboratory and maintained as described by Cockings[3]. These flies were fed on defibrinated bovine blood obtained from a cow maintained in an area free of tsetse fly. It was established that the cow was free from trypanosomiasis by blood-film examination and by the inoculation of blood into mice at weekly intervals over a period of several months. All the flies were given the opportunity of feeding through a guinea pig skin membrane on the defibrinated blood maintained at 30° C. in a capsule. After 1 hr., the blood remaining in the capsule was removed; 0·5 ml. was injected intraperitoneally into each of five mice, all of which developed a patent parasitæmia by the fifth day after inoculation.

The remaining 5 ml. of capsule blood was frozen as follows. To the blood 0·67 ml. of glycerol was added and ten 0·5 ml. aliquots of the mixture sealed in glass ampoules. The ampoules were then placed in a boiling tube containing absolute alcohol at 0° C. The boiling tube was securely corked and wrapped in a jacket of cotton wool 1 cm. thick. The insulated boiling tube was immersed in solid carbon dioxide in a 2 pint thermos jar, which was sealed, and rotated for 2 hr. to ensure uniform cooling of the ampoules. The ampoules were thereafter stored at approximately – 79° C. in an insulated cabinet containing solid carbon dioxide. After 3 weeks, 0·1 ml. of this blood mixture was injected intraperitoneally into each of five mice, all of which developed a patent parasitæmia by the sixth day after inoculation.

The organism produced very high parasitæmias in all the mice. In Giemsa-stained blood films, the trypanosomes were polymorphic, approximately 14μ to 30μ in length, and the majority had long free flagella. These features are characteristic of the *T. brucei* sub-group.

IMMUNOLOGY

Antigen–Antibody Bands in the Micro-Double-Diffusion Agar Technique

Many useful variations of immunodiffusion techniques have been reported[1]. In particular the micro-adaptation has gained wide usage, and the utilization of thiazine red dye to stain the bands *after* completion of the reaction has helped make the lines visible[2]. Yet, after extensive use of these modifications in attempts to reveal anti-spermatogenic antibodies in the sera and tissues of aspermatogenic guinea pigs, our results have been disappointing. First, lines of precipitation were only rarely seen, and when they were observed, they were so faint or faded so rapidly as to instil doubt of their reality. Secondly, the use of thiazine red or other stains in the recommended manner did not improve the visibility or preservation of the lines.

We, therefore, approached the problem from an entirely different point of view. Reasoning that if we could tag one of or both the reactants (antigen and/or antibody) with dyes, we might be able not only to observe the formation of the antigen–antibody lines, but also to enhance the visibility of the lines formed so as to make them easier to photograph and preserve.

The procedure is as follows. A 1 per cent solution of crystalline hæmatoxylin is added to an antiserum or tissue homogenate in the proportion 1 : 2. This mixture is dialysed in Visking dialysis membranes against distilled water in the refrigerator to remove all uncoupled dye (usually 12–24 hr.). The dialysed dye-tagged preparation was placed in peripheral wells of a template on the agar-coated slide as described elsewhere[2]. Antigen was added to the central well. The antiserum had been obtained by cardiac puncture from guinea pigs immunized with homologous testicular homogenate, sperm, or purified aspermatogenic factor as described elsewhere[3–5]. Periodic examination of these slides held at refrigerator temperature disclosed that the reactions became visible within 4 hr.; reactions with other antigens (for example, ovalbumin) require 24 hr. for them to appear.

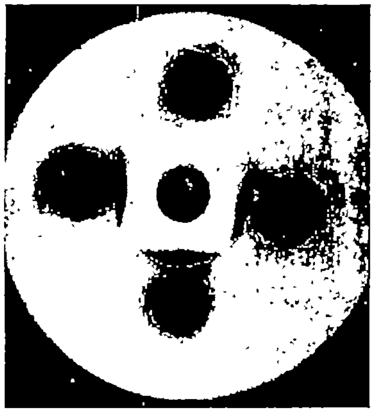

Fig. 1 Reactions between hæmatoxylin-dyed guinea pig aspermatogenic sera (3-, 6-, 9-o'clock wells) and aspermatogen (centre well); control guinea pig serum (12 o'clock well) fails to react

The results are illustrated in Fig. 1, which is a photograph of reactions between the hæmatoxylin-tagged antisera of 3 aspermatogenic guinea pigs (at the 3-, 6-, and 9-o'clock wells) and guinea pig aspermatogen in the centre well. The lack of reaction of a control guinea pig serum (12 o'clock well) is obvious. Comparable tests set up without pre-tagged antisera developed no precipitin bands. The findings illustrated in Fig. 1 were also obtained when the following materials were used: antibody-containing homogenates of spleen, lymph node, ileum and uterus of guinea pigs immunized with testicular antigens; rabbit antisera to heterologous sonicated spermatozoa; sera of infertile human males and females.

Interpretation of the mechanism of action of the tagged dye awaits further exploration. However, there is a suggestion that this technique may be useful for studying non-γ-globulin antibodies and very low molecular weight antigens (for example, insulin). Moreover, the dye-tagging approach provides a means for observing the precipitin lines as they form so that the dynamics of the reactions can be investigated.

RADIOBIOLOGY

Absorption of Radiostrontium by the Gills of Freshwater Fish

In the course of investigations dealing with the fate of radio-nuclides in fresh waters, we wished to find the site of direct absorption of dissolved radioactive strontium by fish. Several experiments were carried out in which the amount of radiostrontium accumulated by goldfish (*Carassius auratus*), with only the head and gills immersed in distilled water containing strontium-90, was compared with that accumulated by goldfish totally immersed in the same solution.

Other workers[1–4] have studied the absorption of dissolved substances using a divided chamber which separates the head and gills from the rest of the body. Several difficulties are introduced by the use of this method—the excretory products contaminate the chamber, the sealing at the body-surface is difficult, and the tightly fitting diaphragm may damage the fish.

The apparatus used in the present experiments was an elliptical tube fitted with an open grid at the lower end. For a 10-gm. fish, tubes 4 in. long with a 1¼ in. major radius and a ¾ in. minor radius were used. Tubes were made from 'Lucite', polythene, or brass mesh. The last-mentioned were found to be most suitable because it was possible to shape them to fit fish of different sizes.

Each fish was placed in a tube with its head resting on the open grid. The tubes were then suspended vertically in the strontium-90 solution to the required immersion-level. The upper ends of those tubes containing the fish with only the head and gills immersed were plugged with damp cotton wool. The entire tank was covered with polyethylene sheeting to prevent the drying of the body surfaces which were not immersed. Continuous aeration of the strontium-90 solution was provided. Preliminary tests showed that fish were undamaged when placed in this assembly and held in a vertical position with either the head and gills or the whole body immersed for periods up to 72 hr.

Using this apparatus and various concentrations of strontium-90 in distilled water, we compared the accumulation of the isotope by fish that were partially immersed with that accumulated by those that were totally immersed. Both groups of fish were exposed at the same time in a single tank containing the strontium-90 solution. Within each experiment, therefore, the temperature conditions were identical for each group. The fish used each weighed approximately 10 gm. and were not fed during the experiments.

At the end of the experiment all fish were removed from the tubes and weighed immediately. Each whole fish was wet-ashed, using concentrated nitric

Table 1. ACCUMULATION OF RADIOSTRONTIUM BY GILL-IMMERSED FISH COMPARED WITH TOTALLY IMMERSED FISH

			Gill immersion		Total body immersion	
Exp. no.	Strontium-90 in water (units of 10^{3} c.p.m. per ml.)	Uptake period (hr.)	No. of fish	Mean c.p.m. (units of 10^{3}) per gram wet weight ± *S.E.*	No. of fish	Mean c.p.m. (units of 10^{3}) per gram wet weight ± *S.E.*
1	1·1	5	5	2·8 ± 0·5	4	4·1 ± 1·8
2	0·8	20	5	6·6 ± 0·9	5	7·4 ± 0·8
3	0·8	24	5	10·1 ± 1·0	6	11·5 ± 0·5
4	1·9	24	4	46·9 ± 9·2	4	56·3 ± 8·3

acid and hydrogen peroxide until oxidation was complete. The resulting solution was prepared for counting by evaporating an aliquot to dryness on a stainless steel planchette.

After 21 days the equilibrium mixture of strontium-90 plus yttrium-90 was measured using a counter equipped with an anthracene crystal for the detection of β-particles. The efficiency of the counter for a standard mixture of strontium-90 plus yttrium-90 varied from 17 per cent to 21 per cent. All counting-rates shown in Table 1 have been corrected to an efficiency of 20 per cent.

Table 1 presents the results obtained in four experiments in which the accumulation of strontium-90 by the fish was measured after immersion for different lengths of time in various concentrations of the isotope. If the mean counts per minute per gram of the gill-immersed fish (Col. 5) are compared with those of the totally immersed fish (Col. 7) it can be seen that the exposure of the additional body surface in the latter group results in only a small increase in the amount of strontium-90 accumulated.

Using the Mann–Whitney *U* test[5,6] in which the counts per min. per gram of the 38 individual fish samples from both groups are ranked in order of increasing amount of strontium-90, a value of $U = 146$ was obtained. With this value of *U* there is no significant difference (at the 0·05 level) between the concentrations of strontium-90 accumulated by gill-immersed fish and totally immersed fish under the same experimental conditions.

Skin Decontamination in Presence of Thallium-204

THE problem of decontamination of the skin is now important with the increased use of isotopes in laboratories, and also the possible contamination from fall-out. Tests have been made with isotopes used for clinical purposes such as phosphorus-32 and iodine-131[1], fall-out[2] and fissible materials.

The ingredients used most are water and soap, detergents, complexing agents, chelating compounds and commercially available hand-cleaning products[3]. It has been shown[4] that the use of some decontaminating solutions may enhance the penetration of the contaminant into the skin, not taking into account the mechanical abrasion of the upper layer of the epidermis through rubbing with brushes or pads. This can be influenced by various factors, such as the length of time taken for decontamination, the amount of water, the nature of the decontaminating agents used, and possible irritation of the skin. The tests I have made were performed with a continuous-flow decontamination system, where rubbing, time, and possible spreading of the contaminant are reduced to a minimum.

The contaminant is a solution of thallium sulphate in water, with a specific activity of 5 mc./ml. of thallium-204. 10λ are dropped on the shaved abdominal skin of Wistar albino rats to the extent of 10 mm. diam. and allowed to dry for 30 min. There are four spots on each rat.

Three decontaminating solutions are used: soap, and sodium and calcium ethylenediamine tetraacetic acid solutions at 1 per cent; their action is compared with that of water. The device used consists of two coaxial glass tubes, of which the inner one is connected to the supply of a decontaminating solution, and the outer one to a venturi (Fig. 1).

The decontaminant is brought on to the skin through the inner tube and re-aspirated through the outer one. The amount of decontaminating solution flowing through can be adequately adjusted by pressure with a finger on the soft rubber exhaust duct, so that at any time one is able to control whether all the fluid is re-aspirated.

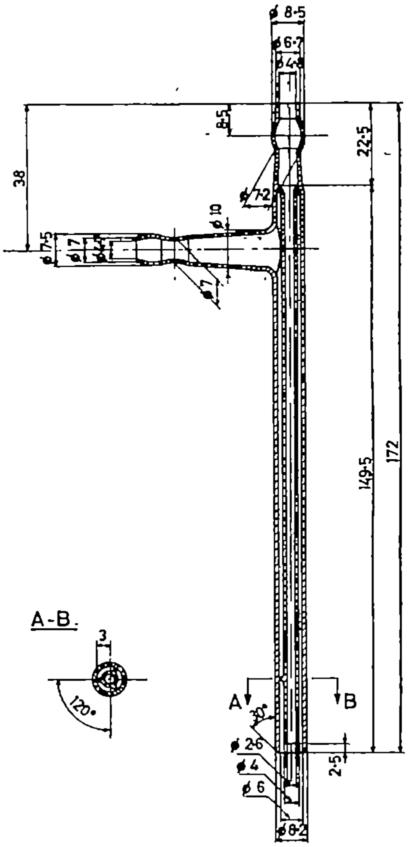

Fig. 1

Measurements have been made with a Geiger counter type Nō. 7 *E* 51 and a scalar model 'C.E.N. Automatic'. The amount of solution used is about 200 c.c. for 30 min. After counting, the procedure is immediately repeated once. Results are given in Table 1.

I, II, III, No. of animal, 1, 2, 3, 4, No. of spot. Decontaminating solutions: *A*, water; *B*, soap, *C*, sodium ethylenediamine tetraacetic acid; *D*, calcium ethylenediamine tetraacetic acid.

The results seem to indicate that in this case a solution of water and soap is the most effective agent for rapid skin decontamination. The total time could be reduced by suppressing the time lost for intermittent countings. I intend to accelerate this technique by monitoring the effluent through a liquid flow counter connected to a ratemeter which indicates almost immediately when contaminant is no longer removed: at this moment, the procedure becomes useless and even harmful for skin penetration. The same instrument can be used with a rubber or plastic cord at the end, for decontamination of hard surfaces.

I thank J. Deman, L. Malfait and J. Van Der Meeren for their help in this work.

BIOLOGY

Responses of *Calanus finmarchicus* (Gunnerus) to Changes of Hydrostatic Pressure

MANY planktonic species show marked responses to changes in hydrostatic pressure[1-3], but there has been some doubt about the behaviour of *Calanus* in this respect. Field observations by Hardy and Paton[4] suggested that the behaviour of *Calanus finmarchicus* might be affected by the change of pressure with depth, but laboratory experiments by Hardy and Bainbridge[1] and by Knight-Jones and Qasim[3] failed to confirm this. Recent books and reviews[5-10] have stressed the apparent absence of a demonstrable pressure response in *Calanus*.

Recent experiments at Port Erin have now shown that definite responses to changes in pressure can be invoked in *Calanus finmarchicus helgolandicus* (Claus) (identification confirmed by Dr. D. I. Williamson). In neither of the previous laboratory investigations on the pressure responses of *Calanus finmarchicus* was the subspecies used specified, but from the known distribution of the two forms it seems probable that Hardy and Bainbridge's animals were mainly *finmarchicus*, while those used by Knight-Jones and Qasim were mainly *helgolandicus*.

The animals used in the present work were mainly adult females and stage V copepodites with a few adult males, and were collected either at about 6 fathoms or at about 35 fathoms off the west coast of the Isle of Man. The results so far obtained do not indicate any major differences between the pressure responses of animals of different sex, stage or origin. The copepods were placed in a 'Perspex' observation tank, 60 cm. long and with a 5 cm. square cross-section, which was completely filled with sea water; within the tank the pressure could be regulated by means of an adjustable mercury column. The experiments were conducted at temperatures between 12° and 16° C. In Figs. 1–3 pressures are given in millibars in excess of atmospheric pressure. The animals used were mainly negatively phototactic and remained close to the bottom at atmospheric pressure with overhead light, but some photopositive specimens were also used.

With the observation tank vertical and illuminated from above (about 1 k.lux at the top of the tank), an increase of pressure produced no migration in any of the photopositive specimens, but about half those which were initially photo-negative exhibited one of two main types of response:

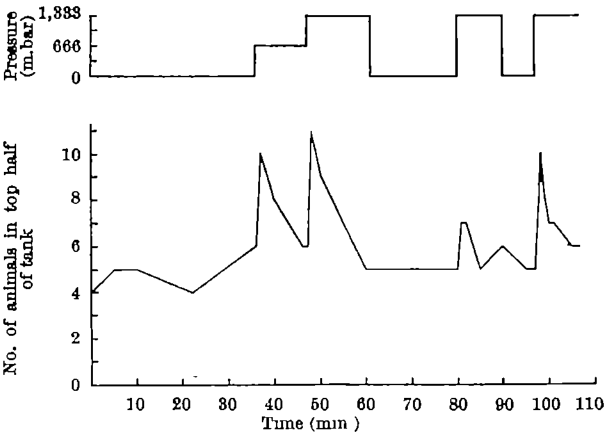

Fig. 1. Distribution during pressure changes of twenty *Calanus finmarchicus helgolandicus* illuminated from above

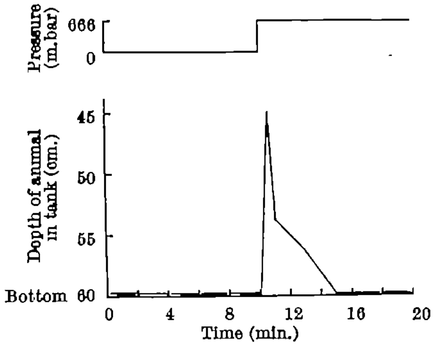

Fig. 2. Movement in response to pressure change of a single *Calanus finmarchicus helgolandicus* illuminated from above

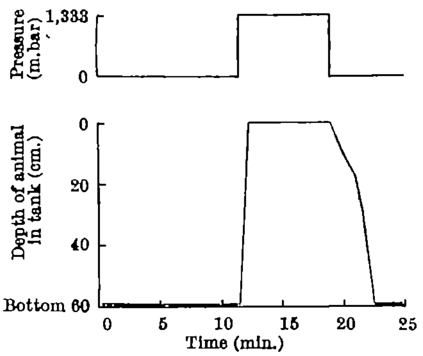

Fig. 3. Movement in response to pressure change of a single *Calanus finmarchicus helgolandicus* illuminated from above

(1) The most frequently observed response (Figs. 1 and 2) was an upward swimming movement towards the light, lasting as a rule for less than a minute. In this time the copepods moved upwards 15–30 cm., then the steady upward swimming ceased and the animals began to sink, with intermittent short periods of upward swimming. The original distribution was usually re-established within 4–5 min. of the pressure change.

(2) A more lasting response to pressure increase was observed in less than 5 per cent of the specimens tested (Fig. 3). In these cases the copepods reacted to an increase in pressure by swimming rapidly to the surface and remained there swimming actively for 15 min. or more if the pressure was not decreased. The upward migration was usually much more rapid than in the previous type of response, with the copepods covering the 60 cm. from the bottom to the top of the tank in 15 sec. or even less. Such specimens would move down again if the pressure was decreased, mainly by passive sinking but also sometimes by intermittent downward swimming.

With illumination from above, a decrease in pressure following an initial increase produced responses in about half the specimens which were originally photopositive. Most of those which reacted sank passively for a period, but swam back to the surface within 1 min. (a reaction comparable with response 1). A few individuals swam actively to the bottom and remained there until the pressure was increased again (see response 2).

In experiments in which the light was directed from below or horizontally, reactions were again recorded in only about 50 per cent of individuals. These usually responded to increased pressure by swimming towards the light, and to decreased pressure by either passive sinking or active swimming away from the light. Another type of response was observed in photo-negative animals in a few of the experiments in which the tank was illuminated from below; in these, increased pressure caused passive sinking towards the light and decreased pressure caused swimming upwards away from the light. The relation between the active and passive phases and the pressure changes in these cases is the reverse of that observed with overhead light.

The few results so far obtained show that the ability to perceive, and respond to, changes in hydrostatic pressure is definitely developed in *Calanus finmarchicus helgolandicus*, but the nature of the response is very variable under laboratory conditions.

Digby[11] suggested that the pressure sensitivity shown by many marine organisms might reside in the properties of a very thin film of electrolytically produced gas; he has since (personal communication) found that carefully handled *Calanus* show definite pressure responses, and suggests that rough handling of the material used might destroy such a mechanism. The animals used in the present work were collected in short hauls, usually with a metre tow-net, and were treated with great care in the laboratory, so that this might explain the differences between previously published results and those presented here.

Effect of Thyroxine on the Permeability of the Isolated Toad Bladder

VIRTUALLY nothing is known of the role of thyroxine in the cellular metabolism of adult Amphibia. Though insulin[1] and vasopressin[2] have received much recent attention as hormones which effect permeability of cells, thyroidal hormones have not hitherto been shown to have this effect. The following is a preliminary report showing that both water transport and oxygen uptake of the isolated bladder of the toad *Bufo bufo* are influenced by thyroxine.

Bladders were removed from the toads and mounted in a manner similar to that described by Bentley[3] except that a modified saline was used. All experiments were performed at 25° C. Thyroxine when dissolved in the normal Ringer solution on the serosal side of the membrane increased the transfer of water from the mucosal to the serosal surface of the bladder. The loss of water prior to and after thyroxine treatment was measured over 45-min. periods, normal values of loss of water being of the order of 11·3 μl./cm.^{2}/hr. The concentration of thyroxine used varied from 10^{-8} M to 10^{-5} M (Fig. 1) and a log dose response curve was obtained; these concentrations may be considered as approaching a physiological level.

When the bladders were everted with the serosal surface inside and the experiment performed in the usual manner with normal Ringer solution outside and Ringer solution diluted 1 : 5 inside the bladder the increased effect of loss of water after thyroxine treatment was again observed. Concentrations of thyroxine used and water-losses measured were of the same order as those shown in Fig. 1 for non-everted bladders. This latter observation stands in contradistinction to all previous observations made on the toad bladder using vasopressin where it has been shown that the hormone exerts its effect on loss of water only from the serosal side. The fact that thyroxine can act when on either side of the mem-

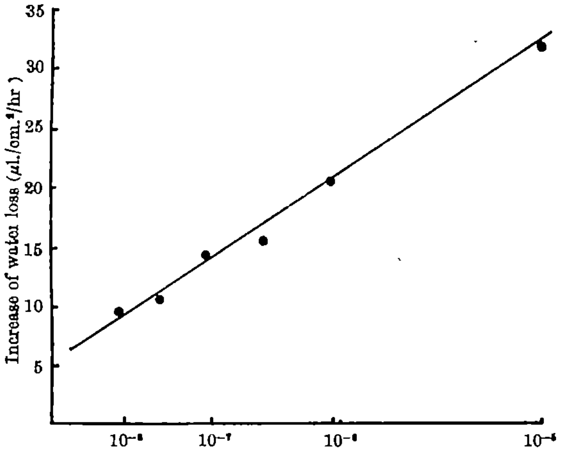

Fig. 1. Log dose response curve of thyroxine on loss of water from isolated toad bladder

brane is probably due to the small size of the molecule compared with that of vasopressin.

The effect of certain inhibitors of oxidative phosphorylation in combination with thyroxine was also examined. 2,4-Dinitrophenol (DNP) at a concentration of 10^{-4} *M* decreased the effect of added thyroxine to a value approaching that in Ringer solution alone. Sodium arsenate at the same concentration had a similar effect on loss of water as DNP. Sodium cyanide at a concentration of 10^{-5} *M* differed from the foregoing two inhibitors in that the effects observed were extremely variable; sometimes reversibility to normal values did not occur whereas in other cases the bladder behaved as though in a thyroxine solution alone. A further investigation of this effect is being pursued. Nitrogen when bubbled through the Ringer solution instead of air inhibited the thyroxine effect on loss of water as did lowering the temperature from 25° C. to 4·5° C. In all experiments using some kind of inhibitor one half of the bilobed bladder was used as a control and treated in a normal way. These inhibitory results obtained from DNP, arsenate, lowering the temperature, and bubbling with nitrogen were not obtained when similar experiments[4] were performed with vasopressin in order to investigate its mechanism of action. It therefore would appear that with thyroxine we are dealing with a different mechanism of water transport. This effect of thyroxine on increased water movement through the membrane and the arrest of this movement by substances which are known to inhibit metabolic activity within the cell suggests that thyroxine is increasing the rate of this metabolism.

In order to elucidate this view, respiration measurements were performed on isolated whole toad bladders. Oxygen consumptions were measured after 40 min. incubation in 10^{-4} *M* thyroxine or in normal Ringer solution alone while bubbled with air. The measurements were made polarographically at 5 min. intervals over 20 min., by a technique to be described elsewhere. The mean value obtained for six control bladders in Ringer solution was 1·21 ± 0·012 (*S.E.*) µl./mgm. dry wt./hr., and for six thyroxine-treated bladders, 2·47 ± 0·022 µl./mgm. dry wt./hr. This result is highly significant ($P < 0 \cdot 001$), the thyroxine more than doubling the normal rate of oxygen consumption of the bladder.

From these results it appears that thyroxine increases the metabolism of the cells and hence the water transport.

This investigation was supported by a grant from the Nuffield Foundation.

Pigment of the Hermaphrodite Gland of *Arion ater rufus* L.

THE hermaphrodite gland of the slug *Arion ater rufus* is pigmented, and changes in the degree of pigmentation are correlated with the sexual stages in the gland[1]. In the early stages of development the hermaphrodite gland is translucent, but during spermatogenesis it becomes opaque and grey in colour, at the oocyte stage dark brown and ultimately, after oviposition, black. The final dense pigmentation is due partly to a gradual increase in the amount of pigment, partly to concentration of existing pigment by shrinkage of the gland.

The pigment was studied in hermaphrodite glands taken from animals a year or more old which had reached the end of their reproductive life. The glands were fixed in 'Formol'-calcium or aqueous Bouin and gelatine and paraffin sections were subjected to a number of the tests described by Lillie[2], Lison[3] and Pearse[4]. The solubility, bleaching properties and staining properties of the pigment were investigated. Special colour tests were also performed for carotenoids and glycerol-mounted sections were tested for porphyrins in ultra-violet light.

In sections treated for general histological examination, dark zones of pigment are present in the connective tissues of the tunica and around and between the acini of the hermaphrodite gland. The pigment resists the usual procedure of embedding in paraffin and is visible in unstained sections as an accumulation of granules of different sizes which vary in colour from yellow to dark brown or black. It is unaffected by 48 hr. treatment with 5 per cent sulphuric acid, 5 per cent concentrated acetic acid, 5 per cent potassium hydroxide, acetone or chloroform, though it is partially soluble in hot pyridine and bleaches slowly in hydrogen peroxide (24 hr.) or potassium permanganate (6 hr.). The appearance and reactions of the pigment generally recall those of the melanins and lipofuscins so typical of animal tissues. Certain of these reactions are, however, shared with carotenoids, which have been found in the gonads of both sexes of *Patella vulgata*[5], and porphyrins, which occur in the integument of *Arion ater ater* (ref. 6). The pigment, however, belongs to neither of these groups. It fails to give the specific colour reactions of carotenoids with concentrated sulphuric acid, concentrated hydrochloric acid, iodine or the Carr–Price test with antimony trichloride in chloroform, and in its insolubility differs from the extremely fat-soluble carotenoids or water-soluble chromoproteins. It is not extracted by methanol and sulphuric acid[6] and does not fluoresce in ultra-violet light, both specific properties of porphyrins.

Differentiation between melanins and lipofuscins is not easy since both react positively to a number of tests regarded as specific for one or the other, for example, the pigment reacts positively to Schmorl's test for lipofuscins, but melanins also reduce ferricyanide to ferrocyanide. Strong alkali destroys the tissue but does not dissolve the pigment, which indicates the presence of lipofuscin[5]. More evidence for the lipoidal nature of the pigment is given by its partial solubility in the pyridine and its partial staining with sudan IV and chromalum-hæmatoxylin. Although the pigment is unstained by sudan black *B*, the larger granules are positive to periodic acid–Schiff and all granules stain with aldehyde fuchsin.

Three final tests clearly indicate that the pigment is lipofuscin and not melanin. (1) Using Masson-Fontana's method[4] the pigment does not reduce ammoniacal silver nitrate and remains unstained. It is therefore not a melanin[2,3]. (2) After bleaching in hydrogen peroxide for 24 hr. the pigment stains blue with Nile blue sulphate[7]—melanin would be colourless. (3) The pigment stains deep blue with 0·05–0·1 per cent Nile blue in sulphuric acid and decolorizes in acetone rinse[8].

The slow accumulation of the lipofuscin *pari passu* with age suggests that the pigment is a waste product. It is presumed to be derived by the progressive oxidation and polymerization of lipids, and the non-uniform reaction to some tests can be attributed to the material being at different stages of oxidation. At the more advanced stages of oxidation the pigment is no longer lipid in the accepted sense and responds negatively to the tests for lipids.

Order of Death as a Test of Therapeutic Effect

In assessing the effect of a treatment on the action of a poison it is usual to measure either the effect on the LD_{50} or on the time to death. In a recent investigation by one of us (D. F. H.) on the effect of treatment with dimethylformamide on the poisoning of male and female rats with dimethylnitrosamine it was found that changes in LD_{50} provided a rather insensitive test of effect, which required large numbers of rats to establish, and that mean times to death in treated and untreated groups were not greatly different after doses which killed all the rats. Dimethylformamide had, however, a very marked effect on the order in which rats died at doses such that a few survived. Times to death cannot be calculated in these circumstances without making arbitrary decisions about "times to death" of the survivors. Orders of death, however, proved susceptible to a more rigid statistical treatment. As this may be of general use it is reported here.

Let there be two groups of n rats, one group receiving the treatment and the other not. Let the order of death be denoted by the rankings: $1, 2, \ldots 2n$. Consider one group. The order in which these die can be denoted by n numbers from the $2n$ possible rankings. On the null hypothesis that the treatment has no effect the average ranking, $\bar{x}$, should be the average of the numbers 1 to $2n$, that is, $n + \frac{1}{2}$. It is required to find the significance of differences between $\bar{x}$ and $n + \frac{1}{2}$.

For $n = 4$, calculation showed that $\bar{x}$ was distributed very nearly normally, and that the normal approximation slightly underestimated the significance of differences. The normal approximation will therefore be adequate for $n \geqslant 4$.

By standard statistical methods, it can be shown that the variance of $\bar{x}$ is given by:

$$V(\bar{x}) = (2n + 1)/12$$

whence, for a normal distribution, and n small, the deviate is given by:

$$d = [\,|\,\bar{x} - (n + \tfrac{1}{2})\,|\, - 1/2n]/\sqrt{(2n + 1)/12}$$

The probability that the deviate will be as great or greater than the experimental value can be found from statistical tables.

In calculating $\bar{x}$ all the animals surviving are given the same ranking, equal to their average rank. This corresponds to the fact that they are experimentally indistinguishable. It follows that the test is most sensitive when the dose is high enough to kill most of one group.

As $\bar{x}$ is distributed normally about $n + \frac{1}{2}$, one must always indicate which group tended to die first, as otherwise confirmatory experiments may give the same probabilities as contradictory ones.

Table 1. EFFECTS OF DIMETHYLFORMAMIDE ON THE TOXICITY OF DIMETHYLNITROSAMINE

		By order of death			By LD_{50}'s	
Sex	$2n$	Order of death	$\bar{x}$	P	No. of rats	P
M	8	*AAAABB*	$(1+2+3+4)/4$	0·015	72	0·006
F	20	7*A*'s,*BABABAB*	$(1+2+\ldots+7+9+11+13)/10$	0·0005	140	0·0002

Rats were given 700 mgm./kgm. of dimethylformamide intraperitoneally 30 min. before dimethylnitrosamine, given intraperitoneally to females and intravenously to males. Compounds were in normal saline. Order of death is indicated, *A* representing a rat which received dimethylnitrosamine only, and *B* a rat also receiving dimethylformamide treatment. The probabilities of the results on the null hypothesis are compared with probabilities estimated from LD_{50}'s (calculated by probit analysis) determined using the number of rats shown

The results of two experiments are shown in Table 1. In both experiments small numbers of rats demonstrated with almost as much certainty as LD_{50}'s determined on much larger numbers that dimethylformamide protected rats from the lethal effects of dimethylnitrosamine.

Production of Insect Juvenile Hormone by the Microsporidian Parasite *Nosema*

WHEN microsporidian parasites of the genus *Nosema* infect insects, abnormal growth and metamorphosis are commonly observed. Heavily infected pupæ of saturniid Lepidoptera moult to adults which retain many pupal characters[1]. When flour beetles of the genus *Tribolium* are similarly infected, they appear larger than normal and die at or before pupation[2]. We have found that the larger size of such infected beetle larvæ is a result of more rapid growth and of supernumerary moults. All these effects resemble those which can be produced by injection of insect juvenile hormone or by implantation of corpora allata, the endocrine gland which produces this hormone[3-6]. Three hypotheses could explain this similarity of parasitic infection and endocrine activity: (1) The parasite might cause hypertrophy of, or hypersecretion by, the corpora allata of the host. (2) The parasite might cause other tissues of the host to produce juvenile hormone. (3) The parasites, themselves, might produce materials with juvenile hormone activity. We have carried out experiments by which we can decide among these alternatives.

Our source of parasites was a group of infected cultures of *Tribolium castaneum*, for which we are indebted to Prof. A. E. Bell, of the Population Genetics Institute, Purdue University. Parasites from this species were successfully transmitted to several insect orders, including the following species: Coleoptera, *Tribolium confusum*, and *Tenebrio molitor;* Blattaria, *Periplaneta americana*, *Blaberus craniifera*, and *Byrsotria fumigata;* Lepidoptera: *Galleria mellonella*, *Bombyx mori*, and *Hyalophora* (*Platysamia*) *cecropia*. In all these species the parasite induces more rapid growth of the nymph or larva and inhibits metamorphosis to the adult stage.

When *Bombyx mori* or any of the Blattaria were allatectomized as nymphs or larvæ the intermoult period was extended by 30–50 per cent, and they moulted to premature adults. Following sham operations the intermoult period was also extended, but only by 15–40 per cent. When *Nosema* was implanted into allatectomized hosts the intermoult period increased 15–40 per cent, but the animals moulted to another nymphal or larval stage. These experiments rule out the first hypothesis since it is apparent that the effects of the parasite are expressed even in the absence of corpora allata and, in fact, the parasite substitutes for the endocrine gland.

The second hypothesis was ruled out by placing parasites in chambers attached to allatectomized hosts. In some experiments the chambers were in direct contact with the hæmocœl of the host; in others, they were separated by a 'Millipore' filter with a pore size of 0·47μ. This pore size is too small to permit the passage of the microsporidia. In no case did the tissues of the host show signs of infection or hypertrophy. Infective parasites were recovered from the chambers. In seven of ten such experiments the response of the host was consistent with production of juvenile hormone by the parasites. In sixty experiments in which the chambers contained tissues of insects free of parasites, a juvenilizing effect was never noted. These experiments show that juvenile hormone is not produced by non-endocrine host tissues.

Finally, 3 gm. of *Nosema* spores were isolated from 48 gm. of dried, infected *Tribolium*, and, by standard techniques[8] used for the purification of juvenile hormone, 11 mgm. of a yellow oil was recovered. This hormone preparation showed activity when assayed on *Hyalophora cecropia*[9]. An extract prepared in the identical fashion from uninfected *Tribolium* displayed no activity.

We believe that these experiments provide strong evidence that this parasite displays a new mode of parasite pathology; that is, production, in excessive amounts, of a substance normal to the host by a parasite. This substance then acts to upset the normal mechanisms of control of growth and differentiation. We know of no previous description of such a pathogenic action by a parasite.

These investigations were supported by the National Science Foundation (*G*–11234) and the Purdue Research Foundation.

Changes in Transpiration induced by Ethyl Alcohol

ETHYL alcohol was used as an auxiliary solvent in the preparation of auxin solutions for a series of transpiration experiments with plants in water culture when the roots were supplied with different auxins at varying concentrations. This method appears to be fairly common for auxin studies[1,2]. After weighing, the auxin is dissolved in a small quantity of ethyl alcohol, and the resulting solution is diluted with water or a nutrient solution to obtain the concentration desired. The small amounts of alcohol used are usually considered to be harmless; nevertheless, it has been shown that ethyl alcohol may have modifying effects in auxin experiments even at low concentrations[3]. In an attempt to determine whether this is also the case in transpiration experiments, some experiments were carried out with nutrient solution to which had been added varying amounts of ethyl alcohol.

The rate of transpiration was measured by means of the corona hygrometer[4], which allows continuous recordings of the transpiration through the determination of the water vapour pressure (pH_2O) in the air which has passed the plant chamber. The following transpiration conditions were used: illumination of about 10,000 lux from a photo lamp of the *B*-type at a distance of 45 cm., the light having been filtered through 10 cm. of cooled water; atmospheric air free of carbon dioxide of a relative humidity of 50 per cent and a temperature of 20° C. being passed along the leaves at a rate of about 1·3 m./sec. When the plants (6–7 days old barley seedlings grown in water culture) had established constant transpiration under these conditions, the nutrient solution surrounding the roots was replaced by a mixture of ethyl alcohol and

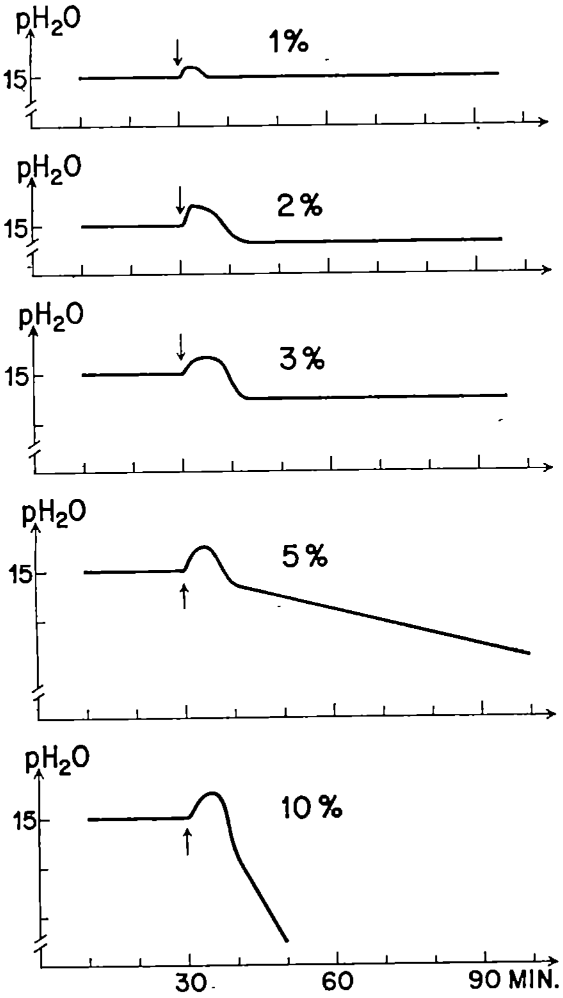

Fig. 1. Transpiration changes in barley seedlings induced by different concentrations of ethyl alcohol in the nutrient solution surrounding the roots. At the times indicated by arrows the plain nutrient solution was replaced by nutrient solution containing the amounts of ethyl alcohol shown

nutrient solution. Past experience has shown that a mere replacement of the nutrient solution does not affect transpiration. Fig. 1 shows that even 1 per cent ethyl alcohol induces a transient, but, nevertheless, distinct and reproducible, change in transpiration. An addition of 2–3 per cent alcohol causes an additional more lasting effect, the rate of transpiration becoming established at a level lower than that maintained prior to replacement of the nutrient solution. An addition of 5 per cent alcohol causes transpiration to decrease slowly following the above brief increase. A concentration of 10 per cent alcohol in the nutrient solution induces a similar reaction which, incidentally, corresponds to the reaction caused by cutting plant stems in air[5], or by treatment of roots with strong auxin solutions.

Due to the fact that the effect of ethyl alcohol reported here sets in so rapidly, in fact almost instantaneously, it appears to be reasonable to assume that it is localized in the roots, and it probably consists in changes of the water permeability of the root cells in one form or another. This must provide the possibility of a brief increase in the water supply to the leaves, allowing an increase in transpiration. At the higher concentrations of 5 and 10 per cent of alcohol, a lasting (irreversible) change in the properties of the root cells appears to occur after a certain period of time, causing a more or less pronounced decrease in transpiration to replace the momentary increase.

It appears that even at the low concentrations of 1–2 per cent occurring in the case of auxin solutions, ethyl alcohol is not an inactive component. Even in cases where growth experiments are not involved, the use of alcohol in the preparation of auxin solutions is inadvisable. Instead, the auxin should be dissolved in basic solution which is then adjusted to the desired *p*H value by means of the appropriate amount of acid, as recommended by Larsen[6].

Translocation of Captan by Broad Bean Plants

CAPTAN (*N*-trichloromethylthio*cyclo*hex-4-ene-1 : 2-dicarboxyimide) is widely used as a protectant fungicide and since its introduction in 1952 claims have been made for a systemic action. Applications of captan to the roots of cucumber[1], broad bean[2], rose[3] and pea[4] plants have been reported to give increased fungal control on the foliage although the results with broad bean have not been confirmed by later workers[5]. Acetone extracts of the leaves and stems of plants the roots of which had been treated with captan have been shown to be more toxic to *Ceratocystis ulmi* than extracts from untreated plants[6,7].

Systemic activity may be demonstrated unequivocally by the chemical identification of the fungicide in parts of the plant not in direct contact with the fungicide. Wallen and Hoffman[4] found, by chemical analysis, up to 0·85 p.p.m. (fresh weight) of captan in pea seedlings the roots of which had been watered with captan solutions. More sensitive analysis is provided by the use of a radio-tracer and we have used this technique to follow the translocation of captan, labelled with sulphur-35, in the broad bean.

Broad bean plants (var. Early Giant Windsor) grown in John Innes compost, in 4-in. pots, were treated with captan solutions when four weeks old. 50 ml. of an aqueous chloroform (at 0·15 per cent) solution containing 375 μgm. captan was applied daily to each pot and after nine days the plants were harvested above the second pair of leaflets. Each pot received a total of 3,375 μgm. of captan. The main stem was discarded and the leaflets, petioles, apical bud and flower buds weighed and rapidly chilled to − 18° C. After 2–3 hr. at − 18° C. the leaves were ground with solidified benzene in a chilled mortar. The warmed mixture was filtered through Whatman No. 54 paper, the filtrate shaken for 20 min. with 4 gm. anhydrous sodium sulphate and 0·5 gm. charcoal and then filtered through Whatman No. 42 paper. This extraction procedure gave 99 per cent recovery of added ^{35}S-captan.

The benzene extracts were evaporated to dryness in a current of clean, dry air and the residue dissolved in 1 ml. benzene. The radioactivity of the sample was determined by spotting a number of 3 μl. aliquots of the extract, to a total volume of 0·5–0·7 ml., on to the same position on a filter paper strip and counting under an end-window Geiger–Müller tube. Each 3 μl. drop spread to a maximum diameter of 16 mm. and was completely dried off before the next drop was added.

The maximum radioactivity found in any plant was equivalent to 0·45 ± 0·06 μgm. captan or 0·09 p.p.m. (fresh weight). Many plants gave lower counting values and some gave counts not significantly different ($P = 0·05$) from that of the background. These values assume that the benzene-extractable sulphur-35 is wholly in the form of captan; any volatile compounds labelled with sulphur-35 produced by the decomposition of captan would be removed in the evaporation process. The presence of such minute amounts of captan in the bean leaves after the application of relatively heavy doses to the roots suggests that any chemotherapeutic effect of captan in these circumstances cannot be attributed to its systemic activity. Even the maximum concentration of captan found in bean leaves is only a small fraction of that required to inhibit the *in vitro* spore germination of plant pathogens; for example, the median effective dose (ED_{50}) of captan against conidia of *Botrytis fabae* Sardiña is approximately 0·7 p.p.m. In view of the known chemical reactivity of captan[8,9] and its capacity to inhibit metabolic processes in plants[10], it may be suggested that interference with host metabolism is responsible for the fungal control observed in foliage after root application.

We thank Mr. C. P. Lloyd-Jones for the radioassay of sulphur-35.

Inverse Ammonia–pH Relationship in Grasses

Two perennial grasses, *Brachiaria ruziziensis* and *Setaria sphacelata*, were sown at the same time in adjacent field plots. The first samples were taken after six weeks and later at weekly intervals during the next 16 weeks. The whole plant was taken from approximately 1 in. above the soil at different growth stages. The samples were dried at 50° C. under forced draught, milled and analysed.

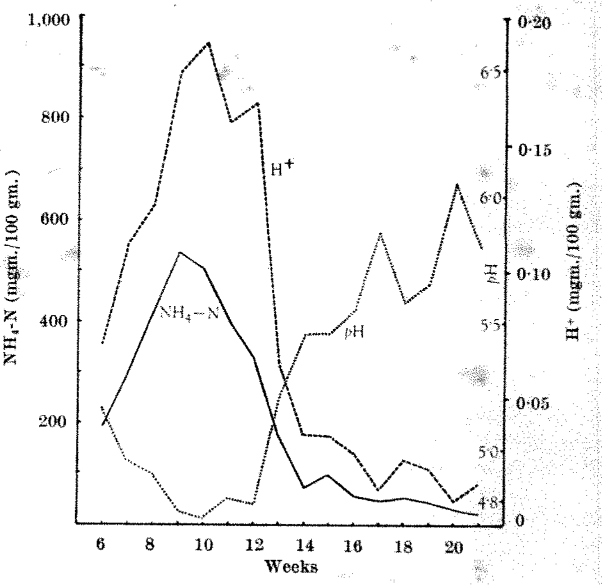

Fig. 1. Ammonia, *p*H and H ion fluctuations during growth of *Setaria*

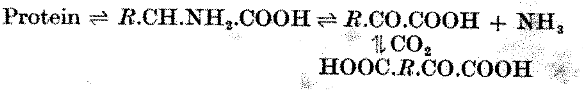
Throughout the period (6–21 weeks) the *Brachiaria* samples showed little variation in water-extractable ammonia (approximately 30 mgm. NH_4–nitrogen per 100 gm. air-dry material) or *p*H, which fluctuated between 6·2 and 6·4. With *Setaria* a completely different pattern of behaviour occurred, as shown in Fig. 1, in which *p*H values have also been converted to mgm. H^+ ions extracted per 100 gm. material. The regression (equation 1) of H^+ on NH_4–nitrogen (each as mgm./100 gm. plant material) was positive, linear and highly significant (r^2 is equal to 0·948):

$$H^+ = 0·000355\ NH_4\text{–nitrogen} + 0·0053 \qquad (1)$$

The regression line passes almost through the points of origin, showing that there was an almost constant proportionality between H^+ and ammonia during their rise and decline. Further, it was found that the amount of ammonia extracted was significantly and directly related to titratable acidity (r^2 is equal to 0·88) such that each equivalent of ammonia was associated with approximately one equivalent of titratable acidity.

From these results and the dissociation constants of the acids, it is considered that in *Setaria* some protein breakdown occurred between the sixth and tenth weeks, as follows:



$$\begin{array}{r}\text{Protein} \rightleftharpoons R.\text{CH.NH}_2.\text{COOH} \rightleftharpoons R.\text{CO.COOH} + \text{NH}_3\\ \upharpoonleft\!\downharpoonright \text{CO}_2\\ \text{HOOC.}R.\text{CO.COOH}\end{array}$$

leading finally to the formation of the acid ammonium salt of the dicarboxylic acid. This satisfactorily explains the equivalence found between ammonia and titratable acidity and the inverse ammonia–*p*H relationship. During protein regeneration (tenth–fourteenth weeks) the proportionality between ammonia and acid was maintained, indicating that the reverse reactions then occurred.

There is evidence that with *Brachiaria* some protein breakdown occurred so far as the amino-acid stage but no further due to lack, or inactivation, of the required enzymes. It is considered unlikely that the difference in behaviour between *Setaria* and *Brachiaria* was due to greater uptake of ammonia by *Setaria* since both grasses were very similar in chemical constitution, including ash contents, indicating similar abilities to take up cations and ammonia. Further, assuming greater ammonia uptake by *Setaria*, it is improbable that this would be paralleled by equivalent acid production within the plant.

It is not known to what extent the behaviour noted with *Setaria* is of rare or common occurrence in plants, as it has not been a general practice to determine ammonia and *p*H simultaneously in aqueous plant extracts. Since, however, the analytical techniques are so simple and the relationship so well defined it should not be difficult to study the frequency of occurrence and the causes involved. If of frequent occurrence, ammonia so derived would complicate the interpretation of trials involving ammonia uptake by plants following various applications of ammonium salts or urea. The occurrence or otherwise of the relationship would also give some insight into the enzyme systems operative during plant growth. Further applications of this relationship, for example, in relation to ammonia detoxication in plants, also suggest themselves, and it is concluded that it would be a good standard practice to include *p*H determinations whenever ammonia is determined in aqueous plant extracts.

Secretion from Pores of Surface Wax on Plant Leaves

THE source of surface wax deposits on plants and their method of formation have been investigated since 1871 by optical microscopy[1] and more recently by electron microscopy. Mueller, Carr and Loomis[2] considered that the wax was probably secreted from pores in the leaf surface, but no evidence of them was seen. A study of leaf surfaces by Juniper and Bradley[3] using carbon films evaporated on the leaf surface also failed to reveal their presence.

Recent work on clover (*Trifolium repens*) at higher magnifications (80,000–200,000 diam.) carried out by us has established that pores are present beneath each particle of wax. Since they have not been seen elsewhere on the leaf it seems reasonable to assume that they are the source from which wax is secreted. Moreover, if leaves are placed in a wax solvent for progressively longer periods, the last wax to disappear is that immediately above the pores.

The only other plant leaves investigated were those of *Brassica oleracea* and *Poa colensoi* and pores were observed in each case. Our present study of the waxy surface of apples has also shown that similar pores are present in the cuticle of fruit.

The pores were recorded only when suitable replica preparations were used, and the following was soon found to be the most satisfactory method. The leaf was immersed in a wax solvent, such as chloroform, for sufficient time to remove most of the wax. Clover leaves required over-night immersion whereas the wax on *Brassica* was removed to the same degree within 10 min. When the wax was not dissolved completely the thin remaining deposits helped in locating the pores. A shadowing layer of uranium oxide was applied directly to the leaf surface, stripped off with collodion and then coated with a carbon film. The plastic was dissolved in amyl acetate leaving a pre-shadowed carbon replica.

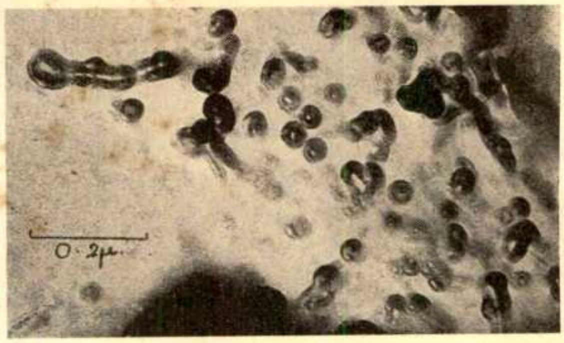

Fig. 1. Surface of a *Brassica* leaf showing pores

It will be seen from Fig. 1 that each wax-free pore appears as a faint circular area in the centre of which is a small depression that could be an opening in the leaf surface. Most of the pores in this micrograph are partially or wholly concealed by incompletely dissolved wax deposits each having a central hole immediately above the depression in the pore. The central hole has a mean diameter of 6 mμ for *Trifolium repens* and 7 mμ for *Brassica oleracea*, and the outer diameters of these wax residues on the two plant leaves are 38 mμ and 45 mμ, respectively.

The form taken by the wax on the surface of the leaf appears to be determined by the number of pores associated with each waxy structure. On white clover, for example, the wax secreted from a group of up to nine pores combines to form a discrete wax particle. The number of pores in each group on the surface of the *Brassica* leaf, however, varies from a few to several hundred under the larger pieces of wax. The small rod-like structures of wax formed on tussock leaves suggest that only one pore is associated with each extrusion, but we have insufficient evidence to be sure. Where a number of pores are inter-connected at the surface (as in Fig. 1), there is evidence that the wax is extruded along the length of this connexion.

MICROBIOLOGY

A Change in Phenotype associated with the Bacteriophage Carrier State in a Strain of *Proteus mirabilis*

Proteus phage *57* forms clear plaques on *Proteus mirabilis* strains *12*, *55*, *57* and *63*[1]. On strains *12* and *57* the central clear hole is surrounded by a spreading halo of altered bacterial growth due to the liberation of a lysin by the phage-infected organisms[2]. This lysin lyses versene-treated suspensions of these strains[3]. No free phage is present in the haloes, and thick saline suspensions of the organisms present in these zones do not adsorb phage *57* under conditions where controls with organisms scraped from unaffected areas of the plate show 99·9 per cent adsorption. This change in surface structure is the only effect of the lysin on untreated cells demonstrated to date. While the organisms in haloes have an obvious alteration in their optical properties they appear normal microscopically and do not show increased osmotic fragility. They are viable and, after a period of growth in the absence of lysin, the progeny are again susceptible to phage *57*.

Phage *57* was isolated[1] by the use of an enrichment technique (with *Proteus 57*) from sewage. Further work on it and *Proteus 57* has shown that phage *57* is liberated spontaneously by *Proteus 57*. It is a virulent variant of a temperate phage for which *Proteus 57* is lysogenic and is able to overcome the immunity conferred by the prophage[4]. Strains *12*, *55*, *57* and *63* are indol-negative, do not ferment maltose or salicin and ferment sucrose late. The late fermentation of sucrose is due to mutants which arise at low rates and rapidly ferment sucrose[5].

When a culture of *Proteus 57* is spread on Bacto nutrient agar containing 1 per cent Seitz-filtered sucrose and Bacto neutral red indicator at *p*H 7·1, the haloes of plaques formed either by the spontaneous liberation of phage *57* or by spotting with this phage are red. The colour which indicates acid production from sucrose never extends beyond the halo and is observed with phage *57* lysates prepared on any of its host strains. No change in colour occurs when the sucrose is replaced by lactose, maltose or salicin nor in plaques of phage *57* on the other 3 strains on media containing any of the four sugars mentioned. If the red growth of *Proteus 57* bordering on the central hole, and therefore contaminated with phage *57*, is streaked on the sucrose medium (on which *Proteus* does not swarm) two types of colony develop overnight. The majority are bright red and have a nibbled edge.

The remainder are pale and entire. On sub-culture the former always yield both varieties of colony while the latter only produce pale entire colonies.

The behaviour of the red colonies is unlike that of sucrose-positive mutants of *Proteus 57* (or other *mirabilis* strains) which are stable *in vitro*[5]. The red colonies are invariably contaminated with phage *57* while the pale ones are free of it. When red nibbled colonies are suspended in phage *57* antiserum and then plated on the sucrose medium all the colonies which arise are pale and entire. These phage-free colonies are sensitive to phage *57*. The red colonies where phage and bacteria exist in a more or less stable equilibrium are called carrier colonies[6]. The organisms in these colonies may owe their immunity to the lysin liberated by the small number of bacteria to which the phage succeeds in adsorbing.

Sucrose fermentation by carrier colonies was thought to be due to phage conversion but in view of the fact that *Proteus 57* is lysogenic for a temperate variant of phage *57* it is unlikely that the virulent phage will convert when its temperate counterpart does not. Conversion was excluded by further observations. The first is that young broth cultures of *Proteus 57*, sonically lysed and sterilized by Seitz filtration, cleave sucrose into glucose and fructose. This was demonstrated chromatographically. Unlysed and unfiltered aliquots are unable to do this. The enzyme system has not yet been identified but is active in a phosphate buffer at *p*H 7·4 and inactive at *p*H 5 with a citrate buffer. Cultures of *Proteus 12*, *55* and *63* treated similarly do not cleave sucrose. The other observation concerns the anomalous behaviour of *Proteus 57* on the sucrose medium and this medium plus 1 per cent Bacto bile salts.

Colonies of *Proteus 57* are pale on the sucrose medium and when replicated to both the latter and the medium with bile, all the new colonies are again pale on the sucrose medium but red and larger on the bile medium. Colonies of the other three strains are pale on both media. Surface-active agents do affect the cell wall of *Proteus*[7] and saline suspensions containing 10^9 organisms/ml. of the four strains undergo rapid and marked clearing in the presence of 1 per cent bile salts. It is suggested that strain *57* differs from strains *12*, *55* and *63* in being genetically sucrose-positive. Whether this is due to lysogenic conversion by the temperate variant of phage *57* cannot be stated at this stage. However, phenotypically it is sucrose-negative. Decryptification is brought about by a change in surface structure rendering the organism permeable to sucrose. This can be done with bile salts or by the surface-modifying effect which the lysin, liberated by phage-lysed organisms, has on neighbouring bacteria.

Recently it has been demonstrated that another virulent phage for *Proteus 57*, phage *69*[1], can enter into a carrier state with *Proteus 57*. The carrier colonies also ferment sucrose. Phage *69* is serologically unrelated to phage 57, and lysing complexes liberate a lysin which also changes the surface of strain *57*.

Sialic Acid in *Pasteurella pestis*

Sialic acid is widely distributed in the animal kingdom as a constituent of mucoproteins, mucolipids and mucopolysaccharides[1-3]. A search among the bacteria[4-13] has disclosed its occurrence in many Gram-negative bacteria[7,10,11]. A polymer of *N*-acetylneuraminic acid called colominic acid[4], a neuraminic acid peptide resembling the cell wall constituents and the corresponding uridine nucleotide which is the biosynthetic precursor[5], and *N*-acetylneuraminic acid and *N* : 7-*O*-diacetylneuraminic acid[6,12] in the hydrolysate of the cell mass with 0·05 *N* sulphuric acid have been reported in *Escherichia coli*. From group *C Neisseria meningococcus*, a group-specific haptenic material has been isolated which contains 3 units of hexosamine and 7 of sialic acid[8,9]. *Citrofactor freundii* has yielded a serologically active polysaccharide which contains 36 per cent sialic acid, 21 per cent hexosamine, and the rest unidentified (no uronic acid and only traces of protein)[11]. Sialic acid appears to be a constituent of the endotoxin[6,12,13], capsular antigen or some surface layers of the cell wall[5,12,13] of some bacteria.

After the detection of sialic acid in the cell mass of *Pasteurella pestis* in preliminary fractionation experiments, we tried to find out whether this acid is connected with the capsular material, protective antigen, and virulence of *P. pestis*. For this, six strains of *P. pestis* were selected with different characteristics given in Table 1. The bacteria were grown in casein hydrolysate medium, routinely used in this Institute for the preparation of the vaccines[14], and at 37° C. and 27° C., since it is known that the production of the protective antigen is maximum at 37° C. and very little at 27° C.[15-17]. After the growth period, the micro-organisms were killed with 0·1 per cent formalin (which did not interfere with the estimation of sialic acid by the thiobarbituric acid method, but did in reaction with orcinol), the cell mass collected by centrifugation, washed with saline, and acetone powders prepared by treating with cold acetone. For each experiment, 50–100 mgm. of the dried material was used. Sialic acid in the extracts was estimated by the thiobarbituric acid method of Warren[18,19] taking the optical densities at 532 and 550 mμ. In case of strong interference with deoxyribose, a preliminary extraction with isoamyl alcohol was carried out which removed most of the chromogen due to deoxyribose[18,19]. The absorption spectrum of the chromogen extracted with *cyclo*hexanone was also taken to check that it tallies with that of sialic acid[18].

Treating the bacterial mass with boiling water[7] extracted less than 25 per cent of the sialic acid; the aqueous extract after hydrolysis with sulphuric acid showed strong interference due to deoxyribose. Heating the bacterial mass with 0·1 *N* sulphuric acid at 80° C. (ref. 6) released about 50 per cent of the sialic acid obtained by the other method given below. Fractionation of the cell mass of two strains (120/5*H* and 139/*L*) successively with 2·5 per cent saline, cold trichloroacetic acid (TCA), 75 per cent alcohol and hot TCA, showed that sialic acid was present in the hot TCA extract and the hydrolysate of the residue with 0·1 *N* sulphuric acid. The routine method adopted finally was to extract the cell mass with cold TCA for 10 min. followed by hot 5 per cent TCA at 90° C. for 30 min. Sialic acid was present in the latter extract and the quantity of deoxyribose varied. Hydrolysis of the residual mass with 0·1 *N* sulphuric acid also furnished some sialic acid. The results obtained are given in Table 1.

No sialic acid was detected in Fraction I (ref. 20), which is supposed to contain the protective antigen and the mucoid substance surrounding the micro-organism[21].

Table 1. SIALIC ACID CONTENT OF THE CELL MASS OF VARIOUS STRAINS OF *P. pestis*

No.	Strain	Virulence	Protection to mice on immunization	Presence of capsule	Temp. of growth (°C.)	Sialic acid content (μgm./100 mgm.) Hot TCA extract	Sialic acid content (μgm./100 mgm.) Hydrolysate of residue
1	139/*L*	Virulent	+	+	27	253	62
2	139/*L*	Virulent	+	+	37	575	226
3	139/*L*	Virulent	+	+	37	127	20
4	195/*P*	Virulent	+	+	27	350	90
5	195/*P*	Virulent	+	+	37	205	14
6	53/*H*	Avirulent	+	+	27	230	108
7	53/*H*	Avirulent	+	+	37	337	40
8	*EV*	Avirulent	+	+	27	632	140
9	*TRU*	Avirulent	0	–	27	384	223
10	120/5*H*	Avirulent	0	–	27	421	87

All strains were grown in Haffkine flasks with 1 l. of medium in each. No. 3 was grown in a shaker for 2 days while the rest were grown in stationary cultures for 6 to 9 days to get significant growth.

The culture filtrates from Exps. 1, 4, 8 and 10 contained respectively 3·1, 3·5, 4·6 and 2·3 μgm. of sialic acid per ml.

No quantitative significance is attached to the figures for comparison since they are likely to change with differences in growth conditions and periods of collecting.

The results show that sialic acid is present in all the different strains of *P. pestis* grown under different conditions and that there is no correlation between its occurrence and the virulence of the organism, presence of capsule, or protective antigen.

Further work is in progress to isolate the macromolecular complex containing sialic acid and to find out its location in the cellular fractions.

We thank the Executive Committee of the Haffkine Institute Diamond Jubilee Fund, for the award of the senior fellowship to one of us (R. J. I.).

CYTOLOGY

Cell Retention and Incidence of Carcinoma in Several Portions of the Gastrointestinal Tract

THE epithelial cells of the stomach, small intestine and colon are subject to rapid renewal[1]. In the mucosa of these organs, cells are produced in proliferative zones which are rather sharply defined. Maturing cells and fully mature cells move in coherent sheets towards the lumen of the gastrointestinal tract or, in one area of the stomach, into the depth of the glands. Generation times of the epithelial cells vary from about ½ day to a few days.

When tritiated thymidine is injected into an animal, the label is available for only a short time, and is incorporated specifically into DNA in process of formation. The location and amount of label can be studied afterwards by microautoradiographic methods[2]. Following the incorporation of tritiated thymidine, the label disappears from the proliferative zone by migration of labelled and later maturing cells. Label remaining in the cells located in the proliferative zone is reduced by 50 per cent at each cell division. Within one week after injection of thymidine, most proliferative cells in the body of the stomach and in small and large intestine have undergone several divisions, which reduces the label to near background-level. Cells that matured within one or two divisions after labelling and were therefore heavily labelled have migrated to the surface and sloughed off. Therefore, one week after injection, the label is not demonstrable in the majority of the epithelial cells. However, although the majority of cells participate in this general pattern of division, migration and dilution of label, some scattered cells do not[3]. These cells, which can be isolated and identified by microautoradiography, are the topic of this communication.

Sixteen *C57* Brown mice and nine rats were injected with tritiated thymidine (0·7 mc./gm., sp. act. 0·3 c./m*M*), and killed at 1 hr. and 1, 3, 5, 7, 10, 14 and 21 days later. Histological sections were prepared from various parts of the gastrointestinal tract and microautoradiographs were made using Kodak '*NTB*' emulsion. In these sections, the percentages of moderately and heavily labelled cells were determined. A heavily labelled cell (Fig. 1) is one that has undergone one or no division since labelling, as ascertained by comparison with cells from animals killed 1 hr. after labelling. A moderately labelled cell is estimated to have undergone 2 or 3 divisions.

Four days following labelling, differences in the number of heavily labelled cells retained in various portions of the gastrointestinal tract begin to become obvious. These differences are well expressed one week following injection. Labelled cells are removed most rapidly from duodenum and least rapidly from stomach and colon. The results of counts taken in two mice and two rats one week after injection are shown in Table 1. At two weeks, there were almost no recognizably labelled cells in the small intestine, and very few in the colon and stomach. Messier and Leblond have reported persistence of label in rats in the colon, tongue, œsophagus and duodenum (listed in order of decreasing amounts)[3].

The persistence of labelled cells in each area cannot be explained unequivocally at this time. They have no distinctive morphological characteristics. Appropriate cytochemical staining procedures[4] have revealed that they are not argentaffin cells. Some take the periodic acid–Schiff stain which is characteristic of goblet cells, but some do not. They may represent the extreme of the distribution of generation times of the general cell population, or they may be members of a specific population which so far has not been identified. In the colon, they could be slowly migrating descendants of the cells located in the bottom of the crypts[5].

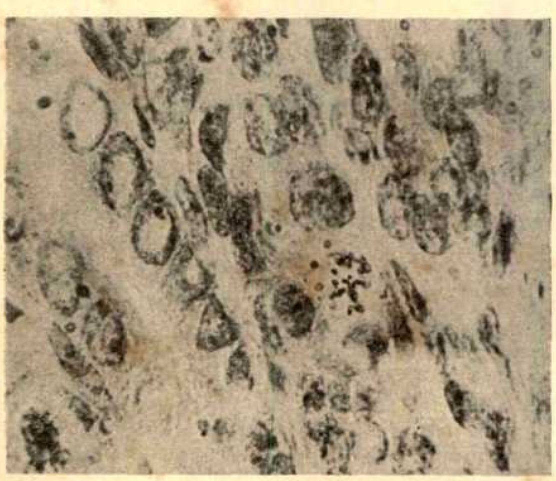

Fig. 1. Microautoradiograph of colonic crypt of mouse one week after injection of tritiated thymidine. One heavily labelled epithelial cell and several nuclei with 1–3 grains

Table 1. RETENTION OF PROLIFERATIVE CELLS IN MAMMALS AND AMPHIBIAN COMPARED TO INCIDENCE OF CARCINOMA IN MAN FOR VARIOUS PORTIONS OF THE GASTROINTESTINAL TRACT

Organ	Occurrence of cells heavily labelled after administration of tritiated thymidine				Frequency of gastrointestinal carcinoma in man in two series	
		Cells labelled (per cent)				
	No. of cells counted in each species	Mouse*	Rat*	*Rana pipiens*†	Ref. 6	Ref. 7
Sigmoid colon	1,000	2·4	4·3	8·4	416	52
Ascending colon	2,000	1·2	5·9		48	11
Jejunum	2,500	0·1	0·3	1·3	9	1
Duodenum	3,000	0	0		2	1
Stomach (mid-portion of body)	1,000	4·0	3·2	5·1	1,405‡	70‡

*, † Mice and rats killed 1 week and frogs 3 weeks after injection of label.

‡ Entire stomach.

The phenomenon is not restricted to mammals. In *Rana pipiens*, there appears to be retention of heavily labelled cells in the colon contrasted with more rapid dilution of label in the jejunum, when tritiated thymidine has been similarly injected and the frogs maintained at room temperature. The results of counts taken in three frogs two weeks after injection of tritiated thymidine are also shown in Table 1. In addition, data in two hamsters at one week revealed retention of heavily labelled cells: sigmoid, 2·9 per cent; ascending colon, 11·6 per cent; jejunum, 0·2 per cent; duodenum, 0·6 per cent; stomach, 2·2 per cent.

It is not known whether in man a similar distribution of retained epithelial cells occurs. We note with interest, however, that the rank order found for retention of labelled epithelial cells in these areas of the species examined is the same as the rank order of frequencies of precancerous and cancerous lesions in the corresponding areas of the gastrointestinal tract of man[6,7]. The retention of labelled and therefore potentially proliferative cells in these areas of the gastrointestinal tract could be associated with malignancy. In general, carcinomas arise frequently in tissues capable of rapid growth. A notable exception is the small bowel. Here, proliferation occurs very rapidly, yet tumours are rare; they are virtually absent in the duodenal bulb (Table 1). This could conceivably be due to a mechanism by which pathological or potentially pathological cells are swept out of the proliferative region in small intestine, while remaining for longer periods of time in other areas of the gastrointestinal tract.

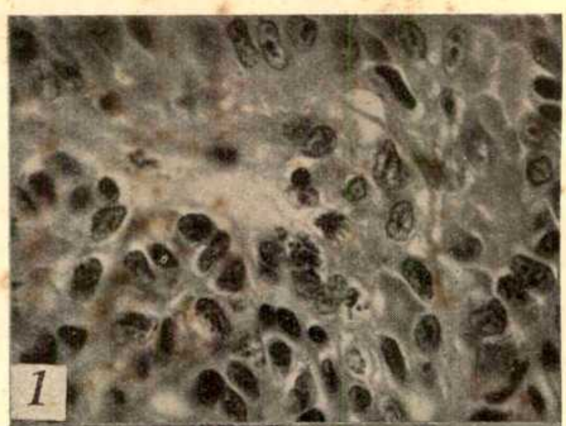
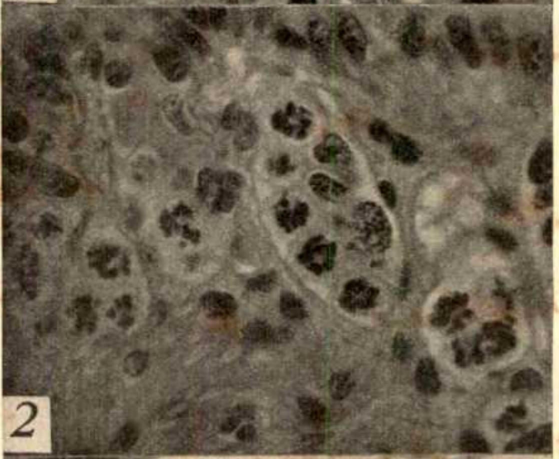
Kinetin, as a Mitotic Stimulant in *Triturus viridescens*

Miller *et al.*[1-3] presented evidence that kinetin when used together with indolyl-3-acetic acid increased cell proliferation in tobacco callus tissue. These authors isolated kinetin from the DNA of herring sperm and calf thymus. Since that time additional evidence indicating that kinetin acts as a mitotic stimulant on plant tissues has been presented. Guttman[4] reported a larger proportion of division figures in the meristematic region of roots of *Allium cepa* following 4 and 24 hr. treatment with kinetin. Torrey[5] noted that kinetin together with 2,4-*D* initiated frequent mitoses in tetraploid nuclei in excised callus tissue from mature pea roots. In the absence of kinetin the tetraploid nuclei remained in the resting state. The action of kinetin on animal tissues is still controversial. Cudkowicz[6] treated mice with kinetin following irradiation and compared these with mice that were simply irradiated. He noted that irradiation inhibited mitoses in the crypts of Lieberkühn. The return to the normal mitotic rate was enhanced by treating the mice with kinetin following irradiation.

Ogawa, Abe and Fujioka[7] and Ogawa[8] examined the effect of kinetin on the mitotic activity of Yoshida sarcoma cells transplanted to Wistar-strain rats. A significant increase in the frequency of mitotic figures was found in the tumour cells following injection of a solution of kinetin into the abdomen. This occurred only if the sarcoma cells were transplanted. Lettré and Endo[9], however, found no changes in cell division or tumour growth following treatment with kinetin in cultures of normal or malignant human and animal cells. Ogawa[10] raised embryos of *Triturus pyrrhogaster* in kinetin solutions of varying concentrations. Kinetin significantly increased the rate of early embryonic development. Guttman and Back[11] noted an increase in the mitotic divisions in *Paramecium caudatum* as the concentration of kinetin was lowered from 4 to 1·5 mgm./l. Moewus[12] reported an increase of mitotic activity by kinetin in *Polytoma uvella*.

Because of the interesting results reported by Ogawa[10] and since *Triturus* is good cytological material, the effect of kinetin on the mucosa of the alimentary tract of *Triturus viridescens* was examined. Adult specimens of *Triturus viridescens* collected in Poughkeepsie, New York, were used in these experiments. The animals were immersed in varying concentrations of kinetin for varying periods of time. In the initial experiments 5 mgm. and 10 mgm. per cent solutions were used alone and in combination with equal amounts of alpha naphthalene acetic acid in the concentration of 5 parts per million in tap water. Two hundred c.c. of each solution were placed in finger bowls together with the animals. The best results were evident after treating the salamanders with a 10 mgm. per cent solution of kinetin for 7–9 days. During the period of treatment the animals were not fed and the solution was changed every third day. The animal was killed after 7 or 9 days of treatment. Portions of the stomach, small intestine, large intestine and cloaca were fixed, sectioned and stained with Heidenhain's hæmatoxylin using standard techniques. Sections of untreated tissue were prepared at the same time.





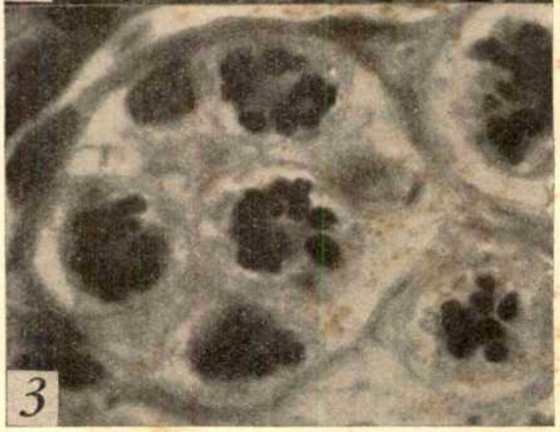


Fig. 1. Photomicrograph of a section of normal stomach mucosa (× 400). Fig. 2. Photomicrograph of a section of treated (kinetin and alpha naphthalene acetic acid) stomach mucosa (× 400). Fig. 3. Photomicrograph of a section of a cell nest in the gastric mucosa following treatment with kinetin and naphthalene acetic acid (× 1,000)

In the normal epithelium of the stomach, small intestine, large intestine and cloaca a relative lack of mitotic activity was found. No divisions were found in the surface epithelium and divisions were uncommon in the nests (Fig. 1). This lack of mitotic activity in the nests was noted earlier by Patten and Andrew[13]. According to their findings normal mitotic activity within the cell nests was present in 0·57 per cent of the cells. In the present work following 9 days exposure to kinetin a marked increase in the mitotic activity was noted. This was evident in the stomach, small intestine, large intestine and the cloaca. No divisions were found in the surface epithelium. The increased activity was noted in the nests. This mitotic activity seemed to be localized in the different areas of the intestinal mucosa. In some areas of the stomach and intestine every cell in the nests was in division. In other areas relatively few cells were in division. The statistical details will be given in a subsequent paper. The divisions in all cases were typical diploid divisions. The animals behaved normally during the treatment. This stimulatory effect of kinetin appeared to be further enhanced when it was combined with alpha naphthalene acetic acid (Figs. 2 and 3).

This investigation was aided by a grant (*G*21381) from the National Science Foundation.

Two Types of Islet α Cells in Different Parts of the Pancreas of the Dog

A CRITICAL evaluation of the argyrophil reaction in the islets of Langerhans in different vertebrates revealed that only a certain number of the α cells are argyrophil (= α_1 cells), while the rest (= α_2 cells), like all the β cells, lack this property[1–7]. Differences were demonstrated between the two types of α cells also with regard to their localization within the islets, the size and eccentricity of their nuclei and the metachromatic reaction with toluidine blue and azure *A*[4–7]. The reports of Bencosme *et al.*[8,9] that the uncinate process of the dog pancreas is devoid of α cells and contains practically no extractable hyperglycæmic activity has lent strong support to the view that the α cells are a source of glucagon. The present investigation is an attempt to find which type of α cell is possibly associated with glucagon secretion by analysing how the α_1 and α_2 cells are regionally distributed within the pancreas of the dog.

Biopsies were taken from the uncinate process, the body and the tail of the pancreas in 8 adult dogs of both sexes, anæsthetized with 'Nembutal^R'. The pancreatic samples were fixed in Bouin's solution and, after dehydration and clearing, embedded in paraffin. Serial sections, 4μ thick, were alternately granule stained with Gomori's chrome-hæmatoxylin or aldehyde fuchsin using phloxine or ponceau fuchsin as counter-stains for the α cells or silver impregnated as previously described[1–2]. Since the initial pre-oxidation in the specific granule staining procedures results in a complete removal of the silver, the islet cells in a section could be examined first in a silver impregnated state and then afterwards granule stained without any alteration of their original staining properties, as shown by comparisons with the alternately directly stained sections.

While the β cell granulation was found to be characterized by the usual staining reaction with aldehyde fuchsin or chrome-hæmatoxylin, the remaining islet cells could be divided into two major fractions because of their affinity to phloxine or ponceau fuchsin. One type displayed the heavy red cytoplasmic staining as seen in the α cells in other species, and the other had a more pink cytoplasmic tinge. The latter cells appeared to be the only argyrophil islet cells in the dog and have therefore been regarded as corresponding to the α_1 cells of other vertebrates. In addition to these types of cells some non-argyrophil islet cells lacking apparent cytoplasmic staining were occasionally observed.

There was a different appearance of the islet tissue in the uncinate process as compared with the remaining parts of the pancreas. In the former region the islets were not only smaller but their cellular composition was also different. While the islets of Langerhans in the uncinate process were devoid of α_2 cells, the contribution of the silver-positive α_1 cells was, on the other hand, comparatively very high in this particular part of the pancreas (Fig. 1). The different arrangement of the islets was also reflected in the position of the elongated argyrophil α_1 cells, which were packed together, mainly in the central parts of the islets in the uncinate process, but more diffusely distributed within the islets of the body and the tail.

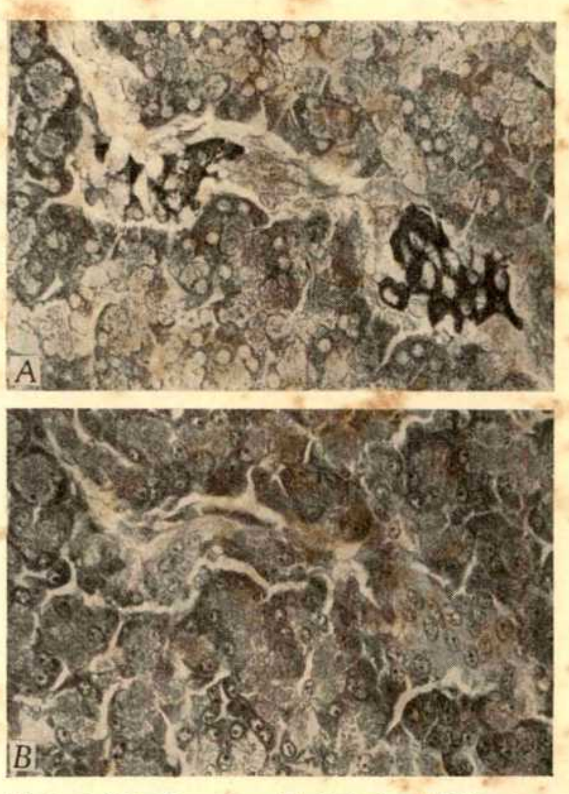

Fig. 1. An islet of Langerhans of typically elongated shape from the uncinate process. (× *c*. 350.) *A*, Islet in a silver impregnated state. The numerous blackened silver cells are characteristically packed close together. *B*, Islet after removal of the silver and stained with aldehyde fuchsin combined with ponceau fuchsin. The formerly argyrophil cells now exhibit a lighter staining than the β cells. In the left upper part of the picture it can be seen that the islet is connected to a small excretory duct. No α_2 cells can be recognized

While in some other species, as in the rat, both types of α cells are equally well stained with phloxine or ponceau fuchsin, it is worthy of note that the α_1 cells in the dog pancreas have lower affinity to these stains. This might well explain why the uncinate process has been considered erroneously to be devoid of α cells in spite of the relatively very high contribution of α_1 cells demonstrated by us in the islets of this particular region. The finding that the uncinate process of the dog pancreas was characterized not only by extremely low or absent extractable hyperglycæmic activity but also by a different cellular composition of the islets due to absence of α_2 cells suggests that this latter type of α cell is the source of glucagon. The recent demonstration[10] of pronounced regressive nuclear changes in the α_2 cells after repeated injections of glucagon to rats supports such a hypothesis.

Spherical Errors

I HAVE read with interest the recent article by N. Singh[1] concerning spherical errors. Work of a similar nature has been done in this laboratory.

It is assumed here that the components of the total errors in the position of an object along three cartesian co-ordinates (x, y, z) are normally distributed with variances σ_x^2, σ_y^2, σ_z^2, and mean at the origin. That is, the probability density of the position of the object in question along the x co-ordinate is:

$$\frac{1}{\sqrt{2\pi\sigma_x^2}}\exp[-x^2/2\sigma_x^2]$$

and similarly for the other co-ordinates. The probability $P(R)$ that the object is within a sphere of radius R about the origin is then given by:

$$P(R) = \frac{2\pi^{-3/2}}{\sigma_x\sigma_y\sigma_z}\iiint_R \exp[-x^2/2\sigma_x^2 - y^2/2\sigma_y^2 - z^2/2\sigma_z^2]\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z$$

where the integration is carried out over the volume of the sphere in question. Unfortunately, this expression for $P(R)$ cannot, in general, be integrated in closed form, nor is it a tabulated function.

In order to avoid the difficulty of a triple numerical integration, it is usual to assume that $\sigma_x = \sigma_y = \sigma_z = \sigma$, whence the expression for $P(R)$ becomes (after conversion to spherical co-ordinates):

$$P(R) \approx \frac{\pi^{-1/2}}{\sigma^3}\int_0^R \exp[-r^2/2\sigma^2]\,r^2\mathrm{d}r$$

If the substitution $r^2/2\sigma^2 = u$ is made, this can be expressed as

$$P(R) \approx \frac{2}{\sqrt{\pi}}\int_0^{R^2/2\sigma^2} e^{-u}\,u^{1/2}\,\mathrm{d}u$$

which is the incomplete Γ function[2], and is tabulated.

In making the aforementioned assumption, personnel normally choose a value for σ^2 which is equal to the sum of the variances of all the errors involved, regardless of their direction. This naturally results in a value of $P(R)$ which is smaller than the actual value. The transition from ellipsoidal to spherical symmetry suggests that a better alternative than the above might be to assume:

$$\sigma^2 = \tfrac{1}{3}(\sigma_x^2 + \sigma_y^2 + \sigma_z^2)$$

As the values of σ_x, σ_y, and σ_z diverge, the spherical approximation to the real case becomes less valid. It is therefore worth while to establish some limits on the actual value of $P(R)$ to increase the confidence in any approximate answer obtained. On examination of the expression for $P(R)$ it is obvious that:

$$\frac{2}{\sqrt{\pi}}\int_0^{R^2/2\sigma_M^2} e^{-u}\,u^{1/2}\,\mathrm{d}u \leqslant P(R) \leqslant \frac{2}{\sqrt{\pi}}\int_0^{R^2/2\sigma_m^2} e^{-u}\,u^{1/2}\,\mathrm{d}u$$

where σ_M is the maximum of $(\sigma_x, \sigma_y, \sigma_z)$ and σ_m is the minimum of $(\sigma_x, \sigma_y, \sigma_z)$. Thus, a set of limits on the actual value of $P(R)$ is established.

Another set of limits may be established by integrating the expression for $P(R)$ over the volume of a cube rather than a sphere, that is:

$$\frac{2\pi^{-3/2}}{\sigma_x\sigma_y\sigma_z}\int_{-R/\sqrt{3}}^{R/\sqrt{3}}\int_{-R/\sqrt{3}}^{R/\sqrt{3}}\int_{-R/\sqrt{3}}^{R/\sqrt{3}} \exp[-x^2/2\sigma_x^2 - y^2/2\sigma_y^2 - z^2/2\sigma_z^2]\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z \leqslant P(R)$$

$$\leqslant \frac{2\pi^{-3/2}}{\sigma_x\sigma_y\sigma_z}\int_{-R}^{R}\int_{-R}^{R}\int_{-R}^{R} \exp[-x^2/2\sigma_x^2 - y^2/2\sigma_y^2 - z^2/2\sigma_z^2]\,\mathrm{d}x\,\mathrm{d}y\,\mathrm{d}z$$

The two cubical regions of integration are taken as the cubes that circumscribe and inscribe the actual region of integration. The limits are then given by the product of three tabulated functions (error functions). This latter set of limits is the more useful when the values of the variances are widely divergent. Taking the larger of the two possible lower limits and the smaller of the two larger limits should establish a fairly good bracket on the value of $P(R)$. A graph of the limits of $P(R)$ versus R then establishes limits for the radius of the 50 per cent probability sphere.

FORTHCOMING EVENTS

Monday, June 25

BRITISH SOCIETY FOR THE HISTORY OF SCIENCE (in the Science Museum, Exhibition Road, London, S.W.7), at 5.30 p.m.—Annual General Meeting and Presidential Address.

Monday, June 25—Tuesday, June 26

INSTITUTE OF RURAL LIFE AT HOME AND OVERSEAS (at the Department of Technical Co-operation, 6 Carlton House Terrace, London, S.W.1), at 10.30 a.m. on Monday and 10.15 a.m. on Tuesday—Twelfth Annual Conference—"Training the Farming Community at Home and Overseas".

Tuesday, June 26

BRITISH SOCIETY FOR RESEARCH ON AGEING (at the Zoological Society of London, Regent's Park, London, N.W.1), at 2 p.m.—Informal discussion on "Age and Cancer".

PARLIAMENTARY AND SCIENTIFIC COMMITTEE (in Committee Room 11, House of Commons, Westminster, London, S.W.1), at 5.30 p.m.—Discussion on "Problem of Diseases Arising out of the Use of New Materials and Processes in Industry and Agriculture" introduced by Prof. H. G. Sanders, Mr. T. A. Lloyd Davies and Dr. Donald Hunter.

Wednesday, June 27

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. I. S. E. Carmichael: "The Crystallization of Feldspar in Volcanic Acid Liquids".

SOCIETY FOR ANALYTICAL CHEMISTRY, MICROCHEMISTRY GROUP (at "The Feathers", Tudor Street, London, E.C.4), at 6.30 p.m.—Discussion Meeting.

Friday, June 29

SOCIETY OF CHEMICAL INDUSTRY, AGRICULTURE GROUP (at Rothamsted Experimental Station, Harpenden, Herts), at 11 a.m.—Annual Summer Meeting.

Monday, July 2—Friday, July 13

IMPERIAL COLLEGE OF SCIENCE AND TECHNOLOGY, DEPARTMENT OF CHEMICAL ENGINEERING AND CHEMICAL TECHNOLOGY (at Imperial College, London, S.W.7)—Summer School in "Health Physics (Radiation Protection)".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER (with special interest in teaching and research in the general field of the strength, elasticity and plasticity of engineering materials) IN THE DEPARTMENT OF MECHANICAL ENGINEERING—The Registrar, Queen Mary College (University of London), Mile End Road, London, E.1 (June 29).

ASSISTANT LECTURER (preferably with an interest in cryptogamic botany) in BOTANY—The Registrar, The University, Nottingham (June 30).

ASSISTANT LECTURER (with special interest in palæontology and stratigraphy) IN GEOLOGY—The Registrar, The University, Sheffield (June 30).

ESSO RESEARCH STUDENT IN THE DEPARTMENT OF CHEMISTRY, to undertake research in the field of chemical crystallography—O.S. Mills, Department of Chemistry, The University, Manchester 13 (June 30).

LECTURER IN EDUCATIONAL PSYCHOLOGY—The Secretary, The University, Exeter (June 30).

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF MATHEMATICS—The Clerk to the Governors, Chelsea College of Science and Technology, Manresa Road, London, S.W.3 (June 30).

RESEARCH DEMONSTRATOR (with good honours qualifications in organic chemistry) IN THE DEPARTMENT OF CHEMISTRY—The Registrar, University College, Singleton Park, Swansea (June 30).

LECTURER or ASSISTANT LECTURER IN THE DEPARTMENT OF METALLURGY—The Registrar, The University, Liverpool, quoting CV/105/T (July 1).

ASSISTANT IN GEOGRAPHY—The Secretary of University Court, The University, Glasgow (July 2).

ASSISTANT LECTURER IN SOCIOLOGY—The Registrar, The University, Sheffield (July 2).

LECTURER IN PSYCHOLOGY—The Secretary, Birkbeck College (University of London), Malet Street, London, W.C.1 (July 2).

JUNIOR RESEARCH OFFICER (with an honours degree in economics, statistics or agriculture with agricultural economics) IN THE FARM ECONOMICS BRANCH—The Secretary, School of Agriculture, Cambridge (July 4).

LECTURER or ASSISTANT LECTURER IN BIOCHEMISTRY—The Registrar, The University, Leeds 2 (July 7).

RESEARCH ASSISTANT (with a good degree, preferably in physics or electrical engineering, and several years postgraduate experience in the following or related fields: electronics, microwave techniques, or semiconductor technology) at the Nuffield Radioastronomy Laboratories, Jodrell Bank, to take a leading part in the existing programme of developing parametric amplifiers for use in conjunction with the 250 ft. radio telescope—The Registrar, The University, Manchester 13 (July 7).

LECTURER or ASSISTANT LECTURER (with an honours degree in chemical engineering or an equivalent qualification, and evidence of research ability) IN CHEMICAL ENGINEERING at Houldsworth School of Applied Science—The Registrar, The University, Leeds 2 (July 9).

READER (preferably with interests in inorganic or physical chemistry) IN CHEMISTRY at Royal Holloway College—The Academic Registrar, University of London, Senate House, London, W.C.1 (July 11).

ASSOCIATE PROFESSOR OF MEDICAL BIOCHEMISTRY IN THE DEPARTMENTS OF MEDICINE AND BIOCHEMISTRY, The University, Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (July 13).

LECTURERS (2) IN PURE MATHEMATICS at the University of Sydney, Australia—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (July 13).

CHAIR OF THEORETICAL PHYSICS in the School of General Studies, Australian National University—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (July 16).

RESEARCH ASSISTANT, for investigation of aspects of zooplankton metabolism under the direction of the Professor of Zoology—The Secretary and Registrar, The University, Southampton (July 16).

CHAIR OF GEOGRAPHY in Monash University, Melbourne—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1, or The Registrar, Monash University, P.O. Box 92, Clayton, Victoria, Australia (July 27).

ASSISTANT LECTURER (with at least a good B.A. honours degree or its equivalent in psychology, and preferably a knowledge of philosophy or physiology) IN PSYCHOLOGY IN THE DEPARTMENT OF PHILOSOPHY, University of Hong Kong—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (Hong Kong and London, July 31).

CHAIR OF THEORETICAL PHYSICS in the University of Auckland, New Zealand—The Secretary, Association of Universities of the British Commonwealth (Branch Office), Marlborough House, Pall Mall, London, S.W.1 (New Zealand and London, August 3).

CHAIR OF LARYNGOLOGY and OTOLOGY at the Institute of Laryngology and Otology—The Academic Registrar, University of London, Senate House, London, W.C.1 (August 16).

CHAIR OF BIOCHEMISTRY—The Registrar, University College, Cathays Park, Cardiff (September 14).

AGRONOMIST (Soils) (male, between 26 and 40, with an honours degree in agricultural or horticultural science with agricultural chemistry as main subject, experience in field experimental work on soil fertility, and a knowledge of tropical soils and crops) IN THE DEPARTMENT OF AGRICULTURE, Sarawak—The Director of Recruitment, Department of Technical Co-operation, Sanctuary Buildings, Great Smith Street, London, S.W.1, quoting Ref. RC.213/123/01/T.

HEAD OF THE MATHEMATICS DEPARTMENT—The Rector, Glasgow Academy, Glasgow, W.2.

MASTER TO TEACH MATHEMATICS AND PHYSICS—The Headmaster, Lawrence Sheriff School, Rugby.

PRINCIPAL LECTURER (with experience of supervising research of an academic standard) IN THE DEPARTMENT OF PHYSICS—The Clerk, Northern Polytechnic, Holloway, London, N.7.

RESEARCH ASSISTANT (either botanist with a good background in physical chemistry or physical chemist with an interest in entering the field of biophysics) IN THE ASTBURY DEPARTMENT OF BIOPHYSICS, for investigation of the permeability properties of timber with particular reference to permeability barriers in the impregnation of wood by preservatives, using physical techniques including electron microscopy—Prof. R. D. Preston, The Astbury Department of Biophysics, The University, Leeds 2.

PHYSIOLOGY

Œstrous and Ovarian Response of the Ewe to a Horse Anterior Pituitary Extract.—Dr. N. W. Moore and J. N. Shelton 1283
Plasma Fibrinolytic Activity in the Immature Animal.—B. G. R. Neville and R. G. Spector . 1284
Effects of Stilbœstrol and Thiouracil on the Electrocardiograms of the Sheep.—Dr. D. N. Mullick and V. N. Murty 1285
Effect of Phenylalanine Diet on Learning in the Rat.—Yen Hoong Loo, Erold Diller and John E. Owen, jun. 1286

HÆMATOLOGY

α-Chain of Rabbit Hæmoglobin.—Jared M. Diamond and Dr. G. Braunitzer 1287
Failure to elicit a Delayed Hypersensitivity Reaction against Blood Group Substance from Erythrocytes.—G. Loewi and E. J. Holborow . 1288

IMMUNOLOGY

Acceptance of Tumour Homografts by Thymectomized Mice.—Prof. Carlos Martinez, Agustin Dalmasso and Prof. Robert A. Good . 1289
Induction of Partial Acquired Tolerance to a Carcinogen.—Dr. Mary R. Anderson . . 1290

BIOLOGY

Preservation of Bull and Human Spermatozoa by Freezing in Liquid Nitrogen Vapour.—Prof. J. K. Sherman 1291
The Placenta as a Homotransplant.—Dr. Jonathan W. Uhr and Dr. S. G. Anderson . . . 1292
Twilight Transitions and Biological Rhythmicity.—Prof. J. Lee Kavanau 1293
New Records of *Gobius forsteri*.—R. G. Hartnoll and P. J. Miller 1295
Dispersal of Coffee Rust *Hemileia vastatrix* B. et Br.—Dr. F. J. Nutman and Dr. F. M. Roberts 1296
Embedding Large Slices of Plant Tissue for Electron Microscopy.—B. E. Juniper . . . 1296

ENTOMOLOGY

Sterilization of the Codling Moth by Gamma-Irradiation.—M. D. Proverbs . . . 1297
A Survey Method of Trypanosome Infections in *Glossina*.—A. M. Simmonds and Miss B. M. Leggate 1297
Flight of Grasshoppers in the Laboratory.—Dr. P. Wm. Riegert 1298

MICROBIOLOGY

Chemotaxis in *Myxococcus*.—Anne McVittie and Prof. Stanley A. Zahler 1299
Ions and the Germination of Spores of *Bacillus cereus T*.—L. J. Rode and J. W. Foster . . 1300

VIROLOGY

Effect of Œstrogenic Hormones on Agglutinability of Chicken Erythrocytes by Arthropod-borne Viruses.—Dr. Aimo Salminen 1301
Some Characteristics of a Virus occurring in Poplars.—Th. M. Berg 1302

PSYCHOLOGY

Absolute Threshold for Electric Shock.—Dr. R. T. Green 1303
Effect of Strain and Group Size on the Response of Mice to 'Seconal' Anæsthesia.—J. H. Mackintosh 1304

Kodak High Speed Ektachrome—fast becoming invaluable in many research projects...

High Speed 'Ektachrome' is the fastest colour film made by Kodak. Rated at ASA 160, it brings black-and-white speed to colour photography. It has proved itself invaluable where coloured dyes are used as markers; in metallurgical analysis by flame propagation; in photo-recording where high-speed galvanometer traces overlap and need to be identified by colour; in photo-elastic stress analysis; in Schlieren photography and in many other fields where high speed transients and identification by colour go together. WRITE FOR DETAILS

Kodak **HIGH SPEED EKTACHROME FILM**

Kodak Limited, Industrial Sales Division,
Kodak House, Kingsway, London W.C.2

'Kodak' and 'Ektachrome' are registered trade-marks

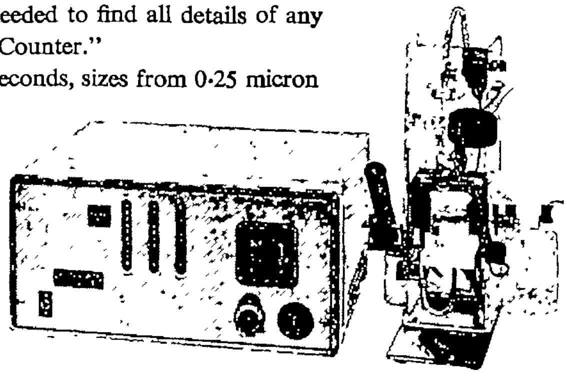
$$d = k\sqrt[3]{t}$$

means the fastest, most accurate sizing and counting ever!

d = *equivalent diameter of particle*
k = *calibration constant of the instrument*
t = *threshold setting*

This is the most involved arithmetic calculation needed to find all details of any particle size or weight distribution with a "Coulter Counter."

And the speed—counts of 75,000 in about 15 seconds, sizes from 0·25 micron upwards with an inherently accurate volumetric response. A "Coulter Counter" will save hours and hours of tedious work at the microscope and release valuable skilled technicians for productive work.



Full details will be sent on request.

COULTER ELECTRONICS LTD. 2-4 Ashwell Street, St. Albans, Hertfordshire. Tel: St. Albans 50828/9

POSITION OF COAL IN ELECTRIC POWER GENERATION

IN a modern industrial community the generation of electrical power becomes one of the essential pillars of national prosperity. In Great Britain, the standards of efficiency of the generation of such power have changed markedly in the past forty years. This change amounts to an improvement in the thermal efficiency of power generation from some 18 per cent at the end of the First World War to a realizable figure of 36 per cent foreshadowed in new equipment at the present time. The coal now used for this purpose represents 84 per cent of all the fuel consumed by the Central Electricity Generating Board. In 1957 the proportion was 95 per cent. By 1965 it may fall to 80 per cent.

The why and the wherefore of these prospects were explained recently in an interesting lecture by Mr. L. Rotherham, the member for research of the Central Electricity Generating Board, on the occasion of the award to him of the British Coal Utilization Research Association's Coal Science Medal*.

Mr. Rotherham discussed the extent to which nuclear energy and oil are likely to be used within the coming decades, and the technical and economic factors affecting the situation.

In 1965–66 nuclear energy will be contributing an equivalent of 6–7 million tons of coal. This consumption of nuclear energy is justified not entirely on economic grounds, but in order to enable the technology of nuclear energy to be developed. By 1970–71 nuclear energy is expected to be contributing some 20 per cent of the energy output of the Board. With oil keeping its position, coal will only be used for 65 per cent of the station requirements. Nuclear energy might have come into the picture earlier; but its advancement has been affected by three principal factors, namely, a less than anticipated rise in the price of coal, improved efficiency of electricity generation and reduction in capital costs in coal-fired stations. Over the period envisaged the rate of energy consumption is anticipated to increase by some 7 per cent per annum. The position of coal varies regionally. The North-West of England is a high coal cost area. The healthy industry in Yorkshire and the Midlands can maintain a high demand for coal. Oil is competitive on the coast, where seaborne oil can compete favourably with rail-borne coal. If the energy transport problem could be overcome it would assist the use of coal from productive East Midland collieries in respect of London and the South.

Mr. Rotherham discussed the factors affecting the economics of the transport of energy. A basic factor is that three units of heat have to be transported as oil, gas or coal for one of electricity. In regard to the transmission of electricity over great distances, 400-kV. lines are preferred for reasons of amenity. A high-voltage grid is indeed a step in the direction of advancing the economic transfer of power, and favours the greater utilization of coal. The hydraulic transport of coal is being studied, an experimental development being the delivery by such means over a distance of 2,000 yards from a colliery to a power station in Wakefield.

Important technical problems arise in the effects and disposal of the ash from the fuel, a nuisance to be paid for. It has been intensively studied, particularly in respect of overcoming the effects of the deposits on boiler surfaces, and the resultant loss of efficiency and productive plant capacity by interrupted operation. The outcome has been a marked improvement in the time in which a boiler remains on load. In this respect, substantial help in the attainment of this result has been derived from the activities of the Boiler Availability Committee, which is supported jointly by the Central Electricity Generating Board and the boiler manufacturers, the research activities being undertaken in the main by the British Coal Utilization Research Association. The limitations in the properties of materials still constitute a problem. Thus, the vulnerability of superheater metals to the corrosive effects of deposits, even if austenitic steels are used, is the main obstacle to the use of higher steam temperatures and improved efficiency in the generating plant.

The layman will be pleased to know that, although electrostatic precipitators are now used for collecting solid particles in chimney emissions to the extent of recovering 99 per cent of the emission from the boilers, the escape of the remaining 1 per cent is still regarded as unsatisfactory, and attention is being devoted to the difficult problem of its dispersion. The collected ash has useful purposes in brick-making and horticulture. When used for land reclamation the presence of toxic constituents, particularly boron and molybdenum, calls for tolerant crops in the early stages of cultivation.

Improvement in thermal efficiency is inevitably accompanied by increase of cost in the necessary complication of equipment, and new fields of electricity generation are being studied—thus fuel cells, thermionic devices and magneto-hydrodynamics.

The final picture envisaged is that coal has an assured place in the generation of electric power at the present time. The future may well depend on the outcome of research. The coal consumption required annually for electricity supply could be expected to rise above 100 million tons by 1970. Marginal economies in utilization could have great significance. The position of coal must, nevertheless, depend largely on the price of coal. With improved methods of mining and an acceleration of research the position of coal could be maintained. Mr. Rotherham has concluded that an interesting and possibly fruitful field of development exists, given the necessary resources for the purpose.

THE SCIENTIFIC WORKS OF LORD RUTHERFORD OF NELSON

The Collected Papers of Lord Rutherford of Nelson, O.M., F.R.S.

Vol. 1: New Zealand—Cambridge—Montreal. Published under the Scientific Direction of Sir James Chadwick, F.R.S. Pp. 931 + 12 plates. (London: George Allen and Unwin, Ltd., 1962.) 126*s*. net.

IN any age there are but a few scientists who are important enough to make it both useful and fitting that all their scientific works should be collected and republished. Ernest Rutherford is certainly one of these rare beings. This first volume of his collected works covers the period from 1894, when the twenty-three-year-old student of Canterbury College, Christchurch, New Zealand, started experimenting on the magnetization of iron by high-frequency discharges, to the end of his time at McGill University, Montreal, in 1907. By then Rutherford had completed the work on radioactivity for which he was awarded the Nobel Prize for Chemistry the following year. During these thirteen years at Christchurch, Cambridge and Montreal, Rutherford published 65 papers, an average of 5 a year, with an average of 14 pages each—a remarkable output. His earliest papers showed his gift for finding the simple and direct experimental approach. When he suspected that the high-frequency electric discharge only magnetized a thin outer layer of a steel needle, due to the skin effect, he just dissolved off the outer layer with acid while watching the magnetization of the needle with a magnetometer: the magnetization first disappeared and then returned weakly in the opposite sense, so demonstrating a surface layer magnetized one way and an inner layer magnetized the other.

Rutherford's arrival in Cambridge in 1896 coincided with the huge impact on the scientific world of the discovery of radioactivity by Becquerel, and of X-rays by Roentgen. He immediately started, in close collaboration with J. J. Thomson, the study of the process of ionization of gases by X-rays, and made his first important contribution to physics by his measurement of the mobility and rate of recombination of ions. He turned his attention to radioactivity as soon as he arrived in Montreal as MacDonald professor at McGill in 1899, at the age of 28. From then on his scientific life's work was settled: all but one of the papers in this volume relate to radioactivity; this is a paper in 1903 entitled "A Penetrating Radiation from the Earth's Surface", in which he surrounded an electroscope with 5 tons of lead and deduced the existence of a radiation which was more penetrating than any known rays from radioactive substances: this was, of course, one of the early investigations of what later became known as cosmic rays.

The high points of this Montreal period were the discovery of thorium emanation, the elucidation with Soddy of the transformation theory of radioactivity, and the detailed study of the alpha particle; for this particle he was later in life to display an almost paternal affection. His wider interests are shown by a 'popular' article in *Harper's Magazine* in 1905, entitled "Radium as the Cause of the Earth's Heat", and two years later a lecture to the Royal Astronomical Society of Canada, "Some Cosmical Aspects of Radioactivity": both make good reading to-day and show Rutherford's interest in geophysics and astronomy.

Sir Edward Appleton has contributed a valuable essay on "The Young Rutherford", and H. L. Bronson and Otto Hahn have told of the time at Montreal.

The second volume will cover the Manchester period, 1907–1919, the third the Cavendish period 1919 to his death in 1937, and the fourth will contain miscellaneous papers, lectures and letters, together with a short biography.

The scientific world is indeed indebted to all those who made this great publishing venture possible: the scientific editor, Sir James Chadwick, the publishers, George Allen and Unwin, and Dr. Paul Rosbaud, who conceived the project. Generous grants from the Government of New Zealand, the National Research Council of Canada, and the Leverhulme Trust in Britain have greatly assisted publication. Here is a 'must' for every library, and a 'should' for many individuals.

P. M. S. BLACKETT

PHYSICAL METALLURGY IN THE SEMICONDUCTOR FIELD

Metallurgy of Elemental and Compound Semiconductors

Proceedings of a Technical Conference, Boston, Massachusetts, August 29–31, 1960. Edited by Ralph O. Grubel. (Metallurgical Society Conferences, Vol. 12.) Pp. xi + 494. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1961.) 13 dollars; 98*s*.

THE fly-leaf of this book identifies the sponsors of the conference, of which it reports the proceedings, as the Semiconductors Committee of the Institute of Metals Division, the Metallurgical Society, and the Boston Section, American Institute of Mining, Metallurgical and Petroleum Engineers. It is a pleasant change to review a book dealing with the metallurgy of semiconductors, as distinct from the solid-state physics approach, although the fundamental background is reviewed in each section in such a way that no physicist would quarrel with it.

The main aspects reviewed are the heavily doped materials for Esaki tunnel diodes, and new techniques of crystal growth. In the latter case, dendritic growth and vapour phase deposition are specifically considered. Part I deals with germanium and silicon for tunnel diodes, with detail of the properties resulting from heavy doping. Patel *et al.* show that the growth of germanium single crystals from the melt can be achieved with a high degree of crystal perfection by using a high concentration of gallium (3×10^{20}/cm.^{3}). The velocity of dislocation movement under shear stress has been measured to assess the effect of thermal stresses or constraint on the crystal perfection. Arsenic doping of germanium decreases the maximum stress for a given dislocation velocity, while gallium doping raises the stress, both compared with the intrinsic crystal. Interesting results on vapour phase deposition of arsenic and phosphorus on silicon are given in a paper from the General Electric Laboratory. Heavily doped layers, pyramids and rods have been made to grow epitaxially on single crystal substrates, or other nucleation sites.

Part 2 is concerned with dendritic growth, with two excellent chapters on fundamentals of such growth. The problem of solute segregation is covered by two further chapters and a final one with the role of surface tension in crystal pulling. Some beautiful pictures of crystal facets and dendrites are presented in this section, and all these papers could be read with advantage by metallurgists concerned with solidification problems.

The third part of this book deals with vapour phase deposition. For silicon, the breakdown of the tetra-iodide, or the disproportionation of the di-iodide can be used, with the addition of impurity elements via their tri-iodides (indium, gallium, aluminium, boron, phosphorus, arsenic and antimony). Several methods are described for the preparation of p–n junctions with controlled impurity concentrations. Similar work is described on germanium, utilizing disproportionation of the di-iodide. Impurities are more difficult to transfer by this method on germanium, but phosphorus, arsenic and antimony are easily transferred. Growth considerations of germanium crystals prepared from the iodide are also covered.

Part 4 deals with compound growth and solubility considerations. This field refers to the more refractory semiconductor materials, which are becoming more important. One method is to grow the compound crystals directly, another to prepare alloys, and a third to utilize solutions of compounds in Group III metals. Germanium–phosphorus, aluminium–arsenic and alloys of germanium–arsenic with aluminium–arsenic are described. The addition of zinc to alloys of gallium–phosphide in silicon is dealt with in one chapter, with interesting structural considerations to explain the properties.

Some consideration was given to other semiconductor materials at the conference, including thermo-electric materials suitable for direct conversion of heat from nuclear reactors. The latter include lead and bismuth telluride, and zinc–antimonide. A final part covers the measurement of Hall effect on tunnel diodide materials and X-ray investigations on the perfection of silicon crystals.

Considering the wealth of information presented in this book and its excellent reproduction of diagrams and photographs, the price is not unreasonable. The title may mislead many who would benefit by reading it, for here is a perfect example of modern physical metallurgy applied to a most fascinating and rapidly expanding field. It deserves to be available in every metallurgical library, not merely those concerned with semiconductor research and development.

C. R. TOTTLE

PLUTONIUM

The Metal Plutonium

Edited by A. S. Coffinberry and W. N. Miner. Pp. xi+446. (Chicago and London: University of Chicago Press, 1961.) 10 dollars; 76*s*.

PLUTONIUM presents a unique combination of properties of scientific, technological and military significance. Since the first minute quantities were prepared in Chicago in 1943, immense efforts have been devoted to the production and fabrication of the metal and to the investigation of its properties and uses. Security requirements have delayed or prevented the general dissemination of this knowledge and experience, and the first comprehensive review of the work concerned was contained in the papers presented, by acknowledged authorities on the subject from the United States, Canada, France and the United Kingdom, at the World Metallurgical Congress in Chicago in 1957. Edited versions of those papers, with some additions covering important work published between 1957 and 1960, have been combined to produce this attractive and interesting book. One can only regret that it was not published immediately after the 1957 conference.

The papers have been grouped under three headings. Of those that constitute the historical review, the accounts of early work in the United States with milligramme quantities or less of the metal are particularly fascinating. Techniques and results included under the heading of plutonium metallurgy deal with radiography, autoradiography and velocity-of-sound measurements as well as physical properties, crystal structure, microstructure, corrosion and alloying behaviour. Conspicuous gaps in the available knowledge and understanding of the behaviour of this extraordinary element are evident from the text; for example, many phase diagrams are ill-defined or unknown, and there is no reference to diffusion coefficients for plutonium in any metal or alloy. The last part of the book is devoted to plutonium in nuclear reactors and presents a useful review of some of the possibilities and problems in the fabrication and use of plutonium, its alloys and compounds in power production.

As a starting point in the study of plutonium metallurgy no better book is available at the present time. For the serious student, the next step will be to read the papers presented at the plutonium conference in Grenoble in 1960. For the general metallurgical reader, parts of this book provide a stimulating indication of the ingenuity, patience and skill that have been devoted to the scientific investigation and safe industrial use of this highly toxic material.

V. W. ELDRED

CURRENT STATUS OF ATOMIC SPECTROSCOPY

Atomic Spectra

By Dr. H. G. Kuhn. Pp. xvi+436+18 plates. (London: Longmans, Green and Co., Ltd., 1962.) 60*s*. net.

ATOMIC spectra have played a large part in the development of modern physics, and the subject was studied most intensively in the 1930's. Interest in the more academic side has since waned because the nucleus has attracted more attention, and, as Condon and Shortley stated in their book *Theory of Atomic Spectra* in 1935, "the interpretation seems to be in a fairly close and highly satisfactory state". (Nevertheless, optical spectroscopy was high on the list of subjects in a recent survey of subjects studied by Ph.D. students.) Its use as a tool either in analytical spectrochemical applications or in the study of plasma physics has, moreover, increased remarkably in the past thirty years, with the recent development of lasers, depending on spectroscopic knowledge of crystals, extending the applied field further. Even for problems connected with nuclear physics the study of hyperfine structure is a powerful means of deriving information on nuclear constants.

In the meantime, steady, although less spectacular, progress has been made in the interpretation of atomic spectra, and Dr. Kuhn's book attempts to present this for the more advanced undergraduate and research worker. As can be seen from the contents list, a wide range is covered. After a short introduction to the subject there appears a theoretical section which surveys the interpretation of spectra in terms of classical and quantum mechanics and the old quantum theory. The various types (and their interrelationship) of spectra from elements throughout the Periodic Table are discussed, ranging from the simple hydrogen atoms to the lanthanide and actinide series. X-ray spectra and calculation of electron structures are treated briefly, while hyperfine structure and isotope shifts are thoroughly discussed. The book ends with a chapter on the width and shape of spectral lines. Tables of intensity ratios in multiplets and information concerning the ground state and ionization of elements and nuclear moments of natural isotopes are included.

The book steers a middle course between the formal treatment given in Condon and Shortley's book and the more experimental approach of White's *Introduction to Atomic Spectra*. In so doing, it gains by the omission of the early historical material which is considered in the latter book and which can often be confusing to the undergraduate reader. It is well produced with clear type and very few misprints which in any event do not give rise to confusion, for example, the misplaced minus sign in the expression $d^{k-2}\,s^{2}$ on page 318. More diagrams would probably encourage the undergraduate.

One reader, at least, is left with the impression both of how many advances have been made in the understanding of spectra and how much more remains to be done on the experimental and theoretical side, particularly in the complex spectra from the lanthanide and actinide elements and which accordingly are only briefly discussed in the book. With the advances in such equipment as high-quality gratings and computers and the powerful techniques based on group theory, one can hope that the graduate reader of this book will have the sound basis to tackle the many unsolved problems in the field. At the undergraduate level, it gives a good summary of the academic side of the subject.

L. Bovey

MALAYAN ORCHID HYBRIDS

Malayan Orchid Hybrids

First Supplement. By G. H. Addison. Pp. viii + 93. (Singapore : Government Printer, 1961.) 21 Malayan dollars.

WITH the steady increase in the production of new orchid hybrids and the continual introduction of fresh species into general breeding it is inevitable that any book providing a comprehensive account of the hybrids cultivated in any given area will soon be out of date. This was recognized by the authors of *Malayan Orchid Hybrids* when they published the book in 1956, and the present work is a first supplement to their previous account, designed to bring our knowledge in this field up to date so far as is possible. This supplement includes illustrations and descriptions of about 90 hybrids additional to the 160 dealt with in the original work. Each hybrid is illustrated by two half-tone photographs showing respectively the general appearance of the inflorescence and a single flower, these being accompanied by a short description and details of the hybrid's origin. Some of the hybrids are illustrated in colour. On the whole the photographs reach a satisfactory, though in my own opinion not such a high, standard as in the original work.

The hybrids figured mostly fall into two groups, the genus *Dendrobium* on one hand, and hybrids produced from various genera belonging to the monopodial *Vandinae*, such as *Vanda*, *Arachnis* and *Euanthe*, on the other. The *Dendrobium* hybrids once again are mostly combinations of species belonging to the two sections *Ceratobium* and *Phalaenanthe*, but with the introduction into the breeding system of further species of both sections a wider range of forms is being produced. Nevertheless, there still seems to be much scope for the improvement of the individual flowers so as to give greater body to the inflorescences without impairing their gracefulness. It would also be interesting to see if some at least of the striking species belonging to such other sections as *Laourea* could be utilized for breeding. Among the monopodial hybrids those in which *Phalaenopsis denevei* is one parent are of special interest botanically, though their short inflorescences are, of course, a disadvantage for cut-flower purposes. Another interesting feature in these monopodial hybrids is the persistent dominance or strong influence of certain floral characters wherever they occur in combinations, such as the flower shapes and colorations in the genera *Arachnis* and *Euanthe*.

Mr. Addison, who is responsible for the preparation of this first supplement, is to be congratulated on such a useful continuation to the original book. Those concerned with orchids everywhere will look forward with interest to the appearance of further supplements in due course.

V. S. Summerhayes

THE CONTROL OF INSECT VECTORS

Insect Control in Public Health

By C. B. Symes, R. C. Muirhead Thompson and J. R. Busvine. Pp. vii + 227. (Amsterdam: Elsevier Publishing Company, 1962.) 60*s*.

BEFORE the discovery of the synthetic insecticides, of which DDT was the first, it was only practicable to control insect vectors of disease very locally, mostly in urban areas. The high toxicity of the new compounds, their relative cheapness, and the long period over which some of them may remain effective as thin residual films has allowed their use in situations in which control was previously impossible. A large number of striking successes has been obtained.

The volume under review is a compendium of the latest information on the chemical methods of controlling all the more important insect vectors of human diseases. The information is detailed and practical and deals with such topics as the constitution and properties of the chief insecticides, the different formulations in which they can be used, the methods of applying them, the dangers to persons using them, and the organization of a campaign for the control of insect vectors. Eleven chapters deal with special features of the principal types of insect-transmitted disease, such as malaria, plague, yellow fever and sleeping sickness. The text is extremely clear and well written so that it will be suitable for all those concerned in controlling insects, even workers with very little specialized training. There are nineteen illustrations, mostly based on excellent photographs. At the end is a short list of selected references, arranged according to the various topics which have been discussed in the text.

The book is very well produced, and the authors state that it is intended to replace a small hand-book of malaria control which the Shell Company produced in 1940. The publishers of the present volume also acknowledge that the Shell International Chemical Company made its publication possible. It is perhaps natural that with this sponsorship the emphasis should be almost entirely on the chemical methods of control.

The information about the insects themselves is very scanty. There is a short but admirable chapter on the development in one species or another of resistance to most of the insecticides. This is now such a menacing development that there is a strong case for devoting more attention to the ecology of the insect vectors and reconsidering the possibilities of some of the older methods of control. It might have been difficult to do this in such a short, concise volume, and what they set out to do the authors have done very successfully. O. W. Richards

FLESH FOOD AVOIDANCES IN THE OLD WORLD

Eat Not this Flesh

Food Avoidances in the Old World. By Prof. Frederick J. Simoons. Pp. xiii + 241. (Madison, Wisc.: University of Wisconsin Press, 1961.) 6 dollars.

This book is the work of a cultural geographer. While travelling across Africa from Ethiopia to Nigeria some years ago, the author noted that there were large areas where a particular flesh food was used and others where the same food was avoided with strong feelings. Following up the interest thus aroused, he examined the cultural and religious prejudices involved in the use of pork, beef and the flesh of horses, camels and dogs. (Curiously, the use of neither goat flesh nor mutton is discussed.) The author exposes the inadequacy of a common assumption that food avoidances are based on rational considerations—he rejects, for example, the thesis that the ancient Jews abstained from pork on hygienic grounds. He points out how in some instances, as abstention by Europeans from the flesh of dogs and cats, there is incompatibility between associating with these animals as domestic pets and treatment of them as a source of food. He lays great stress on the significance of religious belief as an element in food avoidance, and points to the way in which the prophet or other founder of a religion may play a critical part in promoting this. He also indicates how some food avoidances are correlated with the desire of a social group to improve its status relative to others—a process seen in modern India as some caste groups tend to follow the Brahmanical custom of not eating meat.

The general treatment of the book is itemistic, with instances given from a very wide geographical range, without much indication of the social and economic context in which the use or avoidance of the food occurs. Five maps showing the distribution of certain flesh foods are informative, but other maps showing the location of social groups are much less so. About half the book is taken up with maps, notes, bibliography and index.

The study is useful as a general source of information, and stimulates thought about economic and social effects of the great variation in choice of flesh food. The author is less successful in advancing reasons for these food avoidances than he is in describing them. For example, his hypothesis that prejudice against the pig and pork arose as the reaction of Asian pastoralists against an animal alien to their way of life and was then diffused to the sedentary peoples with whom they had contact is not very convincing. But for this he can scarcely be criticized, because of the general lack of historical information about the origins of such customs.

What the book does bring out is the need for more specific analytical studies of food usages directly related in a systematic way to economic, social and ritual considerations in particular communities.

Raymond Firth

DICTIONARY FOR TEXTILE COLOUR CHEMISTS AND PRINTERS

Dictionary of Dyeing and Textile Printing

By H. Blackshaw and R. Brightman. Pp. iv + 221. (London: George Newnes and Co., Ltd., 1961.) 30s. net.

The authors of this little dictionary have spent many years in dyeing and textile printing and so are well qualified for their task. They provide nearly 1,500 definitions relating to dyeing, printing and finishing processes and machines, as well as to the chemicals and auxiliary products used. Other subjects covered are textile fibres, colour terminology, chromophoric systems, natural colouring matters, and fastness testing.

Rather more than 100 of the definitions given are those produced—after much debate—by the Terms and Definitions Committee of the Society of Dyers and Colourists, and these definitions are acknowledged and indicated in the text. Apart from items concerning the Society of Dyers and Colourists, the present dictionary does not overlap to any great extent with the Textile Institute's publication, *Textile Terms and Definitions*, from which the authors have borrowed in a few cases. Sometimes they have preferred to give a fuller definition rather than the very concise official version. It is easy to think of a few more terms that they might have defined, but difficult to think of many.

The authors are very reliable when dealing with their own field, but outside this field they frequently go astray. For example, distillation is confused with fractional distillation, and chelation with intramolecular hydrogen bonding. Proof reading has been adequate, except with empirical and structural formulæ and with equations. It is to be hoped that consultation and careful checking will precede publication of the second edition.

The text is illustrated with thirteen useful diagrams of machines—with the exception of the final one (Fig. 13), which is an unlucky choice. There is, in addition, a "reading list", as well as a useful appendix consisting of an alphabetical index of the more important man-made fibres, although such lists become out of date very quickly.

In view of the slow progress invariably made by committees concerned with terminology, the authors are to be congratulated on their enterprise. Their little dictionary is likely to become popular among those concerned with dyeing and textile printing, very few of whom can be familiar with all the terms defined. C. L. Bird

Advances in Enzymology and Related Subjects of Biochemistry

Vol. 23. Edited by F. F. Nord. Pp. v + 557. (New York: Interscience Publishers, Inc.; London: Interscience Publishers, Ltd., 1961.) 15.50 dollars.

THIS volume of *Advances in Enzymology* contains nine articles covering a useful range of biochemical topics, but unfortunately some are of very poor quality.

Three contributions deal with particular enzymes: "Pancreatic Lipase" by Desnuelle, "Collagenases and Elastases" by Mandl and "Cytochromes of Group A and Their Prosthetic Groups" by Lemberg, all of which are very thorough surveys of their subject, the last-mentioned being particularly concerned with the chemistry of the active site. An interesting feature of the articles by Desnuelle and Mandl is the emphasis given to applications of enzymes particularly as analytical tools. This feature of enzymology is further developed in the stimulating paper "Denaturation and Inactivation of Enzyme Proteins" by Okunuki, which describes the use of proteinases for investigating changes in the secondary and tertiary structure of proteins.

There are two excellent articles on enzymes in metabolic systems, "The Metabolism of 2-Carbon Compounds by Micro-organisms" by Kornberg and Elsden and "Mechanisms of Synthesis of Adenosine Triphosphate" by Racker. The latter is an important review containing a serious attempt to correlate the conflicting findings by different groups on oxidative phosphorylation in mitochondria. The last article in the volume is a short but very topical one on the "Discovery and Chemistry of Mevalonic Acid" by Wagner and Folkers.

Of the two articles not so far mentioned, one deals with the possibility that the configuration of a peptide link may be determined by the side chains of its constituent amino-acid residues. The other attempts to explain periodic steps found in progress curves of enzyme reactions by the assumption that all the enzyme molecules are acting synchronously, this idea being derived by ignoring the statistical concept of thermodynamic equilibrium.

M. J. SELWYN

Introduction to Advanced Inorganic Chemistry

By Dr. Philip John Durrant and Beryl Durrant. Pp. xv + 1,171. (London: Longmans, Green and Co., Ltd., 1962.) 95*s*. net.

THIS book attempts to provide a comprehensive survey of inorganic chemistry based "on the concepts of theoretical chemistry which have been developed in the last twenty years". Approximately a third of the book deals with the physical aspects of inorganic chemistry such as wave mechanics, spectra and X-ray diffraction, and the remainder to descriptive inorganic chemistry. This type of treatment, in a one-volume book, although more than 1,000 pages in length, almost inevitably falls into the error of presenting a little of a lot of large topics. This fault could have been partially remedied for the student and research worker by including references to original literature. In fact very few references are included, and only at the ends of certain chapters are recommendations for further reading given.

The physical-inorganic section gives a lucid and useful presentation of many modern techniques, but also it has some surprising omissions; for example, in the section on spectra, little is mentioned about the spectra of transition metals. Also there is no adequate treatment of possible reaction mechanisms in inorganic chemistry. The descriptive section of the book is traditional in its presentation. It gives an adequate description of most of the properties of the elements with, however, one surprising omission. There is no detailed treatment of the complexes of the transition metals. The reason for this is given as lack of room (p. 988). Since so much of the solution chemistry of the transition metals depends on the nature of their complexes, this omission is a definite weakness in the book. There is a tendency in this section to be rather non-critical, and statements like "liquid hydrogen fluoride is a better solvent than water" require some justification. A number of chemical errors, such as in the preparation of sodium paratungstate, appear in the text, although this is probably inevitable in a book of this type.

All in all, this book presents in one volume much useful information, but it cannot be regarded as a 'must' for the inorganic chemist.

D. H. BROWN

The Birds of British Somaliland and the Gulf of Aden

Their Life Histories, Breeding Habits, and Eggs. By Sir Geoffrey Archer and Eva M. Godman. Vol. 3: Pp. lxviii + 627–1042 + plates 21–27. Vol. 4: Pp. vii + 1043–1570 + plates 28–34. (Edinburgh and London: Oliver and Boyd, Ltd., 1961.) 189*s*. net the set of two volumes.

THE first two volumes appeared in 1937 and are now out of print; the second half of the work will therefore appeal mainly to the veterans and librarians who are enabled to complete their sets. The volumes are very handsomely produced, although orthographical errors are rather numerous. Twelve of the colour plates are from originals made many years ago by Archibald Thorburn and are of interest in being apparently the only examples of that well-known artist's work in which he depicted exotic birds. Sir Geoffrey Archer was governor of what was then British Somaliland from 1912 until 1922, and later held similar office in Uganda and the Sudan; his field observations, together with his collection of some 3,500 skins and more than 1,000 clutches of eggs, form the basis of the work as a whole. To Miss Godman, bearer of a famous name in ornithology, has fallen the museum side of the study and the task of putting the material into the shape of a systematic text-book.

The authors have naturally been embarrassed by the changes in taxonomic thought between their two dates of publication; this has to be borne in mind in placing the book in the general pattern of present-day literature on the birds of Africa. They also appear to have been handicapped by a plan of treatment, set in the earlier days, that involves giving much space to extralimital information readily available elsewhere; thus there are descriptions of the breeding habits in Europe of species known only as migrants in Somaliland. The main value of the book lies in the first-hand accounts of habits, as observed in an ornithologically very interesting area in which relatively few others have had the opportunity of doing extensive field work. This is true alike of species that are well known in Europe in very different circumstances, and of those that are native to the Horn of Africa.

LANDSBOROUGH THOMSON

SCIENCE, TECHNOLOGY AND CIVILIZATION*

By PROF. R. V. JONES, C.B., C.B.E.

Department of Natural Philosophy, University of Aberdeen

THE rise of science and technology is a unique element of our civilization. In earlier times, technology played a relatively small part, and science almost none; and it is worth briefly looking at the two ancient civilizations, those of Greece and China, in which science might have been most expected to flourish.

In Greece, the early philosophers valued the sobering contact of everyday life; and they regarded manual skill as a virtue. The later philosophers developed the conceit that they could think out the whole structure of the natural world from a few axioms; and recourse to experiment was in their view undignified and a sign of intellectual inferiority. This error, perpetuated in our classical education, crippled Greek science.

In techniques, China was far above Greece. Chinese inventions included printing, paper, porcelain, gunpowder, the rocket and the compass; and yet science failed to develop. The explanation may again lie in the surpassing value that the Chinese set on the mind. Scholars were recognized as the top class of the Chinese hierarchy, followed in order by farmers, artisans and traders. The Chinese State was run by civil servants recruited, as in Britain to-day, from the brightest scholars. These could ably govern any situation that they could imagine; but their imagination was never fired by the new experience gained from experiment. The traders or the soldiers might have seen the value of a scientific approach to technology but, if they did, they were not heeded by the scholars. Thus, the two ancient civilizations in which science might have been most expected to flower, because of the value they placed on pure thought, became instead—for this very reason—academic mausoleums.

The heritage of Greece, so prized in Western Europe, almost stifled the development of science here. It would be valuable, incidentally, to know the cause of the emancipation of scientific thought, for in it may lie Europe's claim to a fair share of the world's natural resources. These resources are now being taken over by men who by accident live over them at the present day, and who did nothing either to discover their uses or the ways of winning them. This raises a complex problem of many aspects, which may ultimately be a subject of world argument; but, whatever the reason, the scientific and technical revolution did start in Europe, and in this respect the rest of the world is in its debt.

While the cause is not entirely clear, we can trace one or two steps in the emancipation of science from the arid methods of the medieval school-men, who had said: "If a physical theory is inconsistent with received metaphysical teaching, it cannot be admitted, because metaphysics is the supreme science, not physics"; no progress could be made while such doctrines prevailed. The philosophical break was made by William of Ockham, and the scientific break completed by Gilbert and Galileo.

The philosopher of the scientific revolution was Francis Bacon, who, about 1600, pointed out with comprehensive clarity the advance in knowledge to be gained by adopting scientific method. He valued this knowledge both for its own sake, and for the benefits that would come from its application. Recently we have heard of the "euphoria of gadgets", but Bacon made the valid point that without a "gadget"—the mariner's compass—Columbus might not have discovered America. Macaulay summarized Bacon's contribution: "It was not by furnishing philosophers with rules for performing the inductive process well, but by furnishing them with a motive for performing it well, that he conferred so vast a benefit on society".

Bacon's brilliant advice went almost unheeded for two centuries. In the meantime, science and technology advanced largely through mutual interaction, and thanks solely to a few individuals. Von Guericke's pumps led to Boyle's study of gases. Charles, famous for his gas law, had a vital practical interest in gases—he was in 1783 one of the crew of two on the first hydrogen balloon flight. Gay Lussac had a similar interest—for many years he held the altitude record with a balloon ascent to 23,000 ft. To these men a knowledge of gas behaviour was a technological necessity and a scientific challenge. In this stream we can trace the development of the kinetic theory by Joule—a brewer—its refinement by Maxwell and Boltzmann, and its application back to technology by Langmuir in the high-vacuum pump.

This interaction of science and technology made Britain a great power even after its politicians had lost America. The man who contributed particularly to its recovery was James Watt, at one time instrument maker to the University of Glasgow. Watt there formed, incidentally, a friendship with Joseph Black, afterwards professor of chemistry at Edinburgh, who originated the concepts of specific and latent heats, as a result of being asked by the whisky distillers why they needed much more coal to evaporate the contents of a still than they did to bring these contents to the boil. Watt's engines consummated the Industrial Revolution; and this Revolution, more than anything else, revived Britain after the loss of America.

With no support from the classically educated Government, and in spite of its mistakes, the engineers and scientists built up Britain's industrial pre-eminence to the peak of the 1851 Exhibition, where British firms won nearly all the premier awards. There were even signs that technological education might be taken seriously, although Britain was already lagging behind the Continent. Anderson, professor of natural philosophy in the University of Glasgow, founded in 1798 what is now the Royal

---

* Substance of the Brunel Lecture delivered at the Brunel College of Technology on February 14.

College of Science and Technology. The London Mechanics' Institute was founded in 1823 by Birkbeck, who had come to London from Anderson's institute in Glasgow, and by 1850 there were more than six hundred mechanics' institutes in England and Wales with more than a hundred thousand members. Spencer and Ruskin were pressing the merits of science in education; but prospects for science in the schools were dimmed in 1859 by the scandalized reaction of clerical headmasters to Darwin's *Origin of Species*. Moreover, the scientists could not agree among themselves about which sciences should be taught in the schools, and their opponents exploited their differences.

Prince Albert wanted to start a technical university, and he arranged to buy a site in South Kensington with proceeds from the 1851 Exhibition. Unfortunately, with his death in 1861 the prospect for a technical university receded: and there was little drive for science and technology in the existing universities, where Cardinal Newman's "Idea of a University" of 1873 perpetuated the régime so profoundly criticized by Bacon.

At the Paris Exhibition of 1867, however, British complacency—both academic and managerial—was shocked. Lyon Playfair, professor of chemistry at Edinburgh, who had been a judge at the 1851 Exhibition and who was again a judge in Paris, wrote in *The Times* of May 15, 1867:

"With very few exceptions, a singular accordance of opinion prevailed that our country had shown little inventiveness and made little progress in the peaceful arts of industry since 1862. Deficient representation in some of the industries might have accounted for this judgment against us, but when we find that out of 90 classes there are scarcely a dozen in which pre-eminence is unhesitatingly awarded to us, this plea must be abandoned. . . . So far as I could gather them by conversation, the one cause upon which there was most unanimity of conviction is that France, Prussia, Austria, Belgium, and Switzerland possess good systems of industrial education for the masters and managers of factories and workshops, and that England possesses none. A second cause was also generally, though not so universally, admitted, that we had suffered from the want of cordiality between the employers of labour and workmen, engendered by the numerous strikes, and more particularly by that rule of many Trades Unions, that men shall work upon an average ability, without giving free scope to the skill and ability which they may individually possess."

Playfair had pointed out the dangers of British complacency as early as 1852, and over the next forty years he attacked especially the sterility of the classical basis of education, saying, for example:

"Our Latin and Greek education still goes on, though, for its practical uses, it is as much a survival as the two buttons behind our coats. . . . New professions are arising around, but for these our old Universities make no provisions; and old professions have completely changed their aspects, yet the schools and colleges remain as of old. Perhaps the most robust men of our time have been our engineers and mechanicians, for they have given more impulse to civilisation than any other class of men. But I look in vain for a single representative man among our Telfords, Watts, Stephensons, Arkwrights, Wedgwoods, whose intellect was nurtured on ancient classical learning, or who could find anything in school life to aid the development of their genius."

Incidentally, in the same context (*Universities in their Relation to Professional Education*, 1873), there occurs:

"You must not judge of other Universities by Oxford and Cambridge for they are exceptional. The old English Universities have not the same function as the Scotch and Irish Universities. The former teach men how to spend a thousand a year, while the latter aim at showing men how to make a thousand a year."

Academics have tended to be patronizing towards soldiers, but there was one officer who saw far more clearly than did the common rooms of Oxford and Cambridge and the lobbies of the Houses of Parliament what was needed. He was Colonel Alexander Strange of the Royal Engineers, who in a lecture to the Royal United Services Institution in 1871 said:

"The duty of the government with respect to science is one of the questions of the day. No question of equal importance has, perhaps, been more carelessly considered and more heedlessly postponed than this. And, now that a hearing has been obtained for it, neither the governing class nor the masses are qualified to discuss it intelligently; . . . But there is one part so important that I feel called on to name it—I mean the appointment of a Minister of Science. He need not necessarily be exclusively devoted to science; he might perhaps, with advantage, have charge of education and fine arts also; but someone in Parliament, directly representing the scientific branches of the national services, has become absolutely indispensable. Another urgent want which, as its scientific character is not purely physical, will probably not be dealt with by the Royal Commission on Science, is that of a high war council—a council of naval and military officers of the greatest professional attainments and distinction, constituted for the purpose of advising the government on the highest problems of strategical science. At present we have not a vestige of anything of the kind, and are consequently, as a military nation, almost destitute of the basis of the military art.

"When we have all scientific national institutions under one Minister of State, advised by a permanent independent, and highly qualified consultative body; when we have a similar body to advise the Ministers of War and Marine in strategical science, then the fact that, in accordance with our marvellous constitution, these ministers must almost necessarily be men without pretension to a knowledge of the affairs which they administer need cause us no alarm. When these combinations have been, as they assuredly will be, sooner or later, effected, the wealth, resources, and intelligence of the nation, having due scope, will render us unapproachable in the arts of peace, and unconquerable in war, but not till then."

What Strange said about the Government is still true. What he advocated regarding the Minister of Science and the two committees (anticipating the Advisory Council on Scientific Policy and the Defence Research Policy Committee) has only recently come to pass. Indeed, if we distinguish between a Minister of Science and a Minister for Science, we have not yet gone as far as he wished. In intense admiration for his wide insight, we can only wonder that it was all but lost on so many of his unenlightened countrymen.

Now, what came of all this ? Playfair and Strange carried the British Association for the Advancement of Science and the Society of Arts (the record of which in the matter was admirable) with them, forcing a Royal Commission on Scientific Instruction in 1871 and another on Technical Instruction in 1881. The City and Guilds College was inaugurated in 1878. The Central Technical College, now Imperial College, was opened in 1884. Many technical colleges were started, along with several university colleges having some technological bias.

The movement thus had some substantial results; yet they fell far short of what the originators intended, and what was really required. Manufacturers failed to see that the best hope of improving their products and widening their range lay in educating suitable technologists. Headmasters influenced their pupils away not only from technology but also from science, maintaining that "the proper study of mankind is man", and failing to appreciate the force of a later couplet in the same Essay, "Slave to no sect, who takes no private road, But looks through Nature up to Nature's God". Thus there was no supply of students coming up from the schools for higher education in science and technology; and, indeed, if students had been forthcoming in any numbers, they would have found few employers at the end of their courses.

In such a situation, where no section of the community sees the need to act, there exists the unique opportunity for prescient government. But unfortunately, as Playfair and Strange—and after them many others such as Tizard and Lindemann—pointed out, the members of the Government were themselves products of classical education, and were both blind and deaf to what might be achieved, and what ought to be done. So, even after Playfair went into politics and became chairman of the House of Commons and deputy speaker, the lead from the Government never came.

In what respects is the situation of Britain different to-day ? It has lost its easy markets and its cheap supplies of raw materials. Moreover, it has been overtaken notably by the United States and by the U.S.S.R., where Lenin was fired with an appreciation of what technology could do. "Communism", he said, "is a Soviet government plus electrification"; and the huge electrical and educational programmes in the U.S.S.R. were a direct result.

Finally, British survival in 1940 had depended on an exhilarating partnership between the Royal Air Force and some scientists and engineers, in a way that no post-war Government could ignore. This was followed by the challenge of nuclear energy. Plans were made to expand the numbers of graduates in science and technology. Even then the professional humanists succeeded in maintaining their hold in the universities in 1945 by arguing that the non-science departments should be expanded to the same extent, not for such a fundamental reason as that more non-science graduates would be required, but for the sanctimony of "preserving the balance of the Universities".

At last, there are signs that this prejudice is beginning to disappear; but it is still strong. Until recently, Latin lingered as compulsory for entrance to Oxford; it was this together with Greek that kept Sir Winston Churchill out ("I could not contemplate toiling at Greek irregular verbs after having commanded British regular troops"), and after his example can it be maintained that a knowledge of Latin is essential to the writing of good English ? Nevertheless, there is still a compulsory examination in Latin for entrance to the public schools in Great Britain, and optional papers in Greek and in Latin verse; but there is no paper on even elementary science.

The only fundamental differences from the position of 1880 are the facts that the powers bestowed by science and technology have been forcefully demonstrated, and that the economic position of Britain is much weaker. But for these facts, the advocates of science in education might have been as much ignored in the past decade as were Playfair and Strange a century ago.

Assuming that science now wins its proper place in education, it must not in the process suffocate what is valuable in the humane studies in the way that the humanists tried to strangle science and technology. By themselves, science and technology are not enough, and all men need to pay attention to the humanities. All that men of science ask is that never again should the humanists be allowed to warp the education of the whole man by denying him some of his most exciting intellectual activities and from realizing the wider range of his ability by co-ordinating his physical senses with his mind: and if at some future stage some other branch of learning should become of more urgency than a particular science or a particular technology, or than science and technology altogether, scientists and technologists should not seek to cramp it by their vested interests as the so-called humanists for so long did with science.

If science and technology now jointly receive due weight in education and civilization, men of science and technologists should take care not to perpetuate within their own field the prejudice against which for so long they have fought the external battle. It could happen that the pure scientist, and especially the theorist, might assume the mantle of the classical scholar—he is the one whose activity most closely approaches that of the pure intellect. The greatest theorists have been keenly appreciative of the details of practical experimentation. But there are less good theorists who may tend to look down on contact with experiment, and less good experimenters who may rate a moderate experiment above a superb piece of technology. Some British physicists have frowned on the larger machines of America—as though string and sealing wax were just admissible to assist the pure mind, but that resort to a large machine indicated intellectual failure. Happily, this point of view is disappearing: the elegance of experiment lies in achieving results with economy, and this sometimes involves using large machines because small ones are useless. The use of large machines or of elaborate techniques is, of course, not always justified. Sometimes it contributes merely to a sense of self-importance, and it is salutary to remember Rutherford's "We haven't the money, so we've got to think".

The debt of technology is so obvious that it requires no elaboration; but, apart from the deliberate stimulus to technology from pure science, there are many accidental benefits that are impossible to foresee. Röntgen's researches, for example, on electric discharges in gases would not have received support from a medically minded benefactor in 1895, and yet the X-rays that Röntgen discovered were within a few months profoundly influencing medical technology.

But pure science has its own debt to technology; the example of the kinetic theory has already been mentioned, and there are many others. Louis de Broglie described this debt:

"Every important step forward made by Astronomy, Physics, Chemistry or Biology had one essential condition—the previous existence or invention of certain apparatus; and as the sciences sought to extend their advance, so it became necessary for instrumental technique to develop and to expand in its delicate adjustments. . . . Left to itself, theoretical Science would always tend to rest on its laurels; but experiment, by becoming continually more exact and delicate, has shown us more clearly each day that 'there are more things in heaven and earth than are dreamt of in your philosophy'. By pointing to the infinite complexity of Reality, experiment has broken the circle within which speculative thought might easily risk confining itself, if left to its own devices. And since experiments depend on the perfection of experimental technique, the machine to-day is in a sense one of the essentials of intellectual process" (address to the Lycée Pasteur, July 13, 1932).

Examples of de Broglie's thesis continue to occur. The discoveries of cosmic rays and of radio emissions from stars originated in technology.

It is impossible to draw a clear distinction between pure science and technology; they not only interact, but they also overlap. Playfair saw a happy analogy in an anecdote concerning Faraday:

"Faraday's first experiment, made as a newsboy while waiting outside for a paper, was to put his head through a railing and then speculate on which side he was! Here we see the philosopher acknowledging the head as of preponderating importance, though it was incapable of being disassociated from the body. He got a practical proof of the fact, that both ought to be in good connexion; for, while he speculated, the door opened and he received a severe wrench. Faraday never afterwards disassociated his manipulative skill, great as it was, from his wise head and warm heart" (*On Primary and Technical Education*, 1870).

And in this connexion, it may be worth quoting some words of Lord Cherwell:

"The word 'technician' is used to mean a man who has been trained to carry out established techniques which may be complex, and require a high degree of skill, or to work in a prescribed field under instruction; whereas by a 'technologist' is meant a man who, as a result of broadly based studies and wide practical experience, has acquired a real understanding of scientific principles and can apply them to the development of industrial processes in diverse fields. It may sometimes be difficult to draw a sharp line of demarcation between the technician on one hand and the scientist or the technologist on the other, and nobody would like to see any barrier set up that might discourage the scientifically minded technician from becoming a scientist or technologist" (*Messel Lecture*, 1954).

Scientists and technologists and technicians should see themselves as bound together in a common effort to increase man's understanding of the natural world, and to further his constructive achievements.

Although I have recalled the sorry record of Britain in technological education, it is important to distinguish between the defects of the classical educationists and the merits of the humanities and the arts. In our enthusiasm for science and technology, let us not forget to develop our other interests. If there is a gap between the 'two cultures' it must be bridged; and it can best be bridged by men of science who are versed also in the humanities. The humanist who has not studied science in his youth has little hope of bridging the gap.

If this discussion has tended to take a national point of view, it is largely because most of us have to act inside the framework of the nation: and we must remember that despite the technological superiority of Germany, to which Playfair and Strange rightly directed so much attention, and the achievements of modern U.S.S.R., the British record in treatment of the individual is much better, thanks perhaps in some small part to a lack of obsession with science and technology.

Finally, neither science nor technology knows national frontiers; and in developing them we are sharing in a most exciting field of human endeavour—it is in the common basis of experience and of mutual respect between the scientists and technologists of one nation and of another that there lies one of the best hopes of international understanding.

TEST-TUBE FERTILIZATION IN A FLOWERING PLANT

By KUSUM KANTA, N. S. RANGA SWAMY and PROF. P. MAHESHWARI

Department of Botany, University of Delhi

IN animals artificial fertilization *in vitro* is easily accomplished with fishes and amphibians and recently some successful attempts have even been made with mammals including human beings[1]. However, in mammals the development of the embryo proceeds only up to a few-celled stage in culture. To our knowledge there has so far been no report of fertilization *in vitro* in any flowering plant.

With this aim in view a beginning was made in this laboratory by injecting pollen suspensions into ovaries. The technique involves: (*a*) determination of the time of anthesis, shedding of pollen, and pollination in Nature; (*b*) collection of pollen under reasonably aseptic conditions; and (*c*) insertion of pollen grains into the ovary. The experiments so far made on five species of poppies (*Argemone mexicana*, *A. ochroleuca*, *Eschscholtzia californica*, *Papaver rhoeas* and *P. somniferum*) have already been described[2–4]; but a brief summary may be given here.

In most cases a suspension of pollen was prepared in a solution of boric acid (100–200 p.p.m.) in sterile double-distilled water. After wiping the surface of the ovary with ethanol, two punctures were made on it (Fig. 1). With an all-glass 'insulin' syringe the pollen suspension was injected through one of the apertures until the ovarian cavity was full. The other hole served as an outlet for the air within. After the operation, the holes were sealed with petroleum jelly. Where suspensions proved less favourable, pollen grains were inserted direct into the ovary through a vertical incision made laterally.

Except for minor variations in the growth period all the five species responded similarly and normal fruits were produced (Figs. 1, 3, 4). The pollen grains germinated in the ovarian cavity (Fig. 2), and both endosperm and embryo were formed normally in the developing seeds (Fig. 5). The seeds were fully viable. On germination (Fig. 6) they produced plants which flowered and fruited just like those obtained from seeds in Nature.

It was our success with intra-ovarian pollination and fertilization which led us to wonder whether a simultaneous culturing of excised ovules (taken before pollination) and pollen grains, on the same nutrient medium, could result in fertilization and eventually the formation of mature seeds *in vitro*. Encouraging results have been obtained with the opium poppy, *Papaver somniferum* L.

Under Delhi conditions the anthers of the opium poppy start dehiscing 12–24 hr. before anthesis. Dehiscence of all the anthers of a flower is complete by 10 a.m. on the day of anthesis in the peak period (January–February) or by 8.30 a.m. in the wane period (March). Pollination is effected almost immediately, and the germination of pollen grains begins within 15 min. afterwards. In about 9 hr. the pollen tubes reach the ovary and 24 hr. after anthesis several of them can be seen entering the ovules.

In devising a suitable medium for culturing the ovules we had the benefit of the observations of Maheshwari and Lal of this laboratory, who had already successfully cultured the fertilized ovules of the opium poppy containing either a zygote or a 2-celled pro-embryo (excised 6 days after pollination) and reared them to maturity on Nitsch's agar nutrient medium[5]. The same medium was used by us for the culture of unpollinated ovules and also pollen grains.

Since the anthers begin dehiscing even in the bud, flower-buds were bagged 24 hr. before anthesis. The following day the buds were brought to the sterile inoculation chamber, and the dehiscing anthers collected in a Petri dish and exposed to ultra-violet light for about 0·5 hr. just before inoculation.

Fig. 13. Dissection of 5-day-old seed showing free nuclear endosperm and 4-celled pro-embryo. (× *c*. 220)

Fig. 14. Globular embryo dissected from 9-day-old seed. (× *c*. 515)

Figs. 15, 16. Older embryos from 15 and 22-day-old cultures. (Fig. 15, × *c*. 80; Fig. 16, × *c*. 70)

To obtain unpollinated ovules, the flower-buds were emasculated and bagged considerably in advance of shedding of pollen. The ovaries were gathered on the day of anthesis and dipped in ethanol. After allowing the superfluous alcohol to evaporate, they were flamed and then cut open by a sterile scalpel. The ovules were separated along with portions of the placentæ (1–1·5 cm. long × 0·5–0·75 cm. broad) and sown on the agar nutrient medium in test-tubes. With a sterile needle the pollen was scooped out of the anthers and dusted over the implanted ovules as well as the surface of the agar medium (Fig. 7). A few cultures were also made in Petri dishes to facilitate a direct observation under the stereoscopic microscope.

Nitsch's medium proved quite favourable for the germination of pollen as well as for the growth of pollen tubes. The pollen grains dusted over the ovules started germinating within 15 min. after inoculation while those lodged on the surface of the agar medium required 1 hr. or more. The pollen tubes grew rapidly and within 2 hr. the surface of the ovules was covered by an abundant growth of pollen tubes (Figs. 8, 9). In cultures containing bits of 2 or 3 adjacent placentæ (Fig. 10), the pollen tubes could be seen growing from one placenta to the other. A similar response had also been observed in our experiments on intra-ovarian pollination. Though the pollen grains germinated profusely, only a few of the ovules were fertilized *in vitro*. Presumably the ovules were still rather young and not quite receptive to the pollen tubes. Likewise, when intra-ovarian injections of pollen grains were made on the day of anthesis the seed set was lower than when pollen was injected 24 hr. later (cf. Figs. 3 and 4).

In further experiments the ovules were, therefore, excised 24 hr. after anthesis. A much larger number of ovules now remained healthy and grew in size, suggesting that they had been fertilized (Fig. 11; cf. with Fig. 10). That fertilization did occur *in vitro* was confirmed by dissections as well as microtome sections. During the first 4 days of culture the fertilized ovules enlarged, became turgid and opaque. In another 2 or 3 days they turned mealy white (Fig. 11), a feature natural to poppy ovules developing into normal seeds (see also Figs. 3 and 4). The other ovules shrank and finally collapsed. Sections of normally developing seeds from a 3-day-old culture showed a 2-celled pro-embryo (Fig. 12). Dissections of seeds from a 5-day-old culture revealed a healthy free nuclear endosperm and a 4-celled pro-embryo (Fig. 13), of a 9-day-old seed a globular pro-embryo (Fig. 14), of a 15-day-old seed a differentiated embryo (Fig. 15), and of a 22-day-old seed a fully formed normal dicotyledonous embryo (Fig. 16). In early stages, the rate of growth of the endosperm and embryo in test-tube seeds corresponded with that in the field controls[5] as well as with that in seeds obtained in intra-ovarian pollinations. Later, the growth in artificially fertilized ovules was quicker and better and even surpassed that in Nature[5].

Briefly then, 'pollination', germination of pollen, double fertilization, and the development of endosperm, embryo and seed all go through normally in test-tube cultures of pollen and ovules of the opium poppy. These results prompt us to conclude that with further refinements the technique of test-tube fertilization will prove useful to plant breeders, especially when the two parents are incompatible and the zone of incompatibility lies in the stigma, style or ovary.

ZOOGEOGRAPHY OF EASTERN AFRICA: AN OUTLINE BASED ON ANURAN DISTRIBUTION

By Dr. J. C. POYNTON

Department of Zoology, University of Natal, Pietermaritzburg

THAT the existence of an almost fully developed 'East African' association in northern Zululand should have been generally overlooked until very recently[1] is an indication of the rudimentary condition of zoogeographical studies in Africa. This condition is regrettable, not only because such work has its own inherent interest, but also because it appears to be a prerequisite for evolutionary studies on the nature and origin of the faunal complexes in Africa. Furthermore, an appreciation of the present general patterning of distribution and its causation gives a key to visualizing the overall patterning of distribution under different climatic régimes in the recent past, an insight which should be of value to studies in Quaternary palæontology.

A zoogeographical outline of the portion of Africa south of the Sahara and east of 30° E. is presented here in an attempt to give an overall picture of distribution in this area. This outline is based entirely on the distribution of the Anura, and its primary object is to invite comparisons from workers on the distribution of other groups. Despite the aquatic phase in the life-cycle of most of the Anura, this group shows an essentially terrestrial type of distribution, and as zoogeographical indicators, the Anura have some particular merits[2], not the least of which is the relatively insignificant extent to which human settlement and cultivation have affected their distribution. A zoogeographical account of an area based on the distribution of a single group obviously has its limitations, some of which are shown at the end of this article; but in the present state of knowledge, such inadequacies are inevitable.

Until recently, the only large-scale distributional survey of the Anura in eastern Africa was that of Loveridge[3]. On the basis of the herpetofauna, Loveridge divided East Africa into a number of "ecological life zones". The lists of the forms occurring in the different altitudinal zones are very interesting from a zoogeographical point of view. Species of *Hyperolius* were left out of account, but of the 24 anurans listed as occurring below 1,000 ft., all but

4 (17 per cent) are widely distributed; that is to say, have a range of more than 500 miles in at least one direction. On the other hand, of the 25 forms listed in the highest zone (5,000–12,000 ft.), 52 per cent are not widespread.

The East African lowlands appear to be almost entirely populated by forms that are widely distributed at least along the coastal belt. These forms also extend westwards to a greater or lesser extent up into the highlands, where they form a subtraction margin of the lowlands fauna. This subtraction margin becomes admixed with a variety of more localized upland forms, thereby giving the fauna of the highlands an essentially heterogeneous composition.

It would be an oversimplification to consider the fauna of the lowlands to be completely homogeneous: some altitudinal zonation is shown by a few very widespread forms (notably *Bufo carens* Smith, *Rana angolensis* Bocage). These forms do not occur below 1,000 ft. in the region of the equator, but they do occur below or near this altitude farther south within the tropical belt, and can thus be included in the tropical lowlands fauna. The composition of the lowlands fauna is sufficiently homogeneous to stand in marked contrast to the essentially heterogeneous nature of the fauna occurring in the higher areas. In these higher areas an impoverished fauna extending upwards from the warmer and climatically more equable lowlands becomes progressively replaced by a fauna composed of more restricted forms, which are evidently more adapted to local conditions, or may be unable to maintain themselves among the concentration of dominant forms in the lowlands.

Now this situation is exactly paralleled by the changes which occur to the south of the main tropical lowlands concentration on the east coast of South Africa[1]. North of Lake St. Lucia (28° S.), the amphibian fauna is composed almost entirely of widespread forms, since no less than 86 per cent of the total number of forms occur also in Tanganyika and Kenya. However, only 43 per cent occur to the south of Lake St. Lucia, and those forms which do pass southwards become joined by a 'South African' fauna composed of more restricted forms. South of Lake St. Lucia, therefore, the fauna changes from a homogeneous tropical assemblage to a heterogeneous assemblage.

The amphibian fauna of Nyasaland, lying between southern and East Africa, fits into this picture very well. This fauna has recently been investigated by Loveridge[4,5], and by me. A fully developed lowlands fauna enters the Zambesi–Shire basin, but subtraction commences as the land rises above about 1,200 ft. Here, characteristic lowland forms such as *Hylambates maculatus* Duméril, *Hyperolius argus* Peters and *H. pusillus* (Cope) disappear, and localized endemics make their appearance.

It has been pointed out[6] that in southern Africa the amphibian population is polarized into two main faunal groups, one tropical and the other temperate, and that between these there is an extensive area where the opposing subtraction margins overlap, and where an essentially intermediate or transitional fauna is developed. This tropical-transitional-temperate zonation in the south appears to be but a special case of the distribution of amphibians in eastern Africa as a whole. Because of there being a well-developed temperate fauna in South Africa, this zonation is here very clearly shown, particularly in Natal, where the highlands above 4,000 ft. carry a rich temperate fauna, while the fauna of the north-eastern coastal plain is tropical. To the north, however, this temperate fauna is extremely attenuated. In fact, to the north of the Limpopo River a typical relic pattern is shown, suggesting a former continuous distribution of temperate forms along the length of the highlands from the Cape to Kenya. For the Kenya highlands population of *Cacosternum boettgeri* (Boulenger) and the Nyasaland uplands population *Xenopus l. laevis* (Daudin) are not distinguishable from the South African populations of these forms, and the *Rana fasciata* of Nyasaland barely differs from the *R. fasciata* of eastern South Africa. *Xenopus l. laevis* and *Cacosternum boettgeri* still appear to have a tenuous connexion across the Limpopo; but the *Rana fasciata* and *R. grayi* Smith on the highlands of Southern Rhodesia are completely isolated from the South African populations of these forms. All these various separated populations must have been united during one or more periods of general cooling and/or greater rainfall, and the last period has not occurred sufficiently far back in time to have allowed much differentiation to have occurred between the isolated populations.

While this temperate fauna is now scarcely in evidence in most of eastern Africa, the localized faunal centres of endemism in the zone of tropical and temperate subtraction are a very prominent feature of the whole length of this zone from north to south. In South Africa and Southern Rhodesia there is a complex of these localized faunas[6]. In southern Nyasaland another pocket of endemism is found, which is not very well developed, but is distinct from a well-developed local centre in the northern montane fringe of Lake Nyasa[4,7]. More localized forms are scattered on the East African uplands, forming centres in the area from Lake Tanganyika to Lake Albert, and the Kenya mountains. A localized centre is also present on the Ethiopian highlands[8]. The isolated Uluguru and Usambara Mountains are also local centres of endemism, but they are more remarkable for the relic genera which they possess[3]. These relics have nothing to do with the southern temperate fauna, but show some relationship with the montane forms of the Cameroons[3]. This relationship appears to be due to the peculiar isolation of these mountains favouring the survival of primitive forms.

The great north-to-south expanse of the temperate fauna which must have existed at times in the past, and the more permanent north-to-south range of tropical forms, stand in contrast to the essentially discontinuous series of centres of endemism lying in the intermediate zone. Certainly there are some forms, such as *Leptopelis bocagii* (Günther), which, although confined to this intermediate zone, are widespread within it; but the general pattern is that of localized faunal centres. The localized faunas of this intermediate zone in southern Africa have been called 'transitional faunas'[6]. Now these faunas are zoogeographically no different from the other localized faunas occurring in the intermediate zone to the north. The more northern centres should therefore also be called transitional for the sake of uniformity, even if the 'transition' in East Africa is not through to a currently well-developed temperate fauna[9]. The present pattern clearly suggests the former existence of a more extensive 'south temperate' fauna in East Africa.

In the western region of the East African transition zone, the influence of the West African fauna is very apparent. However, a treatment of this fauna falls outside the scope of the present article.

The general pattern of anuran distribution in eastern Africa can therefore be visualized as having as its basis a largely homogeneous fauna on the lowlands stretching the whole way from Zululand to Somalia. From this assemblage there sweeps a great subtraction margin, covering the rising country to the west and the less-tropical lowlands to the south, becoming ever thinner as it extends outwards. Localized centres of endemism lie scattered throughout the length of this subtraction margin, from the Natal lowlands northwards along the eastern slopes and the crest of the great inland massif all the way to the eastern horn of Africa. Here arid conditions supervene, and the Ethiopian faunal complex eventually becomes halted by the northern desert. Overlying this pattern of predominantly westward subtraction is another pattern of northward subtraction shown by the temperate fauna of South Africa. This fauna occupies the south-western corner of the Cape Province, and has a well-developed subtraction margin on the eastern uplands of South Africa. At present it continues northwards only as isolated vestiges on the highlands north of the Limpopo River. Within the tropical and temperate subtraction zone occur the transitional faunal centres composed of forms with restricted ranges.

The overall pattern is thus one of a tropical-transitional-temperate zonation. This zonation appears to shift, probably as a whole, in accordance with the prevailing climatic régime. The close correlation between the thermal pattern and amphibian distribution indicates that, at least in the Anura, temperature is the main controlling factor of distribution over most of eastern Africa. The zones recognized here may in fact be considered basically to be 'thermal life zones'. In the north, however, the fauna is clearly being limited by arid conditions. At present the uppermost zone has been eliminated from most of eastern Africa, leaving only a scattering of relics to the north of the Limpopo River. This zonal stratification of the fauna is an altitudinal one in the equatorial region, but in the cooler southern latitudes it dips to lower levels. Thus, characteristically south temperate forms such as *Rana fuscigula* D. and B. (with which more northern forms are often confused) and *Kassina wealii* Boulenger occur at sea-level in the region of 34° S., but do not occur below 4,000 ft. north of 30° S.

During a warmer period than the present, the range of the temperate forms would presumably be even more restricted, although a reserve of south temperate forms is likely to be retained permanently in the southern Cape. This reserve could re-populate the northern uplands during a cooler period. The conjunction between the tropical and the transition zones at present strikes the coast in the region of Lake St. Lucia. It is obvious that the faunal composition of this coastal area must be subject to very considerable changes with changes in overall temperature. This instability must exist on the East African uplands as well, but the faunal pattern of the East African lowlands must remain very stable, not only because of the central position of the fauna, but also because temperature fluctuations should be less marked nearer sea-level than at higher altitudes, as well as being less marked near the equator than outside the tropics.

It is therefore probably in the East African lowlands that the fauna of eastern Africa has its main evolutionary potential. This probability is suggested both by Fischer's conclusion[10] that perennially constant tropical conditions are the most favourable for evolution, and by the principle of centrifugal speciation put forward by Brown[11], who points out that "The more important genetic changes tend to be incorporated in the central populations". With fluctuations in climate, the general shifting of the faunal zones in eastern Africa provides ideal conditions for centrifugal speciation to take place. The area which is now covered by the transition zone must in warmer periods have been populated by a richer tropical assemblage, and in cooler periods, populated by a greater number of temperate forms. Repeated expansion and recession over this intervening 'tidal zone' makes the formation of isolated populations within this zone very probable. These isolated pockets and the main faunal assemblage would in time be expected to diverge genetically, and further divergence in the direction of speciation would be likely on the return of the main fauna[11]. It is therefore understandable that the fauna endemic to the transition zone should be composed largely of restricted forms, whereas the fauna of the tropical lowlands is composed of widespread forms. A great number of species occurs around the tropical lowlands, but the pattern of distribution indicates that the major evolutionary activity takes place in the lowlands, and it is probably here that the major phylogenetic advances in the eastern African fauna have their origin.

The fauna of eastern Africa offers an endless and virtually untapped wealth of material for evolutionary investigations. It is hoped that this zoogeographical sketch will assist in ordering the complex patterning of distribution into a general system, which can be used as a background for investigations of centrifugal speciation, character displacement and the like. The pattern shown by the Anura is not comparable in every way with the distribution of the other terrestrial vertebrate groups. Birds and mammals tend to have more extensive ranges (for example, refs. 2 and 9), probably as a result of their homoiothermy. Consequently, at least in the case of birds, a relatively larger proportion of the transitional fauna is continuous from East Africa to South Africa[9]. However, such differences should not be made to obscure the common pattern that seems to exist (for example, refs. 1 and 2): rather the causes of the differences should be sought, and the common underlying factors thereby seen more clearly. A great amount of work by specialists in different groups is necessary before these factors can be understood. Although zoogeography has been in existence for a relatively long time, zoogeographical work in Africa has barely begun. But until this field has been properly worked, its methods standardized and its data published, an understanding of the evolution of the African fauna will remain an impossibility.

I thank Prof. S. F. Bush, Miss M. Beynon and Mr. B. Stuckenberg for criticism and discussion.

OBITUARIES

Dr. D. D. Pratt, C.B.E.

All who at different stages of his scientific career knew Dr. D. D. Pratt will learn with regret of his death on May 5. As recently as 1959 he retired from the post of director of the National Chemical Laboratory after 34 years spent in the scientific service of the State.

David Doig Pratt, born at Anstruther in Fife in 1894, was educated at Waid Academy and the University of St. Andrews, which he entered in 1912. However, he joined the Army when war broke out in 1914, received a commission and served with the Highland Light Infantry. Wounded on the Somme, he was mentioned in dispatches and promoted to captain. After the First World War he returned to St. Andrews, graduated M.A., B.Sc. with honours in chemistry in 1921 and was awarded a Carnegie Scholarship. This enabled him to start research under Prof. (now Sir Robert) Robinson. He took his Ph.D., became a Carnegie Fellow and continued his work at the University of Manchester, still in association with Prof. Robinson. Pratt was one of the first of many in Robinson's school who found the naturally occurring flower pigments a rewarding study.

In 1925 Dr. Pratt made the move which was to determine the course of his future career. The Department of Scientific and Industrial Research was on the point of setting up at Teddington in a very small way a laboratory to be known as the Chemical Research Laboratory. The sponsors of this scheme were Sir Richard Threlfall and H. T. (later Sir Henry) Tizard; Prof. G. T. (later Sir Gilbert) Morgan was persuaded to take charge of what was avowedly an experiment. Pratt accepted a post in the unit when its staff numbered less than a dozen and was Morgan's stoutest supporter in the task of building the prestige of the laboratory and establishing its role as a national institution. In 1958 the embryo of 1925 officially became the National Chemical Laboratory with a staff of more than 200. Pratt had been its director for some seven years, and as officer-in-charge or superintendent he had been its effective head at other difficult periods during and after the Second World War when the post of director had been vacant.

The project which Morgan assigned to Pratt was an investigation of coal tars and liquors, very different in character from the synthetic organic chemistry in which he had made his mark, but equally one which gave scope to his ability as a chemist. Backed by Morgan and aided by a small group which he inspired with his own enthusiasm, Pratt set about nothing less than the complete revivification of coal tar research in Britain. Attention was first directed to tars from the low-temperature carbonization of coal. This method of making smokeless solid fuel was then undergoing development, and it was clear that no process could succeed unless the by-product tars could find profitable application. The extension of precise knowledge in regard to the constitution of these new materials must proceed *pari passu* with utilitarian aims. Aware of the very reactive nature of these tars, Pratt systematized the use of extraction by solvents and vacuum distillation in their rational analysis. But this was no more than a beginning.

The Teddington work, new in pattern, caught the attention of influential leaders in the industry and created a new climate of opinion as to what might be achieved by research well directed. When in 1934 the Association of Tar Distillers gave financial support to the Laboratory for work on one of the industry's most troublesome problems—the disastrously rapid corrosion of tar stills caused by certain types of tar—it had taken the first step on what turned out to be a long road. The industry formed its own Research Association in 1948, and in 1950 the ministerial head of the Department of Scientific and Industrial Research (Sir John Anderson), in the presence of its secretary (Sir Ben Lockspeiser), gave the blessing of the Department to the newly established Coal Tar Research Station at Gomersal. Pratt witnessed with amused satisfaction the lighting of a symbolical Bunsen burner by Sir John, although for him the ceremony was valedictory rather than inaugural.

After 1938 Pratt was fully engaged in the administration of the Laboratory's total research effort. His concern now was to maintain an environment in which good scientific work could be done by his colleagues.

One quality which fitted him for the responsibilities he held so long Pratt possessed in full measure. He had an understanding of human nature and was on easy terms with all members of his staff regardless of status or rank. He was shrewd in judging issues in which policy and personalities were mixed with matters purely scientific.

Dr. Pratt shared most of the simple pleasures of the ordinary man. He had an interest in every form of sport; he particularly liked to be among the crowd at a football match. He grew flowers in his garden; regularly sought relaxation at a variety theatre or cinema; and he could always be persuaded to attend a staff social and play cards, billiards or snooker, or join in a dance.

The effort to make the Laboratory the national institution he thought it should become was steadily pursued, and the distinctions bestowed on Dr. Pratt, C.B.E. and an honorary LL.D. of the University of St. Andrews, were recognition of the merit of his service to the Department and his success in securing for the Laboratory the esteem of the scientific world.

E. A. Coulson

Dr. G. I. Patel

Dr. Govindbhai Ishwerbhai Patel, who died on March 10, was born at Savli, District Baroda of the Gujarat State, on June 21, 1921. He was the second son of the late Ishwerbhai Kesurbhai Patel, an industrious farmer, having 5,000 acres of land under cultivation, who took great interest in the proper education of his sons. Young Govinddas, as he was addressed by his kinsmen, was different from the rest of his brothers and cousins, studying at Baroda. During his school days at Baroda, he showed average progress, but his zeal for knowledge was such that nothing was allowed to come in its way. Leaving aside the hardships of accommodation, food, etc., the main difficulty was the choice of his career. He matriculated in 1939 and joined Baroda College. The new atmosphere had a profound influence on him; the once meek and average student now began to shine as a scholar in the truest sense of the term.

His patriotism and eagerness for the uplift of the rural masses attracted him to the study of agriculture. He then went to the then only college of agriculture, claimed to be the best in South-east Asia, namely, that at Poona. Here his progress was remarkable and he secured first class with distinction in the B.Sc.(Agric.) examination in the University of Bombay in 1946.

While studying he decided to go to the United States in order to study agriculture at an advanced level. There he entered the Graduate School of the Iowa State College and the University of California at Davis. As he was much interested in horticulture, he preferred the University of California and received his M.S. degree in horticulture in 1948 and Ph.D. degree in plant genetics in 1951 working under Prof. H. P. Olmo on the genetics and cytogenetics of the grape vine. During his stay there he competed in two examinations and was awarded two fellowships of several thousand rupees in order to continue his studies. He returned to India in 1951.

He accepted a Class III post in a Government Vegetable Seed Multiplication Farm in the Kulu Valley. After serving there for a year he left and joined the Agricultural Research Institute, Sabour, Bhagalpore, in an honorary capacity to work under Dr. R. H. Richharia, the geneticist and plant breeder and director of the Institute, and he published some important papers. Later, he was appointed cytogeneticist in March 1953 by the Indian Central Jute Committee at its Jute Agricultural Research Institute, Barrackpore. From there he published several important papers on the cytogenetics of jute in several journals, which attracted world-wide attention. His papers on the grape vine were also outstanding. Later in 1956 he was appointed areca-nut specialist at Vittal. He worked there for some time and published a few papers. As the post carried more administration, he left and returned to his native home at Baroda and entered business for two years. Afterwards, he took up horticultural researches on joining the Scientists' Pool organized by the Council for Scientific and Industrial Research, and he was posted to the National Botanic Gardens, Lucknow. To continue his work it was necessary to go to the Banthra Farm, a few miles from Lucknow. On March 9, while cycling to the farm, he met with a fatal accident by colliding with a speeding car. Although he received prompt and adequate medical help, he succumbed to his injuries on March 10.

R. M. Datta

Mr. J. K. Starnecki

Mr. Jerzy Kazimierz Starnecki, who died on May 15, was born in Poland on August 26, 1908. He gained a diploma in engineering at the University of Warsaw and in 1935 was appointed head of the Inspection Branch of the Polish National Armament Factories, Radom. After the outbreak of hostilities in 1939 he served with distinction the Polish Armed Forces in France. In 1941 he was chosen for a special assignment as design engineer with the Research and Development Department of the Polish Army in the United Kingdom.

After the War, Mr. Starnecki spent a short time as a research engineer at Signals Research and Development Establishment; then, in 1947, he joined Pye, Ltd., where, among other projects, he played a leading part in the design of a new optical system used in the gunsight of the Conqueror tank and in the servo-controlled automatic stabilizing gear. After a successful stay of seven years with Pye, Ltd., Mr. Starnecki was appointed chief engineer and head of development of W. G. Pye and Co., Ltd., where he remained until his death. There his great foresight and sound engineering knowledge influenced the design of nearly all instruments. He was an active associate member of the Institution of Mechanical Engineers. He made a constant endeavour to keep abreast of latest scientific developments and several patents are to his credit. He has served on the council of the British Scientific Instrument Research Association and was a committee member of the Scientific Instrument Manufacturers' Association of Great Britain, Ltd.

Mr. Starnecki was a rather quiet little man but with a good sense of humour and a smile for everybody. In his limited amount of spare time he was a keen gardener. His sudden and untimely death came as a great shock. He will be missed by all who worked with him and remembered not only as an outstanding engineer but also for the great range of his human sympathies.

NEWS and VIEWS

International Meteorological Organization Prize for 1962: Dr. A. Ångström

Dr. Anders Ångström from Bromma, Sweden, has been awarded the International Meteorological Organization Prize for outstanding work in meteorology and international collaboration. Dr. A. Ångström studied at the Universities of Uppsala, New York and Jena. He obtained the degrees of Master of Science and 'Filosofie Doktor' and in 1916 became assistant professor of meteorology in Uppsala. After participating in several scientific expeditions and work at Cornell University as a Fellow in physics, Dr. Ångström became State Meteorologist and later First State Meteorologist at the Swedish Meteorological and Hydrological Institute in 1919. In 1940 he was appointed assistant director and chief of the Meteorological Bureau and in 1949 director of the Institute. He retired from this post in 1954. Dr. Ångström is a member of the Royal Swedish Academy of Science and of the Royal Swedish Academy of Forestry and Agriculture. His contribution to international collaboration has mainly been in meteorology, particularly in the field of solar and atmospheric radiation. He has participated in various meetings of the International Meteorological Organization and the World Meteorological Organization as well as of the International Union of Geodesy and Geophysics. The International Meteorological Organization Prize, which consists of a gold medal, was established in 1955 by the World Meteorological Organization in honour of the former non-Governmental Organization which had initiated international collaboration in meteorology in 1878, but which ceased in 1951 when the World Meteorological Organization took over.

Pure Mathematics at Birmingham :

Prof. P. J. Hilton

PROF. P. J. HILTON is vacating the Mason chair of pure mathematics in the University of Birmingham on being appointed to a professorship in pure mathematics in Cornell University. Prof. Hilton, who is thirty-nine years of age, was educated at St. Paul's School and Queen's College, Oxford, obtaining a first-class degree in mathematics while at the latter. After the War he returned to Oxford to work in algebraic topology under the late Prof. J. H. C. Whitehead and was one of the leading members of the brilliant band of topologists taught by Prof. Whitehead. After obtaining the Ph.D. degree he went to Manchester in 1948, where he remained until 1952. He then spent three years in Cambridge as lecturer and returned to Manchester in 1955, where he remained until 1958, when he was appointed to the Mason chair at Birmingham. Prof. Hilton has made outstanding contributions to algebraic topology, particularly in the field of homotopy. In recent years he has worked in close collaboration with Prof. Eckmann of Zurich, and their joint work is among the most interesting and important contributions being made to topology at the present time. In addition, Prof. Hilton has written a tract on homotopy theory and also, in collaboration with S. Wylie, a book on homology theory. Both are clear expositions of algebraic topology.

Prof. A. M. Macbeath

PROF. A. M. MACBEATH, who has been appointed to succeed Prof. Hilton, is thirty-nine years of age. He was educated at the Royal Belfast Academic Institution, The Queen's University of Belfast, where he obtained a first-class degree in mathematics, and Clare College, Cambridge. After obtaining first-class honours in the Mathematical Tripos, he commenced research in the geometry of numbers under Prof. L. J. Mordell. For his research in this subject he was awarded a Smith's Prize. From 1948 until 1950 he was at Princeton University with a Commonwealth Fellowship, where he obtained a Ph.D. degree. From this period dates his interest in measure theory and topological groups, in which fields he has carried out research in more recent times. After his return to England, he went to the University of North Staffordshire from 1951 until 1953 as a lecturer, and was then appointed to the chair of mathematics in University College, Dundee (University of St. Andrews), where he has remained until the present time. As already indicated, Prof. Macbeath's field of research has widened from his original interest in the geometry of numbers to embrace both measure theory and, more latterly, discontinuous groups. While at Dundee he has written a steady stream of papers on these subjects.

Applied Physics at Hull : Prof. J. Ring

DR. JAMES RING, who has been appointed to the new chair of applied physics in the University of Hull, was an undergraduate and research student in the University of Manchester. He later became lecturer, senior lecturer and reader in spectroscopy there. His first postgraduate work was on the improvement of spectroscopic techniques by applying the then new multiple dielectric layers to the Fabry–Perot interferometer. Dr. Ring has continued to play a prominent part in the modern revival of experimental spectroscopy which has resulted largely from recognition of the special qualities and the special optical requirements of such detectors as photomultipliers and infra-red sensitive cells. He has contributed especially by developing pressure-scanned interferometers and by applying them to astronomical and other purposes. He has also worked on the closely related interference filters, dealing with their production, the extension of their spectral range, and their application: astronomy has again received his special interest. In 1960 it was recognized by the Department of Scientific and Industrial Research that Dr. Ring's work, devoted to techniques used over a wide scientific field, occupied a special position, and he was made director of a specially financed project in which a team of research students and more senior assistants, with technical support, developed instruments and methods for use by chemists and astronomers as well as physicists. This team has worked successfully for a year or so and it is hoped that a considerable part of it will be transferred to Hull.

Computer Network for Australia

THE Australian Federal Cabinet has agreed to the establishment by the Commonwealth Scientific and Industrial Research Organization of a system of electronic computers for their own use, universities and Commonwealth Government departments and authorities. It is hoped that the first stage of the project, which will cost more than £1,500,000, will come into operation in about eighteen months time. The central unit of the system will be a large and powerful computer, located in Canberra. The Government is to set aside £100,000 for a laboratory to house it. 'Satellite' computers will be set up in Sydney, Melbourne, Canberra and Adelaide. All the units will be programmed in the same way and will make up an integrated network. About forty people, including twelve scientists, will be appointed to the project. C.S.I.R.O. will be the biggest single user of the network. Several other Government departments and agencies, including the Atomic Energy Commission, the Bureau of Meteorology, the Post-Master General's Department and the Aeronautical Research Laboratories, will make extensive use of the computers. In the future, the Atomic Energy Commission and some departments and universities will acquire their own 'satellite' computers which they will operate themselves as part of the system. It is estimated that by 1965 C.S.I.R.O. alone will need at least 5,000 hr. of 'satellite' computer time in a year, plus 1,500 hr. on the central unit. Other Government users will together need more than that. At the present time, Australia's computing needs are doubling every year.

The Commonwealth Agricultural Bureaux

IN reply to a question in the House of Lords on May 28, the Parliamentary Under-Secretary of State for Commonwealth Relations, the Duke of Devonshire, said that the Government had no reason to believe that the Commonwealth Agricultural Bureaux were unlikely to be able to continue successfully under existing arrangements for scientific co-operation in the Commonwealth. These arrangements for scientific research were a matter for agreement between all participating Governments, and if it became apparent that there might be advantage in reconsidering them, the Government would be ready to join in examining alternative possibilities. An interim conference of representatives of participating Governments was to be convened next year and a special committee appointed to review certain aspects of the working and financing of the Bureaux. This would provide an opportunity for discussion of possible changes in the existing arrangements, including any extension of existing collaboration with non-Commonwealth Governments. He thought that the terms of reference already recommended for the interim conference were wide enough to cover all points, including the cost of the abstract periodicals, the price of which was doubled on January 1, 1962. The Government was reluctant to believe that any of the participating Governments would be so short-sighted as to think of leaving the Bureaux.

The Royal College of Science and Technology, Glasgow

In a written answer in the House of Commons on May 29, the Chief Secretary to the Treasury, Mr. H. Brooke, stated that the University Grants Committee had informed him that, both on general grounds and in view of the need for more university places in Scotland, a decision to enable the Royal College of Science and Technology, Glasgow, to increase its number of degree students and to broaden the scope of its academic work should now be made. In particular, if the new Faculty of Industrial and Social Studies was to be developed adequately within the quinquennium, work on the necessary accommodation and recruitment of the necessary staff must be started this year. Although the work of the Robbins Committee is not yet complete, the University Grants Committee has felt justified to agreeing to the College's proposal to include accommodation for industrial and social studies in their building programme for 1962, and took into account the College's wish to develop these studies in their submission to the Chancellor of the Exchequer on the financial needs of British universities for the quinquennium 1962–67. The Committee accepted the case for the College being granted full university status, including the power to award its own degrees, but pending the report of the Robbins Committee they have deferred their final advice to the Committee and limited present action to that indicated.

The Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme

The eighth annual report of the Royal Society and Nuffield Foundation Commonwealth Bursaries Scheme covers the year ended December 31, 1961 (Pp. 8. London: Royal Society and the Nuffield Foundation, 1962). The report records 18 awards, of which five were for visits from the United Kingdom (three to Australia, one to Australia and New Zealand, and one to South Africa), nine for visits to the United Kingdom (two each from Australia, New Zealand and India, and one each from Malaya, Hong Kong and South Africa) and four for visits between countries of the Commonwealth other than the United Kingdom. At the end of 1961 applications were not accepted from persons wishing to visit South Africa or from South Africans wishing to work in the United Kingdom, but applications would be accepted from South Africans wishing to work in other Commonwealth countries.

University of London Observatory

A new laboratory at the University of London Observatory was opened by Sir Ifor Evans, provost of University College, London, on June 18. The laboratory is built around an Ebert-type plane grating spectrograph vertically mounted in a 12-ft. pit. There will be facilities for a wide variety of light sources including the Sun, fluid and solid rotatory arcs and flash tubes. Above the new laboratory, offices have been provided to relieve the overcrowding of the existing accommodation, allowing better accommodation of staff and postgraduate students. An undergraduate room having places for eight additional students attending practical courses at the Observatory has also been provided.

U.S. Research in Astronomy using High-Altitude Balloons

The Air Force Cambridge Research Laboratories are to conduct a series of research projects in astronomy using high-altitude balloons beginning later this year. Three separate projects, *Star Gazer*, *Sky Top* and *Balast*, are involved. The primary objective is to obtain more complete and accurate information about space environments with emphasis on the Moon, Mars and Venus. Only one of the three programmes, *Star Gazer*, will include a manned balloon flight. *Star Gazer*, under the scientific direction of Dr. J. A. Hynek, chairman of the Department of Astronomy, Northwestern University, Evanston, will measure the effect of turbulence of the atmosphere on image clarity at altitudes up to approximately 86,000 ft. A photoelectric experiment will investigate the variations in brightness of a star image caused by the atmosphere, while experiments will be conducted using infra-red techniques to determine how much effect water vapour has on different wave-lengths of light at different altitudes. The project *Sky Top*, under the direction of Dr. J. W. Salisbury, will carry its experimental payload to altitudes of 86,000–120,000 ft. It is hoped that temperature measurements will be obtained of the Moon at night that are accurate to within 5 degrees. An interferometer will be used to determine the amount of heat-energy released by the Moon at various wave-lengths of the infra-red spectrum. It is also hoped to determine the mean temperature of the reflecting surfaces of Mars and Venus; infra-red spectroscopy will be used to investigate the atmospheric composition of both these planets. The payload of *Balast* will weigh about 1,400 lb. and will be carried to an altitude of approximately 85,000 ft. In contrast to *Star Gazer*, the tracking system uses a completely passive (no moving parts) sensor. The system, under the direction of Dr. J. Strong of Johns Hopkins University, is expected to track Venus and other planets with an accuracy of ± 5 sec. of arc.

Education of Engineers

Prof. G. B. Warburton, giving his inaugural lecture as professor of applied mechanics at the University of Nottingham, spoke about "Some Effects of Recent Advances in Knowledge on the Education of Engineers" (Published in book form. Pp. 23. Nottingham: The University, 1962. 2*s*.). After surveying the present situation in Britain and the United States, he discussed possible changes in undergraduate courses, including regrouping of subject-matter, the provision of 'engineering science' and 'industrial engineering' options, and the provision of degree courses in general engineering with no specialization. He suggests that the new universities have scope for experiments in engineering education along these lines. Postgraduate courses may be of the 'follow up' or the 'new field' type. The former consists of further study in a field which forms part of a conventional honours course, with the intention of bringing the graduate to the boundary of knowledge in this field. The latter comprises subjects which do not follow directly from a major course in an engineering curriculum and are of interest usually to graduates from more than one discipline. Such courses enable the more advanced and specialized topics to be omitted from the first degree course and help to resolve the conflict between the rapid advances in knowledge and sophistication on one hand, and on the other the desire to preserve engineering as a single discipline at the undergraduate-level.

The Library Association

THE annual report of the Library Association for the year ended December 31, 1961, refers to the completion of a survey of library services in certain Commonwealth countries (Pp. 30. London: Library Association, 1962). A copy of the report was sent to Government Departments, members of Parliament and others, with a memorandum stressing the need for financial help in this field. On the recommendation of the Association, the Leverhulme Trust Fund agreed to award three scholarships in librarianship to students from the Commonwealth. There was a net increase in membership of 904, the total now standing at 13,937, including 1,254 institutional members. Reports of representatives on joint committees and other bodies appended to the Council's report include those from the British Standards Institution–Universal Decimal Classification Committee, which was concerned with the preparation of a guide to the Universal Decimal Classification (*BC*1000*C*) and protested to the editor of *Science Abstracts* on the abandonment of Universal Decimal Classification arrangement for *Part A* "*Physics*"; from the British Standards Institution Documentary Reproduction Committee, Photographic Aspects of Documentation Committee; from the National Committee on Regional Library Co-operation; and from representatives to the International Federation of Library Associations.

Schoolmaster's *Treasure Chest*

THE Schoolmaster Publishing Company has published an enlarged edition of *Treasure Chest for Teachers*. This booklet resulted from a series of articles with the same title, which appeared in *The Schoolmaster*, the journal of the National Union of Teachers. The articles showed teachers where they might find teaching aids either free or at low cost. The new edition has been thoroughly revised and, with thirty-two additional pages, is worth the increased price of 3*s*. 6*d*. The information is divided into four main sections—services available from societies and associations which have some bearing on the school curriculum; services available from embassies and legations; services available from industrial, commercial and transport concerns; and a general section giving information about associations which supply films and other visual aids

North Staffordshire Journal of Field Studies

THE North Staffordshire Field Club, founded in 1865, has published a journal for an unbroken period of ninety-three years. In recent years the rising cost of printing, together with other factors, has made it increasingly difficult to maintain the size of the journal. This has happened at a time when there is a growing interest in local studies and an increasing volume of research on the area, some of it initiated by members of the then University College of North Staffordshire. Rather than found a new journal to publish this work, the *North Staffordshire Journal of Field Studies* has been launched in which the *Transactions of the North Staffordshire Field Club* are incorporated (1; 1961. Pp. iii+140. Keele: University College of North Staffordshire, 1961. 25*s*.). The new journal will cover local history, archæology, architecture, geography, geology, and other local studies. While it is expected that these will be centred on North Staffordshire, the area will not be tightly drawn. The first volume of the new journal contains articles by E. A. Watkin on Staffordshire tokens and their place in the coinage of England; Prof. J. M. T. Charlton on excavations at the Roman site at Holditch, 1957–59; A. W. J. Houghton on the Roman road from Wroxeter to Whitchurch (Salop); and Mrs. Joan and Dr. Harold Taylor on the problem of dating pre-Conquest churches. Prof. A. E. Teale writes about the origin of the Keele experiment. Details are available from Prof. J. M. T. Charlton, Department of Classics, University of Keele, Staffordshire.

Scientific Glassworking Equipment

JENCONS' latest illustrated catalogue of scientific glassworking equipment can best be summed up as "everything for the glassworker and research worker using glass". It consists of items of interest in medical and scientific research and glassmaking generally, from small items like glass tubing to the largest glassworking lathes, and includes a comprehensive range of glassworking tools and glass-grinding equipment. The catalogue will save much time otherwise spent searching through numerous makers' catalogues and should be of special interest to physics departments in universities, technical and teachers' training colleges, and schools. Copies of the catalogue are available from Jencons (Scientific), Ltd., Mark Road, Hemel Hempstead, Herts.

Derwent Patents Manual

THE latest in the series of publications of the Derwent Information Service is the *Derwent Patents Manual* (Pp. ii+50. London: Derwent Information Service, 1962. 12*s*. 6*d*. or 2 dollars). It contains useful information for all with interest in the wide field of patents and contains articles on British, French, German, Russian, Belgian and Japanese patent laws and procedures. There is also an interesting analysis of the European patent concept; this describes the work of the European Economic Community's Committee which is at present drafting a new convention for creating an autonomous European patent system. Three new publications are to commence in July 1962, giving abstracts, in English, of Japanese, Belgian and Russian patents dealing with electricity, electronics, communications instruments, control and computation.

Optical Pumping and Masers

IT has been announced that a special supplement to *Applied Optics* will be published in December 1962, which will be devoted to optical pumping and masers. In the supplement all papers on the subject which have been published in *Applied Optics* during

1962, the first year of publication of the journal, will be gathered together and, in addition, there will be articles not previously published together with a 15,000-word review presenting a survey of the present state of the art and of the fundamental theories. The price of the supplement will be not more than five dollars. Orders should be sent to the Optical Society of America, 1155 Sixteenth Street, N.W., Washington 6, D.C.

U.K. Courses in Nuclear Energy, 1963–64

LIST No. 6 (May 1962) of *Nuclear Studies* has been compiled by the Science Department of the British Council. This lists courses in pure and applied sciences concerning the use and development of nuclear energy which may be undertaken in the United Kingdom during the year 1963–64. These courses are full-time and are generally of one week or more duration. The information provided by the catalogue includes notes on each of the courses and the institution at which it takes place; also the fee and qualifications required for participation. Further information can be obtained from the Science Department, The British Council, 59 New Oxford Street, London, W.C.1.

Clinical Research in the United States

THE Clinical Research Centers Program, established by the U.S. Public Health Service's National Institutes of Health on the recommendation of Congress, is now in its third year of operation. The programme seeks, through grants to private and public institutions, to enhance and increase the level of clinical research in the United States into the disease of man and into his fundamental biological conditions and problems. A recent report provides a review of the principal developments in the programme and an idea of the types of investigations undertaken by a few of the forty centres established under the programme of the Division of General Medical Sciences, National Institutes of Health, Bethesda, Maryland.

Fibrinolytic Activity of Arterio-Sclerotic Vessels

COMPARATIVE studies have been made by E. Perlick and A. Deutschinoff (*Hemostase*, 1, No. 3; 1961) on both normal and sclerotic aortic and carotid arteries, which show that tissue extracts made from intima and media of arterio-sclerotic vessels have a high tissue fibrinolytic activity when compared with similar extracts from normal vessels. The activators of fibrinolysis found in these vascular extracts exist in the form of a plasminogen activator or proactivator. On the other hand, an increased amount of plasminogen or a plasminogen-like material was also found. A marked increase in tissue fibrinolysis, resulting from arterio-sclerotic changes in the blood vessels, could be the cause of mural and intramural hæmorrhages in the arterio-sclerotic plaques.

Veterinary Research in Japan

UNDER the title "Deformation of the Vertebral Column in the 'Short-spine Dog' ", Toshihiko Ueshima (University of Tokyo, Japan) has described anatomical studies on four cases and discussed briefly cases in calves of the Oplandske breed in Norway, in turkeys and in a goat (*Jap. J. Vet. Res.*, 9, 155; 1961). Photographs of two dogs and X-ray photographs of the vertebral column of one of them give a clear picture of the condition. There was striking kyphosis in the anterior part of the thoracic segment and in the lumbar segment of the vertebral column, with scoliosis elsewhere. Excess of cartilaginous tissue in vertebræ and other abnormalities are described, with details of histological features and also secondary effects in other adjacent bones.

A new journal, *The National Institute of Animal Health Quarterly*, from Tokyo, completed its first volume in 1961. The director of the Institute is Susumu Ishii, and there are five branch laboratories of the Institute. In No. 4 of the volume there are eight original articles dealing with infective disease research and with irradiation studies.

Apprenticeship Schemes in the Cambridge Instrument Co.

A BROCHURE prepared by the Cambridge Instrument Co. for the information and guidance of young men contemplating a career in the instrument industry gives a brief summary of the role of instruments in the world to-day, sketches of the Company's history, describes and illustrates some of the instruments the Company makes, and provides information on the types of apprenticeships available. These include craft, technical and graduate apprenticeships. The brochure is attractively illustrated and is obtainable from the Personnel Officer, Cambridge Instrument Co., Ltd., Chesterton Road, Cambridge.

Safety in Laboratories

IN the article by Prof. R. A. Morton and Dr. J. Glover, entitled "Safety in Laboratories", which appeared on p. 809 of the June 2 issue of *Nature*, reference is made in the penultimate paragraph to a film, "Safety in the Laboratory", shown by courtesy of Imperial Chemical Industries (General Chemicals), Ltd., at the courses of lectures on "Safety in Laboratories" held at the University of Liverpool during the Lent Term. Imperial Chemical Industries (General Chemicals), Ltd., wish to direct attention to the fact that the title of the film is *Black Monday* and it was produced by the Imperial Chemical Industries Film Unit. While the film was produced primarily for the Company's own use, the needs of universities, technical colleges and schools were taken into consideration. The film is available on loan through the Imperial Chemical Industries Film Library, Imperial Chemical House, Millbank, London, S.W.1.

Mountbatten Research Studentships in Radio and Electronic Engineering

THE Council of the British Institution of Radio Engineers is to establish research studentships to encourage fundamental research in radio and electronic engineering. The award will be named after the Institution's charter president, Admiral of the Fleet The Earl Mountbatten of Burma. It is intended to award one studentship in October 1962, the second in October 1963, and thereafter as they become vacant. Each studentship will have an annual value of £500 plus university or college tuition fees, and will normally be tenable for two years, with a possible extension of one further year. Applications are invited from graduates (or those about to graduate), and the studentships are open to holders of degrees or diplomas in technology (Dip.Tech.) in appropriate subjects from any university or college in the United Kingdom, and can be held in any university or college of advanced technology in the United Kingdom which has established research in radio and electronic engineering. Further information can be obtained from the Secretary of the Institution of Radio Engineers, 9 Bedford Square, London, W.C.1.

Langley Memorial Prize, 1962

The Langley Memorial Prize was founded by the friends of the late Dr. W. H. Langley, principal medical officer, Southern Nigeria, to commemorate his work and the services he rendered both to Nigeria and to those who came under his care and skill. The Prize, value approximately £21, is open to competition among officers, past and present, of the West African Medical Departments; it is awarded periodically for the best paper on one of the following subjects: (*a*) tropical medicine or surgery; (*b*) tropical hygiene and sanitation; (*c*) tropical entomology and parasitology. Special consideration is given to original work. Joint applications are not accepted. No officer who has already been awarded the Prize is eligible to re-enter. Entries, which can consist of either published or unpublished work, should be sent to the Dean, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1, not later than October 1.

University News: Birmingham

The following appointments are announced; Prof. L. E. Davis, professor of industrial engineering in the University of California, to be Joseph Lucas visiting professor for the session 1962–63; *Research Fellows:* Dr. W. N. Cottingham (mathematical physics), Dr. G. P. McCauley (mathematical physics), Mr. J. A. R. Griffith (physics), Mr. H. C. Wilkie (pure mathematics); *Lecturer,* Dr. B. Musgrave (physics).

Bristol

The following appointments are announced: Dr. D. Russell Davis, reader in medical psychology and director of the Medical Psychology Laboratory in the University of Cambridge, to be professor of mental health and head of the Department of Mental Health; *Readerships,* Dr. D. T. Donovan (palæontology), Dr. W. D. Ollis (organic chemistry), Dr. B. F. Folkes (botany), Dr. P. H. Fowler (physics); *Senior Lectureships,* Dr. M. H. Rogers (mathematics, as director of the Computer Unit), Mr. T. V. Lawson (aeronautical engineering), Mr. R. C. Seymour (chemistry), Mr. S. R. Wragg (agricultural economics); *Research Associate,* Dr. J. G. Baker (physics); *Lecturer,* Dr. P. J. Bentley (pharmacology).

Cambridge

The following elections to fellowships at Churchill College have been announced: *Title A,* Dr. A. Howie, demonstrator-elect in the Department of Physics and College lecturer in physics; Dr. R. C. Campbell of Gonville and Caius College, University lecturer in agricultural statistics and College lecturer in mathematics for natural sciences; *Title B* (*Junior Research Fellowships*), B. W. Cherry of Trinity College, for research in metallurgy (the Goldsmiths' Fellowship in Metallurgy); M. A. A. Clyne of Trinity College, for research in physical chemistry; A. E. Dorey of Jesus College, for research in zoology; *Title C,* D. G. Kendall, professor-elect of mathematical statistics.

Oxford

Dr. M. D. Gwynne, Junior Research Fellow at Balliol College, has been elected to the Mount Endowment Senior Research Fellowship in tropical ecology (with effect from September 29) at that College.

Weizmann Institute of Science

The following appointments have been announced: Dr. J. H. Jaffe, to be professor in the Department of Infra-Red Spectroscopy; *Associate Professorships,* Dr. Yehuda Eisenberg (nuclear physics), Dr. David Danon (polymers), Dr. Carl A. Levinson (nuclear physics), Dr. Uriel Littauer (biochemistry); *Senior Scientists,* Dr. N. Haran-Gera (experimental biology), Dr. N. Trainin (experimental biology), Dr. A. Nir (isotopes), Dr. A. Patchornik (biophysics), Dr. A. Frankel (applied mathematics), Dr. A. Aharoni (electronics).

Announcements

Mr. D. G. Ryan has been appointed Rutherford Scholar by the Council of the Royal Society for three years beginning in October. Mr. Ryan will continue his work, in the University of Birmingham, on pion–pion resonances in the deuteron–deuteron interactions.

Prof. A. S. Parkes (Physiological Laboratory, Cambridge) has been elected chairman of the Scientific Publications Council in succession to Prof. G. W. Harris (Institute of Psychiatry, London). Mr. A. V. S. de Reuck (Ciba Foundation, London) has been elected honorary secretary, and the other members of the Steering Committee are Mr. A. L. Bacharach, Dr. R. K. Callow, Prof. G. W. Harris and Dr. D. Richter.

The sixteenth International Horticultural Congress, sponsored by the Government of Belgium, will be held in Brussels during August 31–September 8. Further information can be obtained from the Secretary, Sixteenth International Horticultural Congress, 233 Coupure Links, Ghent.

The Mullard Research Laboratories will be holding open days during July 4–6. During these days, each of the five divisions will be showing aspects of the research programmes in physics, electronics and allied fields that are being undertaken at the Laboratories. Further information can be obtained from Mullard, Ltd., Mullard House, Torrington Place, London, W.C.1.

An international symposium on "Environmental Control of Plant Growth", organized under the auspices of the International Union of Biological Sciences, will be held at the Academy of Science, Canberra, during August 25–31. Further information can be obtained from Dr. L. T. Evans, Division of Plant Industry, Commonwealth Scientific and Industrial Research Organization, P O. Box 109 City, Canberra, A.C.T.

An informal discussion, sponsored by the Faraday Society, on "Forces in Colloidal Systems", is to be held in the Department of Chemistry, University of Nottingham, during September 20–21. There will be two half-day sessions, which will include papers on: (*a*) stability of dispersions in aqueous and non-aqueous systems; (*b*) micellization. Further information can be obtained from Dr. G. D. Parfitt, Department of Chemistry, The University, University Park, Nottingham.

Erratum. In the article entitled "Isotope Effects in the Infra-red Spectrum of 1-^{13}C-Propene-1" by Dr. W. O. George, which appeared on p. 672 of the May 19 issue of *Nature*, the units on the abscissa of Fig. 1 should read 940, 920, 900, 880 and 860, and not 1,040, 1,020, 1,000, 980 and 960 as printed.

ATOMIC PHYSICS IN NORTHERN EUROPE

The Danish Atomic Energy Commission

THE fifth annual report of the Danish Atomic Energy Commission* covers the period April 1, 1960–March 31, 1961. It describes the building operations at the Risø Research Establishment and the work of the six sections of the Establishment; the reactors *DR*1, *DR*2 and *DR*3; international co-operation in the peaceful uses of atomic energy through the International Atomic Energy Agency; regional co-operation in Europe through the Organization for European Co-operation and Development and the European Atomic Energy Society; Nordic co-operation through the Nordic Liaison Committee for Atomic Energy; and various other activities including geological surveys in Greenland, educational and training courses, and general information services.

During the period under review there was no change in the membership of the Commission. Prof. Niels Bohr and Dr. H. P. Christensen continued as chairman and vice-chairman respectively and H. H. Koch, permanent under-secretary of State, as chairman of the executive committee. By the Royal decree of March 26, 1960, the jurisdiction of the Commission was transferred from the Minister of Finance to the Prime Minister. The total staff of the Commission on March 31, 1961, numbered 643, of which 420 were employed in the technical and scientific division and distributed over various sections—reactor, physics, electronics, radiation, agricultural research—and the three reactors. The secretariat consisted of a staff of twenty-two at the central office of the Commission at the Christiansborg Palace and of thirty at the subsidiary office at the Establishment.

After the completion of the third and biggest reactor *DR*3 in the beginning of 1960, building operations were concentrated on various supplementary installations required for the work at the Risø Research Establishment. These included a hot-cell facility, begun in August 1960, and the planning of expansions of certain laboratories, the construction of which commenced in March 1961. Research work, which was extended considerably when the big reactors came into operation, continued to develop, especially in connexion with a series of joint research projects on which the Commission has embarked in co-operation with other national and international atomic energy organizations. The Deuterium-moderated Organic-cooled Reactor study project has provided opportunity for study of the optimalization procedure and technical difficulties in the construction of an organic-cooled type of reactor, and participation in the two joint European projects, *Dragon* and *Halden*, has provided opportunity for following important aspects of development in the field of high-temperature gas-cooled and boiling-water types of reactor. Power production with breeder reactors, plutonium recycling and nuclear ship propulsion have not as yet been investigated at Risø. Neither has the Commission engaged much in fusion research, but both theoretical and experimental studies in plasma physics are being undertaken at Risø.

The physics department of the Establishment consists of the physics laboratory, the meteorology station, the reactor *DR*1 and the linear accelerator laboratory. During the year the linear accelerator was used for an extensive series of irradiation experiments for the Atomic Energy Commission and for industry. This has been reported in *Risø Report* No. 16. A group continued on the construction of a laboratory for the investigation of β- and γ-radioactivity, with the particular view of measuring the fundamental experimental constants of the β-radioactivity of the neutron. The solid-state group carried out intensive work on radiation damage, and some preliminary work on radiation damage to graphite at very low temperatures was commenced. The group working on problems of plasma physics and the utilization of the energy of fusion obtained data from a series of studies of electromagnetic shock waves using an instrument designed for this purpose. An international summer school course in plasma physics was held. This was arranged with the economic support of the Advanced Study Institute Program of the North Atlantic Treaty Organization, and of the Rask-Oersted Foundation. The course lasted 14 days and was attended by 130 delegates from 24 countries.

In the electronics department an experimental set-up was arranged in order to study the stability of photomultipliers and a recording single-channel pulse-height analyser mainly intended for use in γ-ray spectroscopy was developed. In addition to other work of a research and development character, work was carried out on nano-second photography using an image-converter tube, and a radio-altimeter was incorporated in the scintillometer used by the Greenland Geological Survey for uranium prospecting in Greenland. A new development within the electronics department was the introduction of a group for industrial instrumentation, the task of which was to advise on and plan experiments requiring conventional industrial control instrumentation. Since its establishment the group, consisting of two graduate engineers and two technical engineers, has worked on a testing cabinet for Wigner rigs; regulating equipment for the Wigner calorimeter; instrument panels for experiments in heat transmission in helium; and instrumentation for the *SAP*-2 experiments. In the annual report details also are given of the activities of the reactor engineering, chemistry and health physics departments.

A separate chapter of the Report deals with international co-operation in the peaceful use of atomic energy. This is discussed under the headings of the International Atomic Energy Agency; and regional co-operation in Europe, including the Organization for European Co-operation and Development, European Atomic Energy Society and Nordic co-operation. In addition to its direct educational and training activities in technical and scientific subjects the Commission tried to satisfy general public interest in nuclear energy and in the Risø Research Establishment by publications, radio and television broadcasts, and by conducted tours of the Establishment. During the period under review about ten thousand persons visited Risø. On March 31, 1961, the Library of the

---

* Report on Activities of the Danish Atomic Energy Commission for the period from 1st April, 1960, to 31st March, 1961. Pp. 70. (Copenhagen: Danish Atomic Energy Commission, 1961.)

Establishment contained 74,000 bibliographical units, including 66,000 reports of which 25,000 were on microcards. On October 1, 1960, the Library engaged a librarian to act as adviser on Russian.

The report concludes with a list of publications by members of the staff of the Commission and with a detailed map of the layout at the Risø Research Establishment.

Nordic Institute for Theoretical Atomic Physics

The third annual report of the Nordisk Institut for Teoretisk Atomfysik (NORDITA)*, which contains both Danish and English versions of the text and covers the period July 1, 1959–June 30, 1960, reports the work continued on the same lines as previous years. The organization still operated on an interim basis, pending the working out by the committee, appointed by the Governments of the member countries (Denmark, Finland, Iceland, Norway and Sweden) and the Nordic Council, of the general principles for the administration of joint Nordic institutions. During the year the board consisted of four members from Denmark, Finland and Norway, respectively, three from Sweden and one from Iceland, with Prof. Niels Bohr as chairman. The staff comprised Prof. C. Møller as director and four scientific and four administrative staff. There were fourteen research fellows, six of whom had had their fellowships extended for a second year. Eleven research fellows and a member of the staff of Nordita, together with other Danish and Swedish physicists, undertook a week's study trip to Geneva for the purpose of a visit to CERN. The report concludes with nine appendixes in which are listed the various publications and lecture notes issued by the Institute during the year; the colloquia and courses of lectures held; the lectures given by visiting foreign physicists; the visits paid by members of the staff of the Institute to other institutions and the attendance of staff and research fellows at congresses and meetings; and the visits paid by the research fellows to their home institutions.

LONG-TERM PLANNING OF RESEARCH IN JAPAN

IN 1954 the Science Council of Japan, a body consisting of 210 members, formed a committee for long-term planning of research. This committee did its main work between 1954 and 1956, but is still continuing its investigations; among its original members were the chairman (Prof. Arisawa), who is an economist, and three secretaries—one an economist (Prof. Tsuru), the second an agricultural scientist (Dr. Fukushima) and the third a mathematical statistician (Prof. Kitagawa). The Committee was concerned with recommendations on population, food, energy, industrial techniques and fundamental sciences.

Prof. Kitagawa has summarized, in the January issue of the *Australian Journal of Science*, the White Paper on Research, published in 1956 by the Science Council of Japan, which deals with fundamental science.

The method of investigation was that of questionnaires to individuals and institutions, issued with the co-operation of national committees in the various sciences. These consisted of two overlapping sections, the first endeavouring to obtain objective information about the departments in which the individuals concerned were working, and the second part asking for suggestions for the improvement of the departments and of Japanese science in general. The results were then submitted to leading experts in each field investigated, and, after this check, proposals were made to meet the problems outlined.

The recommendations were: (1) To raise the general standard of training and research in universities and research institutes by increasing their budgets, and improving their staff position and equipment. (2) To encourage co-operation among university research workers and promote the common uses of apparatus and facilities, partly in order to avoid unnecessary duplication of expensive equipment. (3) 'The liquid scheme'—a proposal for the establishment of central institutes in specialized topics, which would allow the easy exchange of staff between universities and the institutes. The advantages of this scheme would be improved communication between scientists, and considerable savings on equipment which could be located at the central institutes. (4) The uses of National Committees in respective sciences for discussion of important problems in their fields, and the planning of future developments. (5) Availability to the public of all Governmental data and scientific publications.

The Japanese Government has already taken some steps to meet the first recommendation, the second has been partly realized, the third has been established though with a more moderate budget than had been proposed; recommendations 4 and 5 still await full implementation.

In 1959 a report entitled "The White Paper on Fundamental Science, No. 1" was brought out; this pointed out that the development of fundamental science was essential to technical innovation. Japan was lagging badly in the sciences and, unless strong steps were taken, there was a danger that the country would fall farther below international levels. The White Paper contains a discussion of budgets for the pure and applied sciences, including a comparison of total expenditure for these sciences in Japan with the equivalent expenditures in the United States, the U.S.S.R., the United Kingdom and Western Germany. A comparison with these countries of the ratios: (*a*) budget for sciences/total Government budget, and (*b*) budget for sciences/total national income, showed that Japan's relative expenditure was lagging. An example was also quoted of a particular department showing that only about one-third of the total budget set aside for the sciences, less administrative and other costs, finally found its way to the scientists themselves. A study of the numbers of scientific staff showed that, in 1957, in the Faculty of Engineering of the University of Tokyo, 72 per cent of the scientific equipment was antiquated (dating before 1925). Examination of the research system in universities showed that the yearly system of funds and accounts was unsuitable for long-term planning of research. Moreover, the

Japanese 'chair system', whereby the establishment in any particular subject consists of one professor, one assistant professor and two assistants, is not entirely favourable to the pursuit of research particularly in view of the wide range of modern research work.

On postgraduate training and the numerous newly established universities, the White Paper points out that the number of staff, the budget of departments and the scientific apparatus were insufficient for postgraduate training. It was desirable to achieve high academic standards in the large number of new universities created in Japan since the end of the Second World War: these had made an effective contribution to local culture and technical education, and had produced many scientists.

Finally, recommendations were made for the increase of university salaries including the salaries of technicians and assistants, for the defraying of travel costs to conferences, for book discounts to academies, for tax deductions on donations to universities, for study abroad of Japanese scholars and their attendance at international conferences, as well as the invitation of foreign scholars to Japan, and, finally, the encouragement of universities not subsidized directly by the Government.

Some points on scientific education were discussed. In universities the separation into faculties, which is fairly rigid in Japan, was a bad principle, and departmental groupings would be preferable. Broad groupings under mathematical sciences, physical sciences, chemistry, geology and biological sciences would be better than specialized subdivisions in any of these branches. It was suggested that faculties be abolished so that a student could, for example, graduate in both engineering and mathematics if his specialized field were electronics. This is not possible at present.

The final section of the White Paper consists of comparisons, by experts in various fields, of Japanese science with science in foreign countries.

WOMEN IN SCIENCE AND TECHNOLOGY

THE first edition of *Opportunities for Girls and Women in Science and Technology* was published five years ago and was in great demand, indicating that many schoolgirls, teachers, parents and employers were interested in careers for girls in the scientific and technical field. During the past five years more physics and chemistry laboratories have been built and equipped in girls' schools so that a larger proportion of girls who are interested in science have the opportunity to study it basically and prepare themselves for further specialized training. There has been a substantial increase in the number of girls taking mathematics, physics and chemistry in the General Certificate of Education at Ordinary- and Advanced-level, but still the number of young women scientists entering industry and the professions is disappointingly low. At the same time, there are women of real ability in all branches of pure science. There are now fifteen women who are Fellows of the Royal Society.

When looking for reasons for the reluctance of girls to work in the scientific field, it would still seem that there is some fear on the part of girls, and possibly also of parents, of work which is new and a little unusual. They do not realize the satisfaction to be obtained from practical scientific work at all levels. The reason why some schools have a steady flow of girls into technical positions may be because one or two older ones come back to school and talk with enthusiasm about the work they are doing, and make the younger ones interested.

The present demand for scientific manpower means that there are many opportunities for girls and women who have qualifications or who are willing to study while working. A new edition of *Opportunities for Girls and Women in Science and Technology* * describes the kind of professions which are now offering openings. Mathematicians are in great demand, as are physicists and chemists in laboratories. There are many special branches of science such as metallurgy, biochemistry, biophysics and physiology, which are not school subjects but which depend in the first place on the basic scientific subjects learnt at school. An introduction to these branches of science may only come at university-level, but it is the object of the booklet to indicate that such subjects exist and to point to the sources of further information about them. Engineering also falls into this category, and even now few girls take up this work. It is significant that those who enter this field do well, probably because they have to fight against a certain amount of opposition before they get established, so that only the best survive.

The booklet contains details of the many openings in different careers.

ORAL POLIOVIRUS VACCINATION IN COSTA RICA

AN investigation, planned and carried out jointly by the Yale Poliomyelitis Study Unit and the World Health Organization Regional Poliomyelitis Laboratory of the Americas, during the course of a nation-wide vaccination campaign in Costa Rica*, sought to determine the effectiveness of a trivalent oral poliovirus vaccine in immunizing young children living in a tropical environment. More specifically, its aims were to measure the rate of antibody conversion and antibody increase induced by two doses of vaccine given at a month's interval; to determine the prevalence of non-poliovirus enteroviruses in the children, and their possible inhibitory effect on the efficiency of vaccination; and to estimate the extent to which attenuated strains that had been administered spread within the families of vaccinees, and the duration of their excretion by vaccinees and

* *WHO Chronicle*, 16, No. 4; April, 1962.

other children in their families. At the same time, a study was made of polioviruses recovered from flies caught in the area of the trial to see if they were related to those used in vaccination.

The investigation centred on a group of families living in the same village. In each a single child under two years of age, the index child, received the trivalent vaccine on two occasions. In most of the families there were several children under five years of age. The whole group of vaccinees and sibling contacts was tested for enteroviruses and antibody-levels by means of rectal swabs and blood sampling before, during and after the trial.

The results showed that, in general, the immunizing capacity of this particular vaccine, though moderately good, was not entirely satisfactory. Its effectiveness varied considerably for each of the three strains of poliovirus included. The post-vaccinal response to the Type 3 component was excellent; the first dose produced antibody conversion in 79 per cent of susceptible vaccinees, the second in 91 per cent. For Type 1 the conversion-rate was only 35 per cent after the first dose and 71 per cent after the second dose, while the Type 2 strain had little effect—only 35 per cent being converted even after the second dose. There was some evidence that heavy non-poliomyelitis enterovirus infection preceding the trial reduced the response to the Type 1 component to some extent, and that such inhibition was possibly due to *ECHO* virus 12. This interference did not seem to affect Type 3 responses, and the situation with regard to Type 2 was difficult to evaluate. On the whole, interference by enteroviruses was not of great importance; but interference between the vaccine strains themselves was of some significance—the highly infectious Type 3 seemed to some extent to crowd out the competing polioviruses, as well as other enteroviruses. It might well be desirable to enhance the future efficiency of this particular trivalent vaccine by reducing its content of Type 3 poliovirus and increasing the dose of the other types, particularly Type 2.

The degree of spread of attenuated vaccine strains within families, from the index child to other young children, proved to be considerable, the conversion-rates among susceptible siblings for Types 1 and 3 being 85 per cent and 77 per cent respectively. Type 2 had little opportunity to spread as it infected so few vaccinees. The speed of spread was impressive. Vaccinees could be shown to be excreting virus within 18 hr. of administration, and at least one sibling contact had picked it up within five days of the original infection. This is consistent with the familiar clinical experience that, in family outbreaks caused by wild virulent strains, several cases often appear within a day or two of each other, giving the false impression that a single extra-familial source has been responsible for a number of separate infections.

It was noted that susceptible children, whether vaccinees or only contacts, excreted Type 3 virus after infection for periods of up to 40 days. Half were infectious for at least three weeks. This did not happen with children who had some level of pre-vaccinal antibodies; most of these failed to become infected at all and those who were infected excreted virus for only 2–4 days on the average.

Although it proved surprisingly easy to recover polioviruses and other enteroviruses from flies trapped in the village during the trial, and although the kinds of virus recovered roughly paralleled in incidence those found in rectal swabs collected from children studies, the evidence provided by genetic markers was that many of the Type 3 insect-borne strains were, in fact, wild ones. But not all could be so identified, and it seems quite possible that flies are capable of picking up and disseminating the attenuated strains used in oral poliovaccine campaigns.

INSECTS OF THE PACIFIC AND ANTARCTIC AREA

The first report on the zoogeography and evolution of Pacific insects and studies of airborne insects in the antarctic area, which was supported mainly by grants from the U.S. National Science Foundation, the U.S. Office of Naval Research, U.S. Antarctic Research Program, the J. S. Guggenheim Memorial Foundation, and the U.S. Educational Foundation (Fulbright fellowship), has recently been published*.

Dr. Gressitt is to be complimented on the energy and thoroughness with which he has carried out these projects, and considerable progress has been made in an investigation which will take many years to complete.

In the introduction, Gressitt discusses the history of the zoogeography of the area and the various problems involved. Then follow sections on environment, dispersal, establishment, evolution, nature of island populations and faunal origins and affinities. Next comes a section on the Island Groups including Micronesia. This section is followed by an account of the Papuan Sub-region, Australia, New Zealand, the Sub-antarctic Islands, and Antarctica. The latter two sections are illustrated by excellent colour photographs and the remainder by good photographic figures. Experiments were made in the sub-antarctic in trapping flying insects by means of many large nets flown from the rigging of a ship. Although insect dispersal by air was demonstrated, most insects arriving on the Antarctic continent by this means would fail to establish themselves, because of lack of appropriate food and environment. However, this would not be the case in many of the Pacific Islands, but the impoverished insect fauna of most islands indicates that this method of dispersal is rarely effective.

The rest of the report, illustrated by excellent distributional maps, consists of sections on the detailed zoogeography in the Pacific area of the insect groups, Cerambycidae and Chrysomelidae, by Dr. Gressitt and, in the appendixes, on the Machaerotidae (Hemiptera Homoptera: Cercopoidea) by Dr. T. C. Maa, Tabanidae (Diptera) by Dr. I. M. Mackerras, Phasmatodae by Dr. Setsuko Nakata, and Psychodidae (Diptera) by L. W. Quate.

MESOSPHERIC DENSITY AND WINDS DETERMINED BY THE FALLING SPHERE METHOD AT WOOMERA

By B. ROFE

Weapons Research Establishment, Salisbury, South Australia

KNOWLEDGE of density and wind profiles is important in the design and in the performance assessment of guided weapons and of vertically rising rocket-vehicles. Standard meteorological flights using radar-tracked balloons carrying radiosondes may, under favourable conditions, cover conditions to 120 kft. (1,000 ft.). The space between 120 kft. and satellite height at 500 kft. can only be probed by rocket-borne sensors. The Weapons Research Establishment has designed rocket-vehicles to cover soundings to a height of 300 kft. Mesospheric winds at Woomera have been previously obtained by the radar tracking of 'window' clouds and by the optical tracking of glowing clouds formed by grenade explosions. Temperature and wind profiles have also been determined in the Royal Society programme of *Skylark* rocket firings ejecting grenades and 'window'. The University of Adelaide[1], using the Doppler effect on radio waves reflected from ionized meteor trails, has determined wind profiles in the 260–328 kft. height band. Using all results, the seasonal pattern over southern Australia, particularly of wind profiles, is becoming clearer.

The falling-sphere experiment, where an inflatable sphere is ejected from a high-altitude rocket and, as it falls, is tracked optically or by radar, allows a density and a wind profile to be obtained with a minimum of ground instrumentation. The results are readily analysable using the IBM 7090 computer available at the Weapons Research Establishment, and from the simple relationship which exists to 300 kft. between pressure, temperature, density and height, pressure and temperature profiles may be obtained from the density profile. The simplicity of the experiment indicates that it may be suitable for firings on a synoptic basis.

Table 1. ACCURACY OF TRACKING INSTRUMENTATION

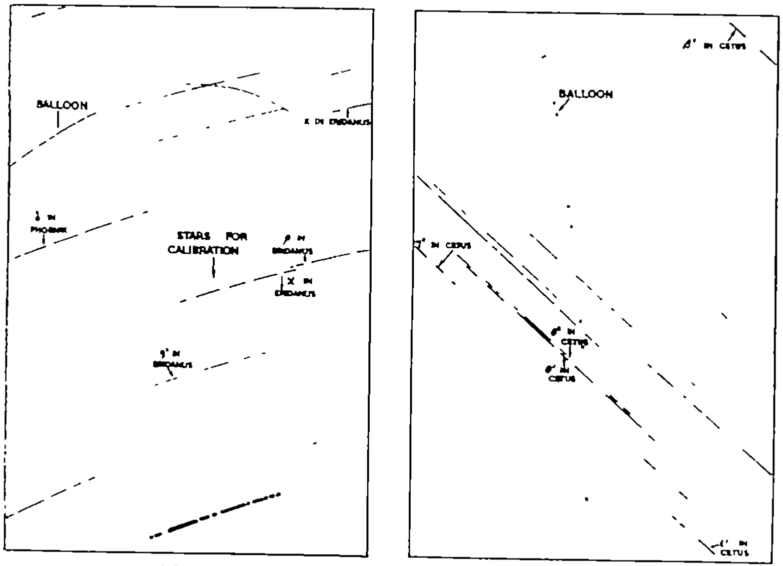
Instrument	Performance and error
*FPS*16 radar Power output of 1 MW. at 6 cm.	A 10-sq.m. target can be tracked to a range of 180 miles with a range error of 5 yd. and angular error of 0·1 mil.
Ballistic cameras on a 50-mile baseline	Can record seventh magnitude stars at stellar rates. The angular accuracy of the instrument is 8 sec. of arc.
Baker-Nunn camera *f*1·0 with 30° × 5° rectangular view	Objects equivalent in brightness to thirteenth magnitude stars and moving at satellite rates can be recorded with an accuracy of 2 sec. of arc.

On December 14, 1961, a sphere was ejected at 384 kft. at Woomera from a two-stage sounding rocket. After inflation, the sphere continued to an apogee of 423 kft., and from the rates of fall during its descent and from the ground projection of the trajectory, density and wind profiles have been determined.

The instrumentation covering the firing was two type *FPS*16 radars, two ballistic cameras and the Baker–Nunn satellite camera. One radar was situated 11 miles behind and the other 105 miles in front of the launch point. Taking the pictures shown in Fig. 1, the ballistic cameras on each flank of the trajectory were using rotating and sequenced shutters to give an analysable time-history of the sphere. Situated some 19 miles behind the launch point, the Baker–Nunn camera, at a slant range of 90 miles, took pictures of the sphere as shown in Fig. 2 at 2-sec. intervals and 1/5th sec. exposure. The performance capabilities of the instrumentation used are given in Table 1.

The sphere was constructed with 20 gores of 0·0005 in. metallized 'Melinex' and inflated to a superpressure of 9 m.bars by isopentane. The diameter of the sphere had been tested prior to the trial, and over randomly selected diameters, the cross-sectional areas varied from those of a 2-metre sphere by less than 0·25 per cent. Previous work at the University of Michigan[2] had determined the drag coefficients of a sphere at various Reynolds and Mach numbers, and these were used in the determination of the density profile.

The firing took place at 1959 C.S.T., 36 min. after sunset when the Earth's shadow extended to 190 kft. The nose cone separated from the body at 270 kft. and some 40 sec. later the balloon was ejected at 384 kft. Sequences as seen by the Baker–Nunn camera are given in Fig. 2. After ejection the sphere rapidly inflated, and was easily seen in the sunlight



(*a*) (*b*)

Fig. 1. *a*, Camera with a rotating shutter; *b*, camera with a sequenced shutter

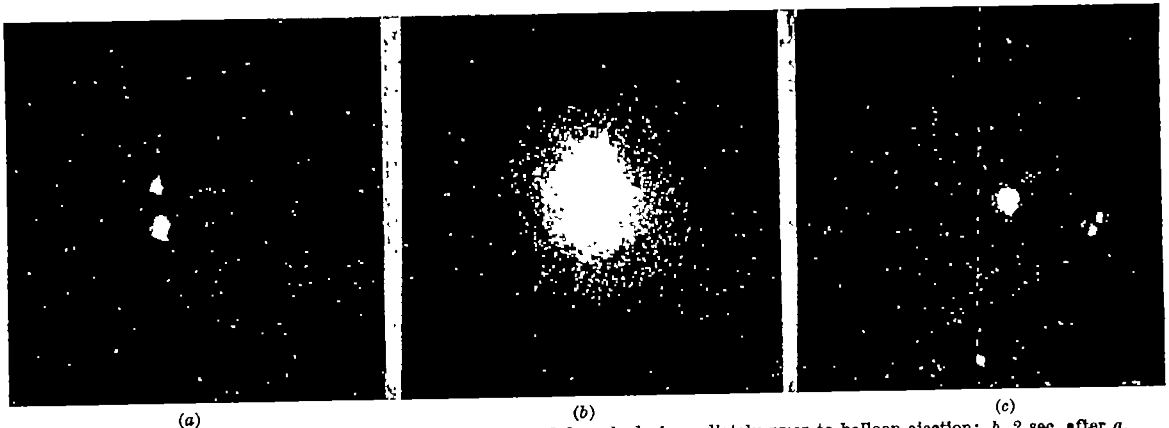


Fig. 2. Baker–Nunn exposures (*c.* × 16) (*a*) head separated from body immediately prior to balloon ejection; *b*, 2 sec. after *a*, indicating reflexion from cloud of French chalk; *c*, 14 sec. after *b*, showing chalk particles travelling with the balloon and images of rocket parts

having an intensity of a $+\frac{1}{2}$ visual magnitude star at apogee, ensuring optical coverage and allowing the radars to acquire the sphere by optical aids.

An initial check on the density at 226 kft., using unsmoothed radar data and the mean of values from 217 to 237 kft., indicates a density 6 per cent lower than the mean *ARDC* 1959 value. Vertical winds in the mesosphere of the order of 50 ft. sec.$^{-1}$ have been previously measured at Woomera[3], and assuming such vertical winds, an analysis has shown that this falling sphere of $\frac{\text{area}}{\text{mass}}$ ratio = 25 will give density with an accuracy of 5–10 per cent for the height-range 240–300 kft. Final figures will be obtained using a smoothing technique for the range elevation and azimuth values of the radar.

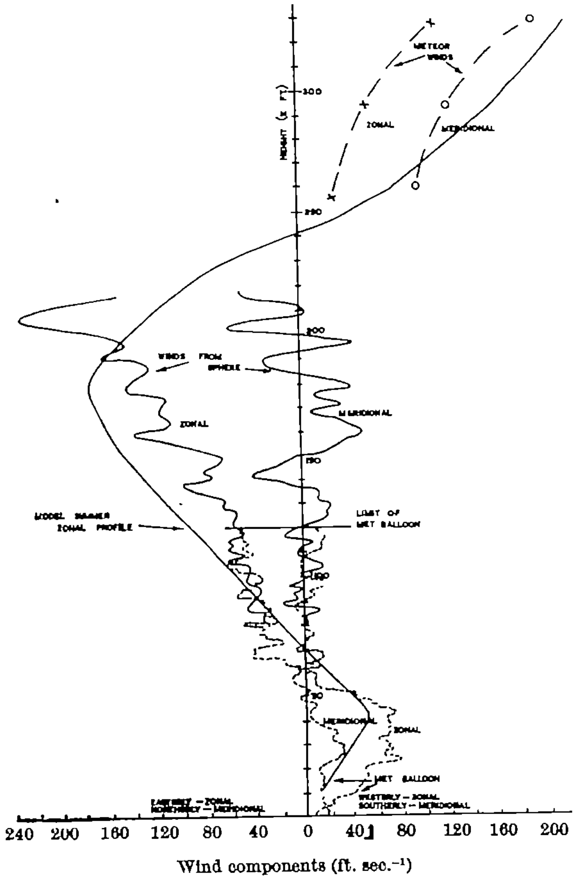

Fig. 3. Composite wind profile, December 14 1961

The rapid rate of fall of the sphere, a maximum of 2,700 ft. sec.$^{-1}$ at 285 kft., did not allow reasonable wind sensing to commence until the sphere had fallen to 220 kft., where the rate of fall was 690 ft. sec.$^{-1}$. The wind profile obtained by the two *FPS*16 radars, although separated by 116 miles, showed reasonable agreement indicating the reality of the fine structure. For the 80–120 kft. region, winds obtained from the falling sphere were compared with winds obtained from a meteorological flight which was about $2\frac{1}{2}$ hr. later at these heights. The differences which are shown in the composite wind profile of Fig. 3 may be due to time variation or a height error of up to 3,000 ft. in the determination of the meteorological balloon height in this region. Winds in the 250–350 kft. region were determined at the University of Adelaide using readings extending over the period December 4–14, 1961, and while the limitations in applying winds taken at Adelaide (lat. 35° S.) to Woomera (lat. 31° S.) and in using mean winds over 10 km. height bands are appreciated, Elford's results[1] indicate the errors are not extreme.

The composite wind profile is compared in Fig. 3 with a model summer zonal profile which had been previously prepared. Although this firing occurred in the first third of the summer, the strongly established easterlies at 150–200 kft. confirm what has been previously noted by Keegan[4] and Rofe[5] that the seasonal transition is often more advanced in the higher levels.

The Baker–Nunn camera, although some 90 miles from the point of ejection of the sphere, gave evidence of an interesting phenomenon. The sphere had been packed with approximately 20 gm. of French chalk for lubrication from the chamber at ejection, and to prevent adhesion between touching gores when packaging. Fig. 2*a* shows the 18-in. nose cone some time after separation from the main body with both portions being seen in the sunlight. 2 sec. later the sphere and the chalk had been ejected as seen in Fig. 2*b*. The image is assumed to be formed from the chalk by the diffuse reflexion of sunlight rather than by excitation of particles in a shock front or by photoluminescence. Assuming an albedo of 0·8 and the mean diameter of chalk particles of 2μ, the luminance is approximately 6,000 candles/gm. Further experiments will be performed using more chalk, and spectra, if possible, will be obtained.

The results reported here are an initial assessment only, and no attempt has been made to analyse errors. Continued experiments with the falling sphere will no doubt reveal differences in the mesospheric structure between the northern and southern hemispheres.

TRANSFER COEFFICIENTS AND THE ACTIVITY OF ELECTRODE SURFACES

By W. A. LEDGER and Dr. A. C. RIDDIFORD

Department of Chemistry, University of Southampton

A GENERAL problem in the investigation of heterogeneous processes at solid/fluid interfaces is the difficulty of accounting quantitatively for variations in the activity of the solid surface from sample to sample, or from point to point on the surface of a given sample. In the case of electrode processes, an alteration in the activity of the electrode surface is reflected by a change in the observed exchange current density, i_0. Similarly, a heterogeneous surface is characterized by different values of i_0 at different points on the surface[1-3]. Presumably, therefore, it should be possible to account for the variation in activity in terms of the factors which influence i_0.

For an electrode process with a single rate-determining step, i_0 is a measure of the velocity, at equilibrium, of the anodic and cathodic partial reactions which constitute this step. Thus, it is essentially the product of a characteristic rate constant and a mass action term, which expresses the influence of the activities of the reactants and products. On this kinetic view, a variation in the activity of the electrode surface can be assessed through a change in the characteristic rate constant.

Often, the rate-determining step involves electron transfer between the electrode and a species adsorbed on its surface[4]. In this case, the rate constant is potential dependent and may be regarded formally as the product of three terms, a pre-exponential factor, an exponential term involving the height of the energy barrier at some arbitrarily chosen potential, and an exponential term which, through the transfer coefficient, expresses the way in which the height of this energy barrier is modified as the potential of the electrode is altered. There is much to be said in favour of choosing, as the reference potential, that value at which the height of the energy barrier is the same for both the anodic and cathodic partial reactions[5]. This has been termed the characteristic potential[6].

It is pertinent to inquire how these three terms alter when the activity of the electrode surface changes, a point which does not appear to have been the subject of explicit discussion. In so far as the question has been considered at all, it may be inferred from the literature that most workers would agree that it is the height of the energy barrier at the arbitrary reference potential which varies, and that the transfer coefficient is invariant. We support this contention by reference to the work of Parsons[7], Gerischer[8] and Thomas[9], in which they consider the variation in i_0 for the hydrogen electrode process on different metals.

On this view, heterogeneity of the solid surface is to be interpreted as a variation in the height of the energy barrier from point to point, reflecting a variation in the adsorption energy, a view which finds its counterpart in the field of heterogeneous catalysis. A refinement leads to the 'differentiated site theory', which was developed for the hydrogen electrode[1,10] from a suggestion by Audubert[11] that charge and discharge do not necessarily occur at the same sites and are not necessarily strictly the reverse of each other.

Audubert's work merits more consideration than it has received, since it indicates that a change in the adsorption energy from site to site on a heterogeneous surface may be accompanied by a change in the transfer coefficient, that is, by a change in the shape of the energy barrier. Certain cases of transport-controlled processes, in which the slope of the plot of the Nernst equation is greater than that to be expected from the stoicheiometric equation, have recently been interpreted from this point of view[4].

We now wish to extend these considerations by observing that, in certain cases at least, a variation in activity can be expressed completely in terms of a change in the transfer coefficient. For the iodine, iodide[6] and ferricyanide/ferrocyanide[12] redox processes at platinum disk electrodes, the apparent transfer coefficient varies with the bulk concentrations of the participating species, and with the angular velocity of the disk. At first sight surprising, this can be attributed to two factors. The method adopted for determining the transfer coefficient from the observed current/potential data considered both the anodic and cathodic partial currents, and was based on the assumption that the electrode surface was uniform, that is, that the anodic and cathodic transfer coefficients summed to unity. This assumption is clearly false for most solid electrodes, but it can be removed by introducing a potential[6] $\varphi_{Z=i}$ defined by:

$$\varphi_{Z=i} = \varphi_0 + \frac{RT}{(1-\alpha)F}\ln i_0$$

where φ_0 is the reversible electrode potential, and $1-\alpha$ is the cathodic transfer coefficient. For a uniform surface, $\varphi_{Z=i}$ is a function of the composition of the solution, but should be independent of the angular velocity of the electrode. Since, however, $1-\alpha$ varied with the angular velocity, $\varphi_{Z=i}$ also varied; but plotting this potential against $1/(1-\alpha)$ gave a linear plot for each different solution. Correcting the slopes to unit concentrations of the participating species gave a constant value for the rate constant at the characteristic potential φ^*, indicating that there was no change in the height of the energy barrier at this potential. Each plot gave

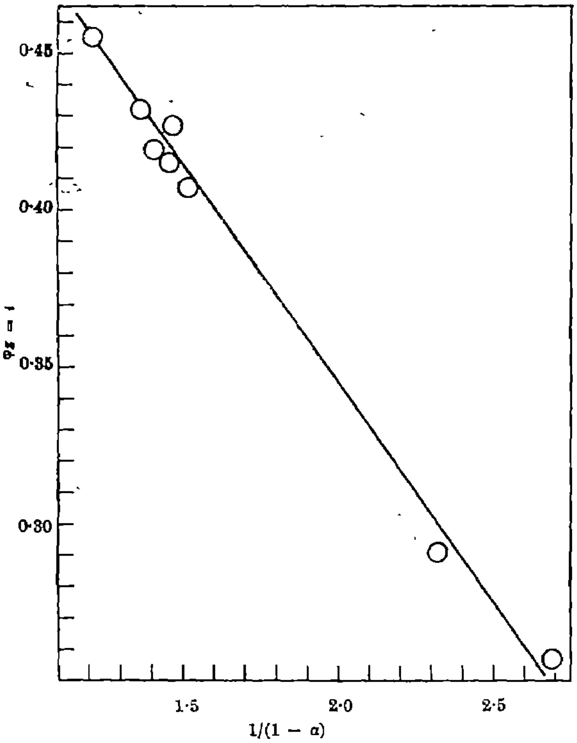

Fig. 1. $\varphi_{E=i}$ (V., on decinormal silver/silver iodide scale) against the reciprocal of the apparent cathodic transfer coefficient. In each case the solution was 1·05 × 10^{-4} *M* in I_3^- and 0·1 *M* in I^-. The disk was rotated at 60 r.p.m.

the same intercept, φ^*, when extrapolated to $1/(1-\alpha) = 0$, and, for both electrode processes, φ^* was close to the standard potential.

In these experiments, no particular care was taken to ensure that the electrode was in the same state of activity each time, and it was noted that duplicate experiments sometimes gave markedly different values for $1-\alpha$ and $\varphi_{E=i}$. Nevertheless, these fitted the linear plot appropriate to the particular solution composition. This suggested that it would be of interest to examine the effect of deliberately altering the activity of the electrode surface to see if the same correlation holds.

Preliminary results on the iodine redox process at platinum disk electrodes indicate that the correlation does hold. In Fig. 1, the points correspond to a series of experiments in which the disk was subjected to different pre-treatments. These included cleaning the disk with a chromic/sulphuric acid mixture, anodically polarizing it in this mixture, and anodically polarizing it in dilute hydrochloric acid for different periods. Between experiments, it was left exposed to a laboratory atmosphere which contained alkyl phenols.

The slope, corrected to unit concentration and unit apparent area, corresponds to a rate constant of 5·6 × 10^{-8} mole.cm.$^{-2}$sec.$^{-1}$, and the intercept gives φ^* = 0·623 V. on the decinormal silver/silver iodide scale. These may be compared with the values 3·4 × 10^{-8} mole.cm.$^{-2}$sec.$^{-1}$ and 0·626 V. found previously in a different laboratory atmosphere[6]. The agreement is satisfactory, particularly in view of the fact that the slope is a function of the actual, rather than the apparent, surface area.

The correlation is striking, although the actual effect of these different treatments on the surface is as yet unknown.

We thank the Chemical Society for a grant to one of us (W. A. L.), and Messrs. Burts and Harvey, Ltd., for providing laboratory facilities.

OSMOLARITY

Dr L. R. KARHAUSEN

Department of Social Medicine, University of Brussels

THE clinical importance of the measurement of osmotic pressure of body fluids led to the definition of a new system of units which are used in biology and medicine, osmoles and milliosmoles. By analogy with molality and molarity, the expressions of osmolarity and osmolality are being used (although physical chemistry ignores them) and represent the molar concentration of all the osmotically active particles which are in a solution; osmolality is expressed per unit of weight and osmolarity per unit of volume.

If the solution is an ideal non-electrolyte, which means that it does not dissociate, the osmolality equals the concentration of the substance. If the substance dissociates and behaves like an ideal electrolyte, that is, an electrolyte which dissociates completely, the expression looks like: osmolality = nC, where n equals number of ions or particles in which the substance dissociates, and C equals concentration of the substance.

Real solutions require a more elaborate equation. The dissociation of a salt depends not only on its concentration but also on its activity, which itself may depend on the *p*H, the temperature, the pressure and even the concentration of the salt. Moreover, splitting enzymes are present in body fluids, which can break larger molecules into smaller fragments, increasing the osmolarity without modifying the solute content. Finally, the presence of ion-complexing substances in body fluids introduces another factor of error.

Differences between calculated and measured values of urine osmolarity can be more than 30 milliosmoles per litre, and percentage differences more than 20 per cent[1]. The same discrepancies between calculated and measured values have been observed in the plasma of patients with abnormal osmotic pressure[2].

When reference is made to osmolarity in this article, it concerns measured osmolarity. There will be no mention of the so-called 'ideal' osmolarity which represents the expected osmolarity, assuming a complete dissociation.

"Measurement," writes Nagel, "has been defined as the correlation with numbers of entities which are not numbers." Measurement leads to define units, and there are two kinds of units. First of all, units measuring additive or extensive qualities, units of weight, for example. On the other hand, densities, for example, are intensive or non-additive units, since mixing two liquids of known density does not result in a mixture the final density of which equals the sum of the two initial ones. The same holds for osmotic pressure.

E. Nagel[3] mentions a series of axioms which are the formal conditions of measurement. Assuming that a, b and c are three entities to be measured, then: (1) either $a > b$, or $a < b$, or $a = b$; (2) if $a > b$, and $b > c$, then $a > c$; (3) for every a there is an a', such that $a = a'$; (4) if $a > b$, and $b = b'$, then $a > b'$; (5) if $a = b$, then $b = a$; (6) for every a there is a b, such that $a > b$ (within limits); (7) for every a and b there is a c, such that $c = a + b$; (8) $a + b > a'$; (9) $a + b = a' + b'$; (10) $a + b = b + a$; (11) $(a + b) + c = a + (b + c)$; (12) if $a < b$, there is a number n, such that $na > b$ (also within limits).

The last six axioms are to be fulfilled if the measured quantities are to be additive. It is clear that, in the case of osmoles, axiom (9), for example, is not necessarily fulfilled. If two solutions of salts are mixed and if these salts are totally dissociated, and have no common ion, the final number of osmoles might equal the sum of the osmoles measured in the two initial solutions. However, if the same operation is made with two salt solutions having a common ion (in the presence of a common ion, the dissociation diminishes), or if their dissociation is dependent on temperature or pH, and if one of these parameters changes, the final number of osmoles may not be equal to the sum of the initial ones. So it appears that a major shortcoming of the concept of osmole is that this unit is not additive, although it was intended to be so, as shown by the analogy of nomenclature with moles, which are additive units.

Gamble[4], for example, evaluates the number of osmoles excreted per 24 hr. as a function of the diet with the implicit assumption that a patient must be in osmolar balance and must excrete as many osmoles as his diet brings him.

Another restriction imposed on the osmolarity comes from such metabolites as urea and glucose, for example, which can diffuse in the cellular department. Urea diffuses so freely through the body membranes that, physiologically, it exerts no osmotic effect, except at the level of the renal tubule, which is not permeable to urea. It is therefore evident that urea should not be accounted for in the measurement of the blood osmolarity, and some authors indeed subtract it from the measured values and express their units in terms of 'efficient osmolarity'. The reverse is true for the urine where such a subtraction should not be done, since urea exerts an osmotic pressure during the elaboration of urine in the kidney.

Examination of water excretion led some authors to consider two fractions or clearances, the osmolar clearance and the free water clearance. C_{osm}, the osmolar clearance, is that water which would contain a concentration of osmoles equal to that of the parent filtrate. C_{H_2O} or the free water clearance is positive or negative according to whether the urine osmolarity is smaller or higher than that of the glomerular filtrate[5].

$$C_{\text{osm}} = \frac{U_{\text{osm}}V}{P_{\text{osm}}}.$$

This equation might be very difficult to apply, since U_{osm} is a partial function of V; that means that the total number of osmoles depends on the urinary volume, which is another example of the non-additivity of osmoles. (Multiplication is repeated addition: U times V corresponds to adding U, V times to itself.) Moreover, what is the clearance of osmoles in a uræmic patient ? Should the osmolarity of the blood urea be subtracted from the measured value ? What then about the urine urea ?

In summary, the purpose of this article is to point out some of the inadequacies of the concept of osmolarity, and its fallacies: (1) Osmolarity is not necessarily a linear function of the amount of solutes. (2) Osmoles are non-additive units. (3) 'Efficient osmolarity' adds more imprecision to the evaluation and the comparison of biological data.

USE OF SURFACE ACTIVE AGENTS FOR ESTIMATING THE CHARGES IN GELATIN AT THE ISOELECTRIC POINT

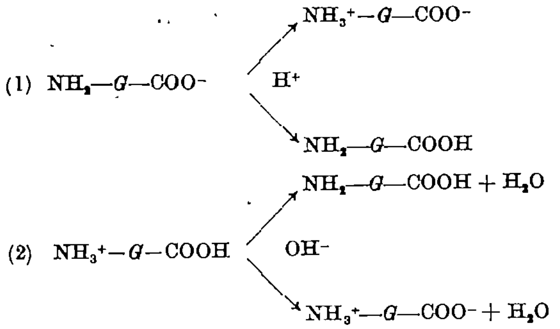
By M. G. T. SHONE*

Soil Science Laboratory, Department of Agriculture, University of Oxford

THE titration of gelatin with acids and alkalis gives information on the net combining power of the basic and acidic groups on the protein molecules. This method has been used[1,2] to estimate the position of the isoelectric point, at which the number of positively and negatively charged groups are equal. thus, Hitchcock[2] measured the pH of sols of gelatin in dilute hydrochloric acid and sodium hydroxide at various concentrations. From the measured pH, he calculated the free H^+ and OH^- concentrations in the sols. He considered that the difference between these values and the molarity of the acid and the alkali used would represent the amount of H^+ or OH^- which had combined with the gelatin. These reactions may be schematically represented thus:

---

* Present address: Agricultural Research Council Radiobiological Laboratory, Letcombe Regis, Wantage, Berks.



$$(1)\ NH_2{-}G{-}COO^- \xrightarrow{H^+} \begin{cases} NH_3^+{-}G{-}COO^- \\ NH_2{-}G{-}COOH \end{cases}$$

$$(2)\ NH_3^+{-}G{-}COOH \xrightarrow{OH^-} \begin{cases} NH_2{-}G{-}COOH + H_2O \\ NH_3^+{-}G{-}COO^- + H_2O \end{cases}$$

In these equations, G represents the protein residue, and NH_3^+, COO^-, refer respectively to all the positively and negatively charged groups attached to the protein residue. At pH 4·9, Hitchcock showed that there was no difference between the H^+ concentration of the sol and the molarity of the hydrochloric acid solution used, thus characterizing the isoelectric point.

Titration methods involving acids and alkalis give no indication of the actual number of positive and negative charges at the isoelectric point. It was thought that a study of the uptake of surface active agents could lead to a value for this quantity, which does not appear to have been reported in the literature. Pankhurst and Smith[3–5] have shown that gelatin forms complexes with anionic and cationic surface active agents (for example, sodium alkyl sulphates and cetyl pyridinium bromide respectively). They conclude that under the following conditions the polar groups of the surface active agents unite stoichiometrically with the charged nitrogenous and carboxyl (or phenolic) groups: (1) absence of concentrated electrolyte solutions; (2) relatively low pH values (that is, less than about pH 7).

In the presence of molar potassium chloride, and at high pH values, anionic surface active agents can be taken up in far greater quantity and appear to unite with the peptide groups of the protein chains. This effect is less pronounced for the secondary alkyl sulphates (for example, 'Teepol'[6]) than for the primary compounds.

Cetyl pyridinium bromide (CPB) solutions are easily standardized with potassium dichromate using the method of Epton[7], who also describes a technique for standardizing sodium alkyl sulphates against CPB. Solutions of 0·00912 N CPB and 0·00507 N 'Teepol' were prepared in this manner. 0·1 gm. powdered bone gelatin, purified by the method of Northrop and Kunitz[8], was added to 20-ml. portions of standard CPB or 'Teepol' solution in a series of test-tubes. To each of these were added 20 ml. dilute hydrochloric acid, water or dilute potassium hydroxide in order to vary the pH of the aqueous phase. The tubes were corked and the contents equilibrated on a rotary shaker for two days at room temperature, at which the solubility of the gelatin was found to be not more than 0·2 per cent. The gelatin was allowed to settle, and aliquots of the aqueous layers of the CPB series were titrated with standard 'Teepol'. Similarly, the 'Teepol' series was titrated with standard CPB. The quantities of surface active agents taken up by the gelatin were given by the difference between the quantities present in the original standard solution and those in the final aqueous phase, calculated from the titres.

Enough solid potassium chloride was then added to each tube to produce saturated solutions. The pH of these was determined by means of a Cambridge pH meter. The potassium chloride was introduced in order to suppress H^+ concentration gradients in the gel phase, so that the measured pH of the aqueous phase should more nearly approximate to that in the gelatin[9]. A sample of the original gelatin was dried to constant weight in an air oven at 100° C. so that the results could be expressed as uptake of 'Teepol' or CPB per gm. oven-dry gelatin. These results are plotted against the measured pH in Fig. 1. The point at pH 2 (0·87 m.equiv./gm.) for the anionic surface active agent is taken from the results of Pankhurst[5], who used sodium dodecyl sulphate.

The pH at which the 'Teepol' and CPB curves intersect should represent the isoelectric point. The value of 4·9 is in good agreement with that derived from titration curves and from electrophoresis experiments. Fig. 1 also shows that there are still about 0·2 m.equiv. of positive and negative charge per gm. gelatin at this point.

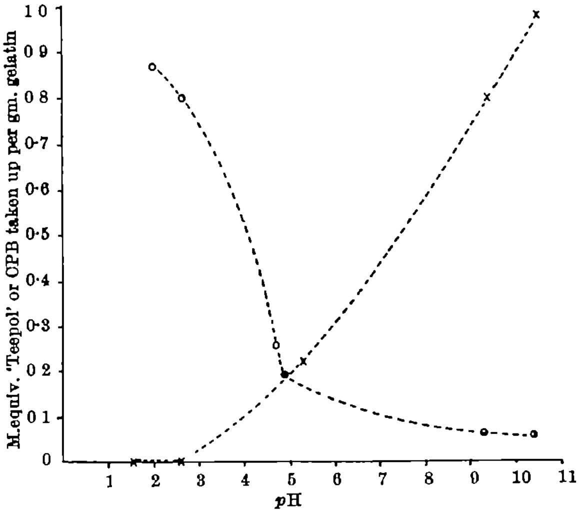


Fig. 1. Uptake of 'Teepol' (○) and cetyl pyridinium bromide (CPB) (×) with varying pH

Published titration curves[1,2] indicate that at pH 2, at which the carboxyl groups are almost entirely undissociated, there are about 0·9 m.equiv. of positive charge per gm. gelatin, which agrees reasonably well with Pankhurst's figure of 0·87. The results obtained at the alkaline end must be treated with caution; the general form of the 'Teepol' curve is, however, consistent with the progressive discharging of the imidazolium (pK 5·6–7·0), α-ammonium (pK 7·5–8·4), ε-ammonium (pK 9·4–10·6) and guanidinium (pK 12·0–13·0) groups in gelatin. Possible hydrolysis of —CO—NH— linkages at high pH values introduces uncertainties in the value of the total negative charge developed at the far alkaline end; Pankhurst's results indicate that at pH 12·5 this may have a value of from 1·3 to 1·7 m.equiv. depending on the chemical nature of the cationic surface active agent.

MODEL COMPOUNDS FOR METAL–PROTEIN INTERACTION: CRYSTAL STRUCTURES OF TWO GLYCYLGLYCYLGLYCINE–COPPER COMPLEXES

By T. COOPER*, Dr. H. C. FREEMAN, Dr. G. ROBINSON and Dr. J. C. SCHOONE†

School of Chemistry, University of Sydney

IN an effort to gain a detailed understanding of the steric relationships involved in metal–protein interaction, we have embarked on a programme of crystallographic studies of metal–peptide complexes[1]. In this article we wish to describe the first two determinations of the crystal structures of complexes between a metal and a tripeptide.

When a concentrated aqueous solution of equimolar proportions of cupric chloride and glycylglycylglycine is allowed to stand for some days, stable blue-green crystals of glycylglycylglycino copper(II) chloride 1·5-hydrate (compound *a*) are formed. The crystals have the shape of a distorted boat: two parallel faces are planar, while the two other faces are distinctly curved and meet at the 'bow' and 'stern' of the boat. The sides of the boat are not perpendicular to the top and bottom faces. The crystals are monoclinic, space-group $C2/c$, with $a = 21{\cdot}36$ Å., $b = 6{\cdot}72$ Å., $c = 15{\cdot}64$ Å. and $\beta = 98°\ 15'$. With eight formula units in the unit cell, $D_x = 1{\cdot}88$ gm./cm.^{3}.

Under alkaline conditions, cupric ion and glycylglycylglycine yield a completely different complex. Violet crystals of sodium glycylglycylglycino cuprate(II) monohydrate (compound *b*) may be obtained by a method described by Rising, Parker and Gaston[2]. Freshly precipitated cupric hydroxide dissolves in a solution of glycylglycylglycine containing an excess of alkali. When the resulting violet solution is added to a large excess of an alcohol–ether mixture and is allowed to stand for some days, violet crystals of the glycylglycylglycine–copper(II) complex are formed. These crystals are flat hexagonal prisms, monoclinic, with space-group $I2/c$. There are eight formula units in a unit cell with dimensions $a = 14{\cdot}33$ Å., $b = 10{\cdot}56$ Å., $c = 13{\cdot}18$ Å., $\beta = 92°\ 58'$, $D_m = 1{\cdot}92$ and $D_x = 1{\cdot}94$ gm./cm.^{3}.

The structure of compound *a* is shown in Fig. 1. It was determined by three-dimensional Patterson and Fourier methods from the complete data observable with copper K_α-radiation. In addition to the water molecule included in the formula of the substance written as a monohydrate[2], an additional water molecule was discovered on a two-fold axis, so that the correct molecular formula is that of a 1·5-hydrate. After preliminary least-squares refinement with a single isotropic temperature factor and two cycles of refinement including individual anisotropic atomic thermal parameters, the residual $R = 14{\cdot}1$ per cent.

For compound *b*, the structure was similarly solved by using the three-dimensional copper K_α-data. After least-squares refinement with anisotropic thermal parameters, the residual $R = 13{\cdot}2$ per cent. The structure is shown in Fig. 2.

The details of the structure analyses and refinements will be reported in subsequent communications. This article is confined to a general description of the two structures and to some comments on their relationship to some other recently determined structures of metal complexes.

In compound *a*, the peptide chain is attached to two copper atoms, and each copper atom is bonded to two different peptide molecules. Five-fold co-ordination about each copper atom results from a square-pyramidal arrangement of nearest neighbours. The base of the pyramid consists of the nitrogen and peptide oxygen atoms of the first glycine residue of one peptide molecule, the negatively charged oxygen of the terminal carboxyl group of another peptide molecule, and a chloride ion. The three peptide ligand atoms are all about 2 Å. from the copper atom, and the chlorine is located 2·2 Å. from it. At the apex of the pyramid, 2·3 Å. from the copper, lies the oxygen atom of a water molecule. The copper atom itself lies slightly 'above' the base of the pyramid, that is, displaced in the direction of the water molecule.

An additional water molecule (the .5-H_2O in the formula) lies on a two-fold symmetry axis, neatly hydrogen-bonded between four peptide chains.

The copper atom in complex *b* is also 5-co-ordinated. Its nearest neighbours are a square of three nitrogen atoms and one oxygen, all about 2 Å. away, plus a fourth nitrogen lying along the normal to the square and about 2·6 Å. above the copper. This complex has a dimeric character, the two halves of the dimer being related by a two-fold axis. In each half of the dimer the peptide molecule lies close to the plane of the three nitrogen atoms which are bonded to the copper. Only the terminal carboxyl group leaves this plane so that one oxygen atom occupies the fourth position in the co-ordination square of the adjacent copper atom. The third nitrogen atom of the peptide is not only bonded to one copper atom but is also at the apex of the square pyramid about the other copper atom of the dimer. The Cu–Cu distance is about 3·1 Å., and the copper atoms are not quite co-planar with the four closest ligand atoms.

The sodium ion and the water molecule occupy interstitial sites in a way which suggests that they make links between the dimers. The water molecule is hydrogen-bonded to a free carboxyl oxygen of one dimeric complex and to the first peptide oxygen of another. A pair of hydrogen bonds links the terminal amino nitrogen to the free carboxyl oxygen of one neighbouring complex and to the second peptide oxygen of another.

The glycylglycylglycine complexes *a* and *b* extend a series of structure determinations beginning logically with those of *bis*-glycine copper(II) monohydrate (compound *c*) and glycylglycino copper(II) trihydrate (compound *d*). The structure of compound *c* was recently determined by Tomita and Nitta[3] (and confirmed by M. R. Snow in our Laboratory), and that of compound *d* by Lindqvist, Strandberg and Rosenstein (private communication).

---

* Present address: School of Chemistry, University of New South Wales, Kensington, Sydney.

† Permanent address: Crystallographic Laboratory, Catharijnesingel 51/2, Utrecht.

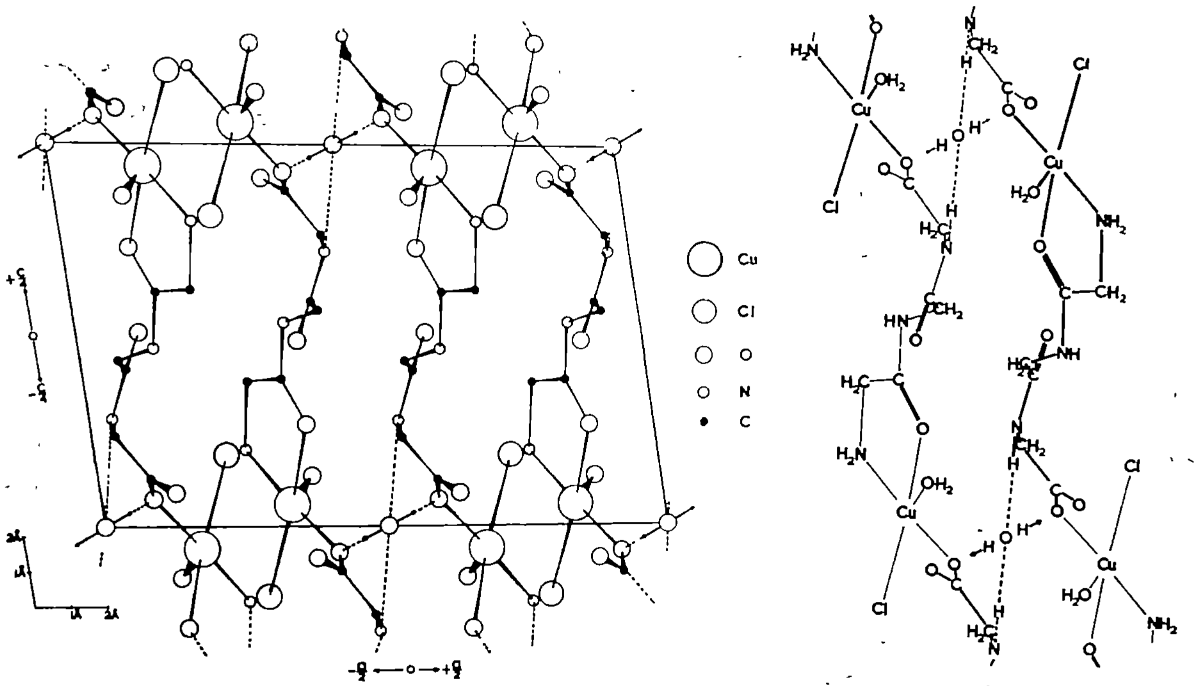

Fig. 1. (*a*) Projection of unit-cell of [Cu(glyglygly)]Cl.1½H₂O (compound *a*) along *b*-axis; (*b*) explanation of molecular arrangement in (*a*)

A significant structural feature which compounds *a*, *b* and *d* have in common is the planarity of their peptide groups. The fact that this characteristic feature of the un-complexed peptides is retained (as it is in two biuret–copper complexes[1]) implies that the complexes tend to form without sacrificing the resonance energy of their peptide groups. On the other hand, none of the chelated peptide residues in compounds *a* and *b* or in the biuret–copper complexes is quite co-planar with the copper atom to which it is joined. This statement applies also to compound *d*, in which the central copper atom does not lie in the plane of the reportedly flat dipeptide molecule (Lindqvist *et al.*, private communication). Accordingly, the orbitals of the peptide ligand atoms are not pure sp^2.

A second property shared by compounds *a*, *b* and *d* is the 5-co-ordination of the copper atoms. It remains to be seen whether this is characteristic of copper–peptide complexes or not. It is possible that in complex *a* the 5-co-ordination may be a result of steric hindrance: the orientation of the carboxyl group which is linked to the copper through one of its oxygen atoms is such that its second oxygen atom obstructs the approach of a sixth ligand to the copper. In compounds *b* and *d*, on the other hand,

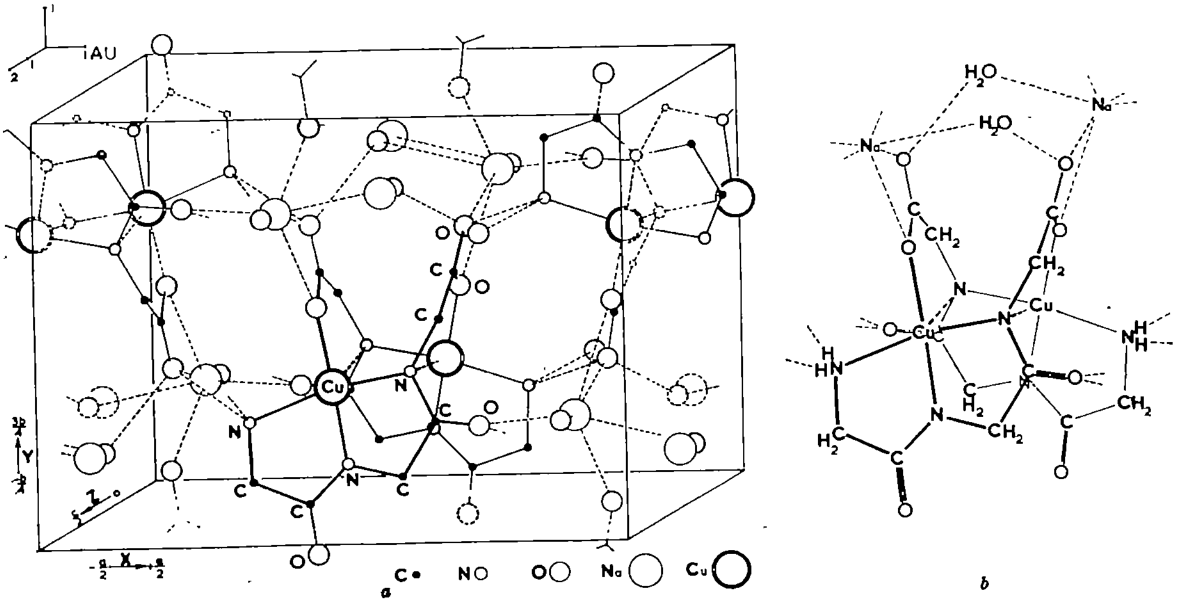

Fig. 2. (*a*) Unit-cell of Na[Cu(glyglygly)].H₂O (compound *b*); (*b*) explanation of molecular arrangement in (*a*)

no such steric factors hinder copper from adopting its more common 6-co-ordinated, distorted octahedral configuration.

A number of structures in which 5-co-ordinated copper(II) occurs have recently been described[4]. Whether 5-co-ordination of a metal is related to catalytic activity is another speculative matter: there has recently been a suggestion that the catalytic activity of metal chelates depends on the existence of vacant valences ('*Koordinationslücken*')[5].

Glycylglycylglycine is the shortest peptide which gives the characteristic 'biuret' colour-change in the presence of an alkaline solution containing cupric ions. The participation of the peptide oxygen atoms of triglycine in chelation in neutral solution parallels the use of the amide oxygen atoms as donors in the blue-green complex, *bis*-biuret copper(II) chloride[1]. In alkaline solutions, both biuret and triglycine use the maximum numbers of nitrogens as ligand atoms and form violet copper complexes. Under the same alkaline conditions, glycine and glycylglycine yield only blue solutions from which the blue crystalline substances *c* and *d* have been isolated.

The two structures *a* and *b* thus illustrate the extremes of the change which occurs when a neutral solution of copper ions and a peptide is made strongly alkaline. We are attempting to produce suitable crystal specimens of the blue intermediate complex Cu(glyglygly).$3H_2O$ which was reported by Manyak, Murphy and Martell[6]. This neutral complex would represent the mid-point of the transition between the blue-green cation $[Cu(glyglygly)]^+$ and the violet anion $[Cu(glyglygly)]^-$.

On the other hand, a crystal structure analysis does not provide proof that a complex has a particular structure in solution. For example, compound *b* may not retain its dimeric form when dissolved; the fourth position in the plane of the three peptide nitrogen ligand atoms may be taken up by a water molecule, with two other water molecules—less strongly bonded—completing an octahedron about the copper atom. Similarly, in the parent copper–biuret complex, potassium *bis*-biuret cuprate(II) tetrahydrate[1], two nitrogen atoms of adjacent complexes occupy the 'polar' positions in the co-ordination octahedron about each copper in the solid state. These more distant nitrogen atoms are apparently replaced in solution by loosely bonded water molecules, without any change in the violet colour of the complex. (*Note added in proof.* Recent unpublished potentiometric, spectral and kinetic measurements (Koltun, W. L., Roth, Reta H., and Gurd, F. R. N., private communication) suggest that the dimeric form of compound *b* does not persist in solution. Compounds *a* and *b* correspond to species in solution represented by the above authors as $CuGGG^+$ and $CuGGG^-$, respectively.)

With this general reservation, the four structures *c*, *d*, *a* and *b* support the scheme for metal–peptide interaction proposed by Rabin[7] on the basis of potentiometric and spectroscopic measurements. In particular, in neutral solution the tripeptide binds the copper atom *via* the nitrogen and oxygen atoms of the *N*-terminal peptide residue as predicted, while in the complex formed in alkaline solution the bonding is *via* the nitrogen atoms of three adjacent amino-acid residues. The structures of *b* and *d* were also predicted correctly by Manyak, Murphy and Martell[6].

Although Rabin considered that (in dipeptides) copper–carboxyl bonding is unlikely at pH's where the first peptide protons are not dissociated[7], the terminal carboxyl group in complex *a* as well as that in complex *b* is attached to a copper atom, albeit not the same one as is bonded to the rest of the same peptide molecule. In the cationic complex *a*, this quasi 'side-chain' behaviour of the carboxyl group is reminiscent of the otherwise incorrect extended chain structures proposed by Klotz *et al.*[8].

Finally, the dimerism of complex *b* suggests a way in which metal atoms in proteins may help to stabilize the tertiary protein structure. In crystal *b* we have a potential model of a set of geometrical conditions for the metal-linking of two polypeptide chains.

In future communications we hope to be able to report our crystal structure analyses of complexes between copper and glycylglycylglycylglycine, alanylglycylglycine and other short peptides with acidic and basic side-chains. Endeavours to extend this work to the peptide complexes of other transition metals have hitherto been limited to those of cobalt by our inability to produce suitable crystalline specimens of complexes from other metals. Even with the copper and cobalt complexes which we have at present under investigation we are working with compounds the compositions of which we do not know: our preparations have been carried out on such a small scale and our crystal yields have been so low that chemical analyses have not been possible.

This investigation was supported by a research grant (*A*-3460 *B.B.C.*) from the Institute for Arthritis and Metabolic Diseases, U.S. Public Health Service; and by the award of an Alexander Boden Fellowship at the University of Sydney to one of us (J. C. S.).

CONVERSION OF SHIKIMIC ACID TO AROMATIC COMPOUNDS

By PAULINE N. MORGAN, DR. MARGARET I. GIBSON and DR. F. GIBSON

Bacteriology School, University of Melbourne

THE synthesis of aromatic amino-acids is now known to follow a common pathway at least so far as shikimic acid. The number and identity of later common intermediates is not yet established. The experiments outlined here concern the conversion of shikimic acid to anthranilic acid and other aromatic compounds by cell-free extracts of various strains of *Aerobacter aerogenes* and *Escherichia coli*. The cells were grown in limiting indole medium as described by Gibson and Yanofsky[1] and the cells disrupted using an M.S.E. Mullard 500-W. ultrasonic disintegrator. The substrate mixture used with crude

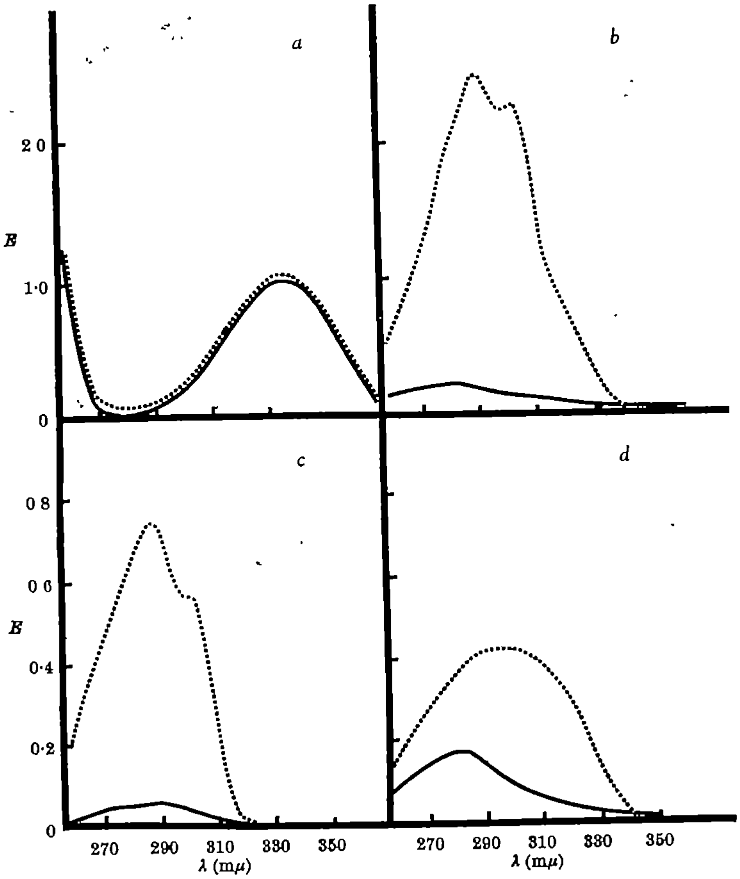

Fig. 1. Formation of anthranilic acid and phenylpyruvic acids in the presence and absence of glutamine respectively. *a*, Spectra of anthranilic acid in ethyl acetate after extraction from acidified reaction mixture. Test consisted of crude extract of *A. aerogenes T*17 (1·7 mgm. protein), shikimic acid (1 μmol.), diphosphopyridine nucleotide (1 μmol.), adenosine triphosphate (1 μmol.), magnesium chloride (5 μmol.), ribose-5-phosphate (2 5 μmol.), L-glutamine (5 μmol.), *tris* buffer *p*H 8·2 (50 μmol.) in a final volume of 1 ml. Incubated 45 min. at 37°. After acidification with hydrochloric acid the experimental samples were extracted with 4 ml. ethyl acetate, the spectra measured at 5 mμ intervals or less immediately and after storage of the ethyl acetate extract overnight at 30°. The spectra are identical with those given by synthetic anthranilic acid. *b*, Substrates and conditions as above except glutamine omitted from reaction mixture. *c*, Spectra of an ethyl acetate solution of phenylpyruvic acid obtained by acidifying 1 ml. of an aqueous solution (0·25 μmol. in 0·05 *M tris* buffer *p*H 8 2) and extracting with 4 ml. of ethyl acetate. *d*, Spectra of 4-hydroxyphenylpyruvic acid obtained as for (*c*). ———, Immediate spectrum. . . . , Spectrum after storage of ethyl acetate extracts at 30° C.

extracts consisted of shikimic acid, adenosine triphosphate, magnesium chloride, diphosphopyridine nucleotide, ribose-5-phosphate and L-glutamine in *tris* buffer. The substrates differed from those originally described by Srinivasan[2] for anthranilic acid synthesis by crude extracts of *E. coli*. We find that shikimic acid is an effective substrate and that ribose-5-phosphate or glucose-6-phosphate or fructose-6-phosphate stimulate up to ten-fold the amount of anthranilic acid formed. Adenosine triphosphate was usually included, although it was not always found to stimulate anthranilic acid formation.

When glutamine was omitted from the mixture already described it was found that anthranilic acid formation was greatly reduced but other compounds were formed. These compounds were detected after experimental samples had been acidified and extracted with ethyl acetate and the ultra-violet absorption spectrum of the solvent layer examined (Fig. 1). It was found that after incubation of the ethyl acetate layer at 30° overnight, peaks developed with maxima at 288 mμ and 302 mμ (Fig. 1*a*, *b*). These peaks appear to be due to a mixture of phenylpyruvic acid and 4-hydroxyphenylpyruvic acid, these compounds also giving spectra showing increasing optical density following ethyl acetate extraction from acidified aqueous solution in *tris* buffer (Fig. 1*c*, *d*).

Concentrates of the ethyl acetate solutions obtained as already indicated from the reaction mixture without glutamine were chromatographed in three solvents and sprayed with several detecting reagents. By this means the presence of phenylpyruvic acid and 4-hydroxyphenylpyruvic acid was confirmed. 4-Hydroxybenzoic acid and other unidentified compounds reacting as phenols were also found to be present. Phenylpyruvic acid and 4-hydroxyphenylpyruvic acid are established as intermediates in the formation of phenylalanine and tyrosine respectively. The immediate precursor of the phenylpyruvic acids, prephenic acid, if present in experimental samples would have been converted to phenylpyruvic acid following acidification for extraction with ethyl acetate. The mode of formation of 4-hydroxybenzoic acid is not understood and it is hoped to gain some information about it using the system described above.

In preliminary purification procedures the nucleic acids were precipitated from crude extracts using manganous chloride, the proteins precipitated by ammonium sulphate, re-dissolved in *tris* buffer and dialysed. The dialysates were examined for their ability to convert shikimic acid-5-phosphate to anthranilic acid and the phenylpyruvic acids. Reduced diphosphopyridine nucleotide was regularly required and phosphoenolpyruvate stimulated either conversion. One experiment showing these requirements for anthranilic acid formation is illustrated in Table 1. It was not necessary to add diphosphopyridine nucleotide in the presence of reduced diphosphopyridine nucleotide. Boiled crude extracts were found to contain an unidentified factor or factors, which restore activity lost in dialysates stored at −20°.

The stimulation of both anthranilic acid synthesis and the formation of the phenylpyruvic acids by phosphoenolpyruvic acid would suggest at least one

common intermediate containing the pyruvate side-chain as proposed by Davis[3] rather than a pathway branching at 5-phosphoshikimic acid[4]. However, the possibility remains that the effect of phosphoenolpyruvic acid is an indirect one, and more information is needed about the metabolism of compounds such as 3-enolpyruvylshikimate-5-phosphate[5].

Several amino-acids have been shown to inhibit the first reaction specific to their own formation. Moyed[6] has shown that tryptophan inhibits the conversion of shikimic acid to anthranilic acid by cell-free extracts. Our experiments show that this inhibition is accompanied by the formation of the phenylpyruvic acids (Fig. 2), indicating that intermediates which would be converted to anthranilic acid are diverted by tryptophan along the phenylalanine–tyrosine pathways. This provides evidence that end-product inhibition by tryptophan, like that of other amino-acids, concerns the first specific reaction.

The observation of the formation of phenylpyruvic acid, 4-hydroxyphenylpyruvic acid and 4-hydroxybenzoic acid in the absence of the nitrogen source, glutamine, for anthranilic acid synthesis agrees with similar results using suspensions of whole cells[7]. This supports the suggestion of the above authors that the nitrogen for anthranilic acid formation may be introduced in the first reaction specific to the tryptophan pathway.

This work was supported by grants from the National Health and Medical Research Council of Australia and the United States Public Health Service (*A*4632). We thank Dr. C. H. Doy for a gift of shikimic acid-5-phosphate.

ELECTRIC BIREFRINGENCE INVESTIGATIONS OF DEOXYRIBONUCLEOPROTEIN FROM RAT THYMUS

By Dr. RUTH F. ITZHAKI*
Department of Radiotherapeutics, University of Cambridge

NUMEROUS physico-chemical studies have been made on deoxyribonucleoprotein (DNP), but only rarely have reproducible results been obtained and there have been few estimates of the dimensions of the molecule. In the present work DNP has been investigated chiefly by the method of electric birefringence, which was used by Benoit for DNA[1] and by O'Konski *et al.* for proteins and viruses[2–4]. Satisfactory reproducibility has been obtained on material which, judging by its very large molecular size, may be undegraded. The birefringence Δn and relaxation time T of decay of birefringence on removal of the electric field give information about the electrical properties and the length ($2a$) of the molecule respectively, the latter by the following relationships:

$$T = \frac{1}{6D} \qquad (1)$$

$$D = \frac{k_1}{a^3}\left(\ln \frac{2a}{b} - k_2\right) \qquad (2)$$

where D is the rotary diffusion coefficient, $2b$ is the molecular diameter and k_1 and k_2 are constants.

Preparations of DNP were made from rat thymus by homogenization in 0·9 per cent sodium chloride solution followed by dispersion in water to give, finally, a rigid gel. Electric birefringence and centrifugation studies were made on dilutions of the gel in 10^{-3} *M* disodium hydrogen phosphate solution, *p*H 7. DNA concentrations were measured by the Dische diphenylamine method[5], and protein concentrations by a modification[6] of Zamenhof and Chargaff's method[7] involving measurement of the ultra-violet absorption of the copper-biuret complex. The curves of decay of birefringence were investigated initially by drawing graphs of log Δn against time. In later experiments T was measured by a method involving comparison of these decay curves with those produced by two condenser resistor circuits of known time constants[6].

---

* Beit Memorial Research Fellow.

The results showed that two main molecular components were present in the DNP preparation; their decay times will be referred to as $T_{\max}$ and $T_{\min}$. The relaxation times were found to be independent of concentration of DNP over a sevenfold range and the mean values of $T_{\max.}$ in a series of ten experiments was 165 msec. with standard deviation of ± 33 per cent of the mean. The error in measuring $T_{\min.}$, however, was as much as 100 per cent[6], the values usually being about 1/50th of $T_{\max}$.

The Kerr law states that:

$$\Delta n = B\lambda E^2 \qquad (3)$$

where B is the Kerr constant, λ is the wave-length of the light used and E is the electric field strength. This law was found not to be obeyed by DNP, Δn depending on a power r of the field of less than two. The reproducibility in measurement of Δn at a given voltage was good, the agreement being within 5 per cent for two samples diluted to the same concentration from one gel and within about ± 15 per cent for different preparations measured at the same concentration.

A progressive decrease in Δn but not in T was observed on keeping the DNP dilutions at 4° C. This was enhanced if the dilutions were incubated at 37° (Table 1). The approximate constancy of T indicates that 'ageing' is not a process of degradation along the length of every molecule. It could be due to a decrease in the number of molecules of the long component; however, the ratio of initial birefringence of the short component to that of the long component at the instant of removal of the electric field (which depends on both the number and the length of the molecules) remains approximately constant. In fact, decay curves of the same initial height from DNP samples of different ages could be superimposed exactly, indicating that the distribution of molecules remained constant. In contrast to this effect of ageing, both irradiation and re-precipitation of the DNP[6] with 1·4 M sodium chloride solution caused a decrease in Δn and no change in T but an increase in ratio of the initial birefringence of the short to the long component, indicating that the number of molecules of the latter had decreased.

A possible explanation of the ageing effect is that the DNP consists of laterally bonded three-dimensional aggregates or particles of unit DNP molecules, the change of Δn with time being due to lateral disaggregation, that is, partial or complete breakage and removal of some of the sub-units by enzymatic action. Such changes would not affect the overall length since this would depend on the unbroken sub-units, and the change in axial ratio would not affect T significantly since it occurs only as a logarithmic term in equation (2).

The finding that Δn depends on a power of E of less than 2 indicates that saturation of birefringence occurs, presumably because the alignment of the molecules in the electric field is not countered sufficiently by Brownian motion. Experiments on the effect of proteolytic enzymes (trypsin and subtilisin) and of urea added to the DNP, and on DNA extracted from the DNP[6], all show that the power r increases on destruction or removal of the protein component, indicating that the DNA moiety is considerably smaller in volume than the DNP.

Centrifugation of the DNP at 12,000g for 30 min. yielded a gel residue. The DNP concentration of the clear supernatant liquid was usually about 30–50 per cent of the total value. Similar centrifugation of DNA prepared from the DNP caused, as would be expected, no phase separation. However, the relaxation times of decay of birefringence of DNA were found to be only slightly less, $T_{\max.}$ being about 100 msec. The very large volume of a DNP aggregate or particle could explain this very high sedimentation-rate compared with that of DNA although the lengths of the two molecules could be very similar.

If axial ratios of about 5 : 1 and 50 : 1 are assumed for DNP and DNA respectively, the very large values of 15,000 Å. and 17,000 Å. are obtained for the lengths of the major axis, $2a$, using equations (1) and (2). The latter value for DNA is considerably greater than that usually found from measurements of rotary diffusion coefficient (even allowing for denaturation caused by use of a medium of low ionic strength) although it is within the range found for various DNA preparations by Reichmann *et al.*[8]. It is possible that the DNA here is cross-linked by residual protein present, but, after addition of proteolytic enzymes to DNP, similar values of $T_{\max}$ are obtained and it seems fairly unlikely that either the protein fragments, or the enzymes themselves, would cross-link the constituent DNA (which, presumably, is released by the enzyme action) to give values of $T_{\max}$ similar to those of DNA extracted from the DNP.

In summary, although constancy of T is clearly not a good proof of constancy of molecular volume, when considered with the fair reproducibility of Δn, it indicates that these DNP preparations do not consist of mere randomly sized particles of gel but that they may be aggregates or particles of more or less constant size formed by lateral association of unit DNP molecules. A detailed account of other investigations on the properties of DNP, including their concentration dependence, will be given elsewhere.

I thank Prof. J. S. Mitchell for advice and the Nuffield Foundation for a grant with which I began this work.

ACUTE RADIATION INJURY: PATHOPHYSIOLOGICAL ASPECTS OF THE MASSIVE LEAKAGE OF ALBUMIN INTO THE GASTROINTESTINAL TRACT

By G. BIRKE, S.-O. LILJEDAHL, L.-O. PLANTIN and J. WETTERFORS

King Gustaf Vth Research Institute and Radiumhemmet Karolinska sjukhuset, Stockholm 60

PHYSIOLOGICAL accumulation of albumin in, and leakage through, the gastrointestinal wall is documented[1–4,12]. Quantitative studies of this leakage have shown that the bulk of the 'catabolism' of albumin occurs via the gastrointestinal tract, both in man[4] and in animals[5,6].

It is thus reasonable to assume albumin leakage from the gastrointestinal tract when this tract is in a pathological state. This was first demonstrated in ulcerative colitis and terminal ileitis by Steinfeld *et al.*[7] and in 'exudative gastroenteropathia' by Citrin *et al.*[8], Gordon[9] and Schwartz and Jarnum[10]. These findings have since been confirmed[11–13].

Cancer of the stomach, too, has proved to be associated with a pathological leakage of albumin[2,3,12] as well as a pathological distribution of albumin[13].

It is therefore reasonable to suspect that damage to the gastrointestinal capillary system as well as the known injury of the epithelium in the acute radiation syndrome would give rise to excessive loss of protein. Barandun *et al.*[14] have found, moreover, an increased percentage of PVP-^{131}I in the cœcal contents of mice exposed to 1,000 r. In order to investigate the clinical significance of these injuries the following experiments were conducted.

Following irradiation of rabbits by a medical cobalt-60 γ-irradiation source (group I, 250–400 r.; group II, 650–850 r.; and group III, 1,200–1,600 r.) the degradation and distribution of albumin were investigated by means of 70–100 μc. intravenously administered ^{131}I-labelled rabbit albumin. Plasma activity, total body activity and urinary and fæcal excretion of radioactivity were determined daily. In the first two groups the ^{131}I-albumin was injected 42 hr. after irradiation, and in the last group after 18 hr.

The degradation and distribution of albumin, determined by the methods of Matthews[15] and Campbell *et al.*[16], in controls and irradiated animals are tabulated in Table 1, as are the half-life values. Initial plasma volumes and amounts of intravascular albumin are also given. A clearly elevated degradation can be observed in the irradiated rabbits except in rabbit No. 4 which showed a nearly normal value. The half-life is inversely proportional to the radiation dosage. Figs. 1, 2 and 3 also show the cumulative urinary excretion of radioactivity, which normally amounted to 30–40 per cent of the administered dose in 11 days, but was 60–70 per cent in irradiated groups I and II. Fæcal excretion of radioactivity in controls was < 0·07 per cent during the period of investigation (11–13 days). Groups I and II showed an increased excretion (1·03–1·76 per cent and 0·17–0·45 per cent respectively), as did group III during the 4–7 days these animals lived (0·17–0·71 per cent). The ratio of intravascular to extravascular albumin was 1 : 1·5 in controls and in group I. A lower extravascular albumin pool was recorded in group II, possibly indicating a non-steady state. In the last group (Fig. 4), in which the animals died, extensive extravascular retention of ^{131}I-albumin was found.

On analysis of the plasma activity curve in its exponential parts, the half-life of the initial distribution in controls was found to be equal to that in group I (half-life = 0·7–0·8 day), whereas in group II the half-life value was ~ 0·2 day. In group III, on the other hand, a half-life of 0·4–0·5 day was found, probably because of the earlier start of the ^{131}I-albumin study in those animals (18 hr. after irradiation).

In group III both animals died. The rabbit which had received 1,200 r. showed, on the sixth day of the experiment, a high urinary excretion of radioactivity (Fig. 4), and simultaneously a steeper slope of the plasma activity curve was observed. This is interpreted as a massive re-absorption of degradation products of ^{131}I-albumin which has leaked into the gastrointestinal tract, denoting at least a partial restitution of the re-absorption capacity of the intestine. No corresponding signs of re-absorption were observed in the animal which had received 1,600 r. Autopsy revealed general œdema of the gastrointestinal tract, most pronounced in the ileum and colon, which were partially dilated. The changes were most accentuated in rabbit No. 8 (1,600 r.), in which 47 per cent of the retained dose was found in

the gastrointestinal tract, its walls and contents, particularly in the ileum (no blood). In rabbit No. 7 (1,200 r.) 20 per cent of the retained dose was located in the gastrointestinal tract, but the highest values were referable to the upper portion. Other organs showed in both animals the same relative values for retained dose.

Values for degradation and distribution of ^{131}I-rabbit albumin in the controls are consistent with those found in earlier investigations[15]. A shorter half-life was found in all irradiated animals: the longer the exposure to irradiation, the shorter was the half-life. The injection of ^{131}I-albumin was given after irradiation to avoid denaturation of the labelled protein. Corresponding values for the half-life of retained dose (total body activity) and half-life of plasma activity were obtained in the controls and in groups I and II, demonstrating the validity of the methods of measurements. Common to all irradiated groups was an increased catabolism of albumin, strongly indicative of an increased leakage of albumin through the gastrointestinal wall. This was also evident from the increased fæcal excretion of radioactivity. With lower radiation doses the gastrointestinal epithelium and the capillary bed appear to be the initial sites of damage. When LD_{50} is reached, a more general, or more pronounced, disturbance of gastrointestinal permeability seems to occur, yet no extravascular retention of albumin is apparent. For doses exceeding LD_{50}, on the other hand, the retention points to definite disturbances of permeability, at least in the gastrointestinal tract.

The extension and significance of the capillary damage in other organs are now being investigated. Although there is considerable accumulation of albumin in the intestinal wall, the bulk escapes into the intestinal lumen and is thereby lost to the circulation.

In groups I and II the determinations of plasma activity and total body activity were suggestive of a decreased leakage around the twelfth to fourteenth day after irradiation. The excessive excretion of radioactivity in rabbit No. 7 (1,200 r.) indicates at least partial restitution of the re-absorption capacity of the intestine, since radioactive degradation products are excreted through the kidneys. The continuous

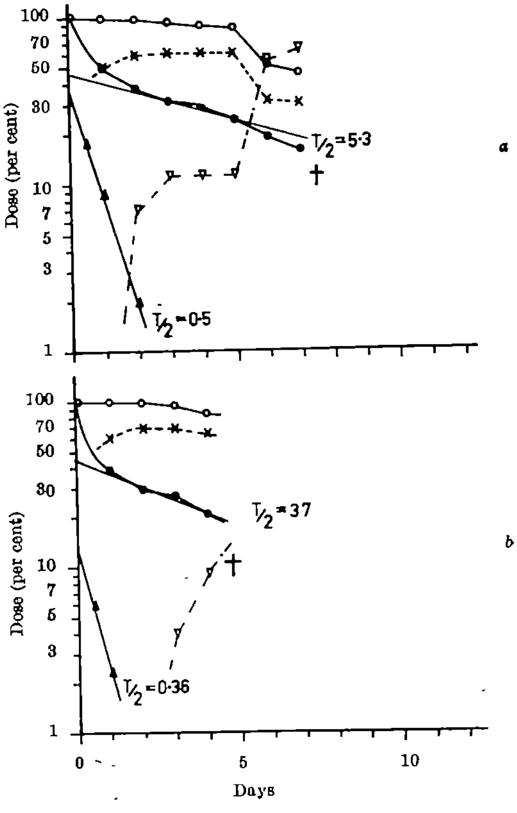

Fig. 4. Rabbits irradiated with 1,200 (*a*) and 1,600 r. (*b*). Death is denoted by +. In rabbit No. 7 (*a*) the *T*/2 for the last three days is not indicated in the diagram, but corresponds to 3·3 days

leakage of serum albumin results, however, in hypovolæmia, shock and death, as was conspicuously evidenced by the 1,600 r. animal. This rabbit died earlier than the other and about half the total albumin pool (retained dose) was located in the gastrointestinal tract—either in the wall or as degradation products in the lumen.

This preliminary work, which is part of a more extensive investigation now in progress, demonstrates excessive losses of albumin into the gastrointestinal tract after total-body irradiation.

These substantial losses of albumin are due to the fact that the epithelium, and evidently the capillaries, of the gastrointestinal tract constitute the most sensitive system during this phase of radiation injury.

The implication is that this important mechanism, hitherto not definitely recognized, at least partly underlies the shock which characterizes the acute radiation complex. Injuries to other capillary systems in the organism are at present being investigated. This work raises the question of therapeutic aspects concerning adequate substitution with colloids such as plasma, albumin and blood.

CHEMICAL PROTECTION AGAINST ALPHA-PARTICLE IRRADIATION

By TIKVAH ALPER

Medical Research Council, Experimental Radiopathology Research Unit

AND

D. K. BEWLEY and J. F. FOWLER

Medical Research Council, Cyclotron Unit, Hammersmith Hospital, London, W.12

CELLS are in general considerably more resistant to ionizing radiation when they are anoxic, and many agents which modify radiation damage do not act *per se*, but rather by bringing about a change in oxygen concentrations in the vicinity of the cells under test[1,2]. The ratio of radiosensitivities of well-oxygenated to anoxic cells depends on the linear energy transfer of the radiation used, being in general smaller with radiations of high than of low linear energy transfer[3,4]. It follows that a 'chemical protector' which acts by inducing anoxia[5,6] will likewise be less effective when the linear energy transfer of the radiation is high. Reports on reduced effectiveness of chemical protection against radiations of high linear energy transfer have been based on observations with organized systems[1,7] in which oxygen tension was not under control. The evidence from such experiments cannot therefore be regarded as demonstrating a general feature of 'true' chemical protection, as distinct from the induction of anoxia.

Preparations of free-living cells, and particularly of bacteria, can be irradiated under well-controlled gas conditions, and therefore afford a suitable system for testing the dependence on linear energy transfer of true chemical protection. Both glycerol[8,9] and cysteine[10] have been shown to afford protection to bacteria irradiated in anoxic as well as in fully oxygenated conditions. We have therefore tested the ability of these compounds to protect cells of *E. coli B/r* against 27-MeV. and 5·2-MeV. α-particles (linear energy transfer 25 and 86 keV./μ respectively). Preliminary experiments with 8-MeV. electrons showed that glycerol (used at 1 *M*) and cysteine (0·15 *M*) were efficient protective agents when they were incorporated in agar gel, on which were placed 'Cellophane' carriers with the bacteria spread on these in a monolayer, and in a concentration such that an easily countable number of colonies would grow out when the 'Cellophane' carriers were transferred after irradiation to the surface of nutrient agar. This method of preparing samples was well suited for use in α-particle irradiations.

The beam of α-particles, from the Medical Research Council Cyclotron at Hammersmith Hospital, was defined by a horizontal slit 6 cm. × 1 mm. It was convenient to use 'Cellophane' carriers of about 2 cm. diameter, and it was necessary therefore to arrange that they were scanned by the 1 mm. high beam. The irradiation vessels were placed tangentially on the circumference of a wheel, 30 cm. in diameter, which was rotated once per second in a vertical plane, so that each carrier, moving downward through the beam, was exposed for approximately 1 m.sec. in each revolution. The beam current was so adjusted that each dose was delivered during at least ten revolutions of the wheel, to average the effect of variations in beam current during the exposure. The wheel carried sixteen irradiation vessels, eight of which, usually, contained agar gel incorporating the protective compound, while the other eight contained agar gel only. One sample in each group of eight was protected from α-particle bombardment by a disk of copper 0·25 mm. thick, and these samples, together with others not taken into the cyclotron chamber, served as controls.

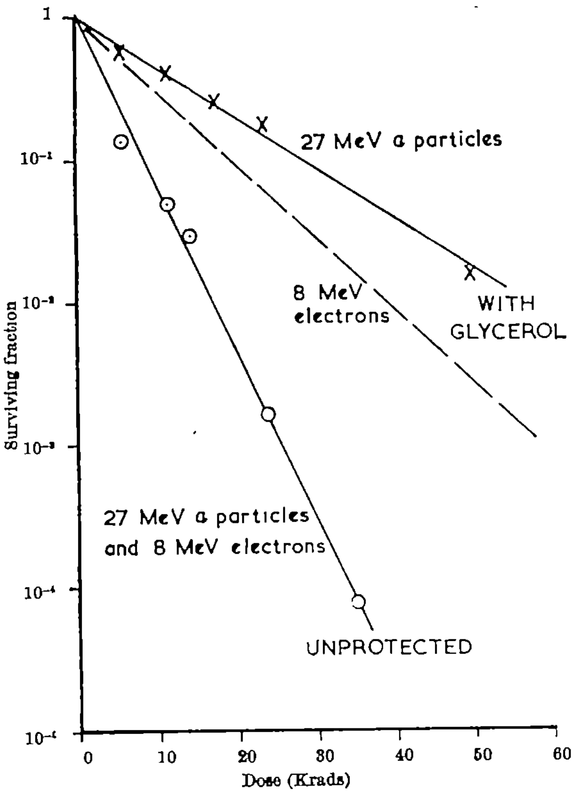

Fig. 1. *E. coli B/r* exposed to 27-MeV. α-particles or 8-MeV. electrons

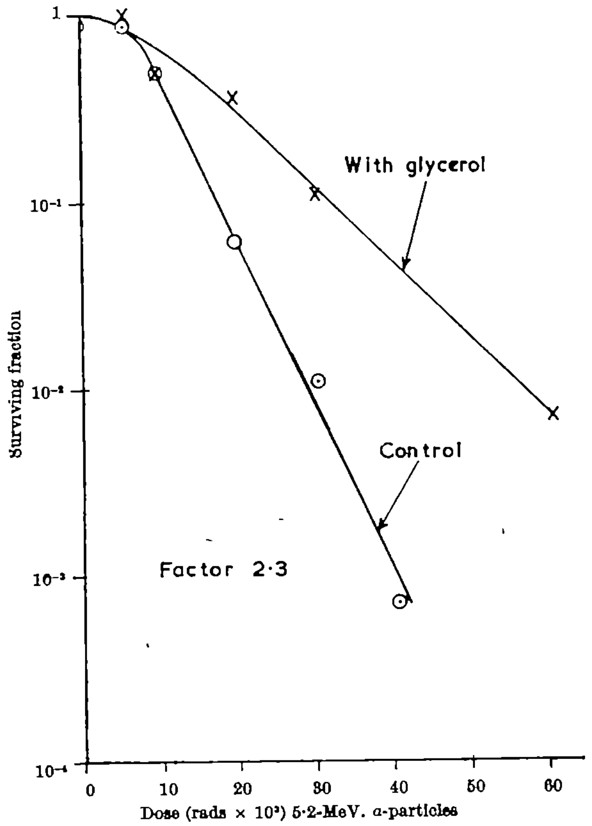

Fig. 2 *E coli B/r* exposed to 5·2-MeV. α-particles

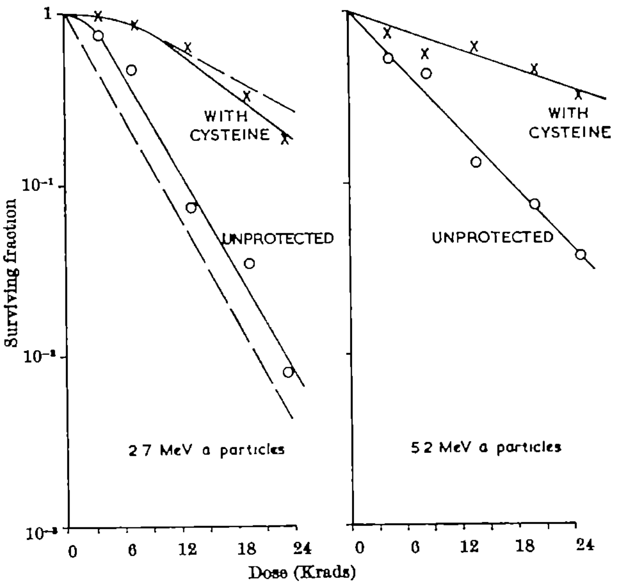

Fig. 3 *E. coli B/r* exposed to 27-MeV. and 5·2-MeV. α-particles. Broken lines in left-hand diagram show survival curves for 8 MeV. electrons in similar conditions

The α-particle beam (current 1 μamp., reduced to 0·04 μamp. by the slit) passed between the parallel plates of an ionization chamber used as monitor. Absolute doses were determined from the defined geometry, and were confirmed by using a Faraday cup.

Figs. 1 and 2 show the extent to which glycerol protected against 8-MeV. electrons and 27-MeV. α-particles, and against 5·2-MeV. α-particles; 'protection factors' against these radiations were respectively about 2·3, 3·2 and 2·0. Data for protection by cysteine are shown in Fig. 3. Survival in the presence of cysteine was not reduced to a sufficiently low level to enable us to estimate protection factors; it can be seen that cysteine protected the cells to roughly the same extent against all three qualities of radiation, at least up to doses of 24 kilorads.

Extension of these preliminary data awaits the completion of modification of the cyclotron, now under way. We are of the opinion that the results warrant an interim report because work in the field of chemical protection is being actively pursued in many places, and our data have a bearing on some suggested mechanisms of 'true' chemical protection:

(1) *Reduction in yield or effectiveness of radiolysis products of water, which are agents of radiation damage.* This mechanism has been supported by some authors, particularly in respect of protection by glycerol[9,11]. Protective action by scavenging of OH or H radicals, or by dehydration, could be expected to decrease with increasing linear energy transfer, since short-lived radiolysis products of water are produced in lower yield as linear energy transfer increases; the yields of OH and H radicals in irradiated water are less by factors 4–5 with polonium α-particles than with cobalt-60 γ-rays[12]. Our results show that glycerol protects bacteria to roughly the same degree against 8-MeV. electrons and 5·2-MeV. α-particles.

(2) *Production of anoxia within the cell.* It is sometimes suggested that chemical protective agents may act by depleting the cell of oxygen, even though there is sufficient oxygen in its immediate vicinity to confer full radiosensitivity in the unprotected state. The operation of such a mechanism would

also lead to reduced protection factors at linear energy transfer values where the overall oxygen enhancement ratio is low.

(3) '*Mixed disulphide' formation*. This mechanism has been postulated by Eldjarn and Pihl[13] to account for protection by sulphur compounds when 'direct action' on biological target molecules is involved. Our data on cysteine protection are not inconsistent with this mechanism of action, but it could not account for protection by glycerol. It may be that two (or more) different mechanisms of action must be invoked to account for true chemical protection. There are, however, striking similarities in the radiobiological action of these two dissimilar compounds: both protect bacteria much more effectively against radiations delivered in aerobic than anaerobic conditions; and, when *E. coli B/r* is irradiated in suspension, both compounds tend to change the shapes of survival curves, causing these to become sigmoid[14]. It seems likely that true chemical protection of bacteria by these compounds has a common mechanism, different from any so far proposed.

EFFECT OF PRETREATMENT WITH NITRIC OXIDE AND N-ETHYLMALEIMIDE ON THE LEVEL OF SULPHYDRYL COMPOUNDS IN BACTERIA AND ON THEIR SENSITIVITY TO X-IRRADIATION UNDER ANOXIA

By JOHN P. LYNCH and P. HOWARD-FLANDERS

Department of Radiology, Yale University School of Medicine, New Haven, Conn.

NITRIC oxide increases the sensitivity of anoxic bacteria, insect, plant and mammalian cells to X-irradiation[1–4]. At concentrations less than 100 μM, this gas is as effective as oxygen in raising the radiosensitivity of *Shigella sonnei* in aqueous suspension[5]. The radiosensitivity is increased almost to the maximum level by 15 μM, but pretreatment or post-treatment with nitric oxide at this concentration is without effect on the sensitivity to irradiation under anoxia[5]. It has been found, however, that the pretreatment of *Shigella flexneri* with 1 mM nitric oxide increases the sensitivity to a subsequent X-irradiation under anoxic[6,7] but not aerobic conditions[8]. A similar increase in the radiosensitivity occurs when *E. coli B/r* is pretreated with the sulphydryl reagent *N*-ethylmaleimide (NEM) (refs. 9 and 10). Again the bacteria are rendered more sensitive to X-irradiation under anoxia, but the aerobic sensitivity is not increased to the same extent.

It has long been known that sulphydryl compounds are among the most effective agents for protecting against the effects of X-rays, but more recently it has become evident that sulphydryls play an essential part in the protection afforded cells by anoxia, as has been shown in experiments on bacteriophage and transforming principle. When protected from indirect effect by the addition of nutrient broth or other organic substances, neither bacteriophage nor transforming principle shows any appreciable oxygen effect[11–13]. When inside the cell, however, bacteriophage[14,15] and transforming principle[16] are in contact with sulphydryls such as glutathione and are protected against X-irradiation by anoxia. Anoxic protection is observed also if sulphydryl compounds are added to a suspension of bacteriophage or transforming principle[17–19] while it is reduced when phage-infected bacteria are treated with NEM (ref. 20). In all these experiments, anoxia is protective when, and only when, sulphydryl compounds are present.

It seemed of interest, therefore, to test whether the reduction in the protection afforded by anoxia to *Shigella* of either strain following treatment with nitric oxide[7] was due to the depletion of the intracellular sulphydryl compounds.

Experiments were carried out on *Shigella sonnei* grown overnight on nutrient agar, collected, washed and resuspended at about 10^{10} cells per ml. in 0·15 M sodium chloride, 0·1 per cent serum albumin, 10^{-4} M Ca^{++}, 10^{-4} M Mg^{++} and 0·02 M phosphate buffer at pH 6·8. The cells were exposed to nitric oxide in four circular flasks fitted with stopcocks and a magnetic stirring bar[7]. The flasks were evacuated and flushed with nitrogen three times to remove oxygen and were filled with a 50 per cent mixture of nitric oxide and nitrogen. This gas mixture was obtained from the Matheson Co. and was passed through a solution of sodium hydroxide to remove nitrogen dioxide. Cells gathered from nutrient agar plates would tolerate exposure to 1 mM nitric oxide for periods up to 90 min. with a 40–50 per cent loss of colony-forming ability. Cells grown in Difco nutrient broth were killed more rapidly by this procedure and were not used in these experiments. After each flask was exposed to nitric oxide for the required period, it was evacuated and flushed with nitrogen three times. A small sample was taken for use in the X-ray experiments, while the bulk of the cells were centrifuged preparatory to measuring the sulphydryl content of the bacteria. The cells from each flask were spun and the pellets were extracted with 0·3 M trichloroacetic acid. The extract was spun at 20,000g for 15 min. and the clear supernatant was then estimated for sulphydryl content by the nitro-prusside method[11].

The irradiations were carried out with X-rays generated at 250 kV. and 15 m.amp. with about 1 mm. aluminium and 2 mm. 'Pyrex' glass added filtration. The dose-rate in the irradiation vessel was determined by measuring the rate of oxidation of acid ferrous sulphate solution and was close to 3,000 rads per min. Nitrogen anoxia was obtained by passing oxygen-free nitrogen through the irradiation vessel while stirring magnetically for at least 10 min. before starting the irradiation.

The effects of exposure to nitric oxide or NEM on the sulphydryl content of the bacteria are shown in Fig. 1. Cells from experiment II exposed to nitric oxide for 60 and for 70 min. were used in X-ray experiment. The numbers of normal and nitric oxide-treated bacteria that survive X-irradiation under oxygen or under anoxia are shown in Fig. 2. Results with NEM-treated cells are shown in Fig. 3. It is seen in these figures that cells are less well protected by anoxia after pretreatment with either agent. The addition of cysteine to the pretreated cells just before irradiation increases the protection afforded by anoxia to a level slightly beyond that obtained with untreated cells.

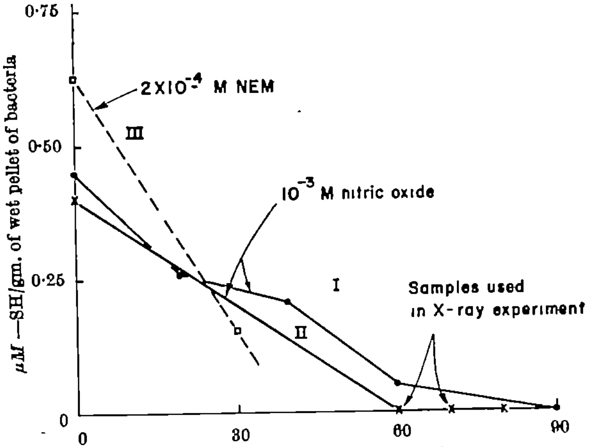

Fig. 1. The sulphydryl content of *Shigella sonnei* after exposure to 1 m*M* nitric oxide or 0·2 m*M* *N*-ethylmaleimide at 22° C.

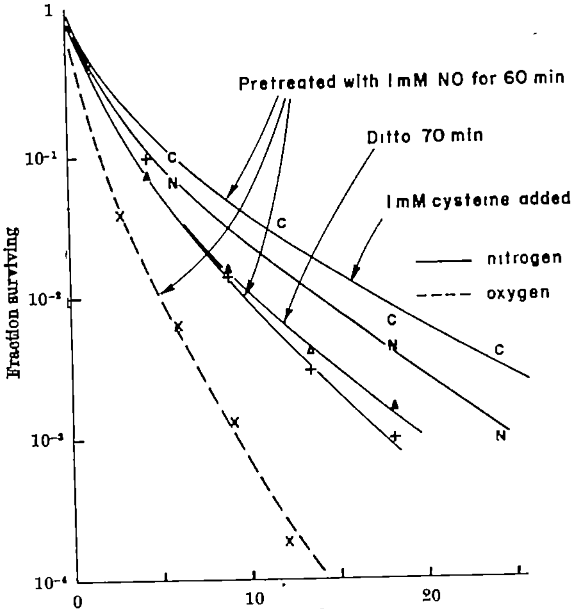

Fig. 2. Survival of colony-forming capacity as a function of the dose of X-rays delivered with or without oxygen. Survival curves are given for *Shigella sonnei* both untreated and after pretreatment with 1 m*M* nitric oxide for 60 or for 70 min. The cysteine was added to the pretreated cells just before irradiation

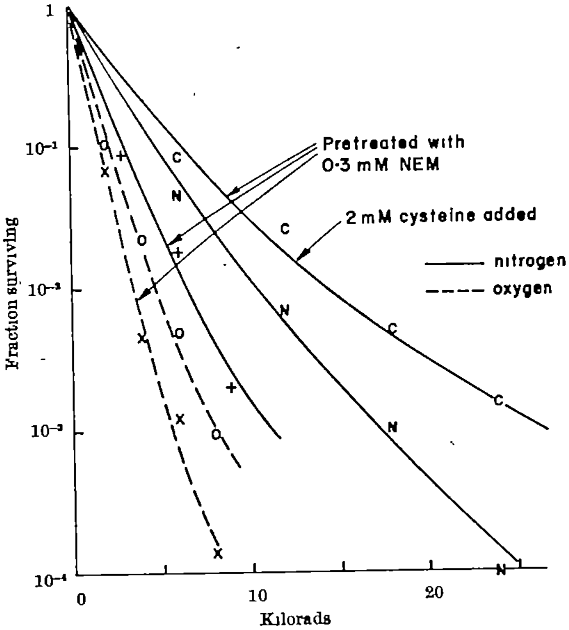

Fig. 3. Survival of colony-forming capacity as a function of the dose of X-rays delivered with or without oxygen. Survival curves are given for *Shigella sonnei* both untreated and after pretreatment with 0·2 *M* *N*-ethylmaleimide for 30 min. The cysteine was added to the pretreated cells just before irradiation

These results are in accord with those of Dale, Davies, and Russel[7] and Bridges[9,10] in showing that bacteria can be rendered more sensitive to anoxic X-irradiation by pretreatment with either nitric oxide or with *N*-ethylmaleimide. They also show that the amount of sulphydryl in the bacteria is drastically reduced by these treatments. There are several reasons for thinking that the increase in the anoxic radiosensitivity is due to the reduction in the level of the intracellular sulphydryl compounds in the cells used in this experiment. (1) The full level of protection under anoxia is readily restored to the pretreated cells by the addition of cysteine just prior to irradiation. (2) Similar effects on radiosensitivity are obtained following a reduction in the level of endogenous sulphydryl compounds by either substance. (3) With a suspension of free bacteriophage, sulphydryls have been found necessary for anoxic protection, while the anoxic protection of phage-infected cells was reduced by pretreatment with NEM (ref. 20).

The main features of these results are in accord with the reaction mechanism proposed[16,19,20] to explain the results obtained with bacteriophage:

$$RH \xrightarrow{\text{radiation}} R^{\cdot} \tag{1}$$

$$R^{\cdot} + \text{—SH} \longrightarrow RH + \text{—S}^{\cdot} \tag{2}$$

where *R*H is biologically active DNA and *R*· is a DNA radical formed by the loss of a hydrogen atom. Evidence that DNA is the sensitive site in bacteria is seen in the work on radiosensitization of bacteria and transforming DNA as the result of the incorporation of unnatural pyrimidines[22]. Protection by anoxia is the result of reaction (2) and is blocked if oxygen or nitric oxide reacts with the DNA radical $R^{\cdot}$, or if the amount of —SH is depleted by pretreatment with NEM or NO. It is to be expected that sensitization to anoxic irradiations would require the reduction of sulphydryls in the cell to some critical level at which the cells remain viable, but which is inadequate for efficient anoxic protection. The factors which determine the level to which sulphydryl compounds may be reduced without killing the cell have not been fully explored as yet, but might be of importance for the avoidance of anoxic protection as an adverse factor in the treatment of partially anoxic malignant tumours by X-rays.

This research was supported by grants from the Jane Coffin Childs Fund and the U.S. Public Health Service.

CONTAMINATION OF COMMERCIAL PREPARATIONS OF GLUCOSE OXIDASE WITH BETA-FRUCTOFURANOSIDASE

By DR. G. SCHARLACH, DR. J. ROBBINS and DR. J. WOLFF

National Institute of Arthritis and Metabolic Diseases, National Institutes of Health,
Bethesda, Maryland

THE glucose–glucose oxidase system is frequently used for the generation of hydrogen peroxide in various oxidative reactions. Using this system in experiments with thyroid particles prepared in 0·25 *M* sucrose we found that the enhancement of organic iodine formation usually resulting from addition of glucose and crude glucose oxidase also occurred in the absence of glucose. It has been known for some time that sucrose is not a substrate for purified glucose oxidase[1]. As this effect of glucose oxidase alone did not occur with saline-prepared particles (Table 1), it seemed possible that the oxidase preparation was contaminated with β-fructofuranosidase. Subsequent work confirmed this supposition. Apparently sufficient sucrose remained in the packed particle pellet to form enough glucose as substrate for the oxidase.

Sheep thyroid tissue was homogenized in Krebs–Ringer phosphate solution *p*H 7·4 (1 gm./3 ml.), with an all-glass homogenizer. Nuclei and debris were removed by centrifugation for 10 min. at 600*g*. The supernatant solution was then sedimented at 39,000 r.p.m. (Spinco model *L* centrifuge, No. 40 rotor) for 45 min. and the resulting pellet was washed and centrifuged twice with 12 ml. of the Ringer medium. The washed pellet was re-suspended in Ringer-phosphate solution and an amount equivalent to 100 mgm. of fresh thyroid tissue was added to Ringer-phosphate medium containing 10^{-6} *M* potassium iodide and 2 μc. iodine-131 in a total volume of 2·5 ml. (refs. 2 and 3). Incubations were at 37° and reactions were stopped after 1 hr. by freezing. Chromatography was in ethanol : *n*-butanol : 0·1 *M* ammonium carbonate (*p*H 7·4) (2 : 1 : 1) on Whatman No. 1 paper and sections thereof were counted in a well-type scintillation counter for origin and remaining radioactivity (mainly or entirely iodide).

Table 1. COMPARISON OF IODINATION BY SALINE-PREPARED AND SUCROSE-PREPARED SHEEP THYROID PARTICLES

Particles	Glucose oxidase alone	Glucose oxidase and glucose (10^{-3} *M*)
	mμmoles organic iodine per hr.	mμmoles organic iodine per hr.
Saline-prepared	47	197
Sucrose-prepared	230	200

Each flask contained particles from 0 1 gm. of sheep thyroid, 10^{-3} *M* glucose, 10^{-6} *M* I^-, Ringer-phosphate medium *p*H 7·4 in a total volume of 2 5 ml. Flasks with saline particles had 0·5 mgm. and sucrose particles had 0·25 mgm. of glucose oxidase (Prep. *B*). Temp. 37° C.; duration 1 hr.

To inhibit the glucose oxidase, reactions were performed anaerobically in Thunberg tubes which had been evacuated and re-filled with nitrogen three times. In some cases comparable aerobic studies were carried out. Reactions were carried out at room temperature (see Table 3 for conditions) for 1 hr. and terminated by placing the tubes in a boiling-water bath for 5 min. Sucrose, raffinose, trehalose, maltose, lactose were commercial preparations of high purity. α-Fructofuranoside was kindly supplied by Dr. H. G. Fletcher. Glucose oxidase preparations were obtained from Squibb and Co., through the kindness of Dr. D. Perlman (Prep. *A*), Nutritional Biochemical Corp. (Prep. *B*), Takamine Chemical Co. (Prep. *C*), Pfanstiehl Co. (Prep. *D*) and Worthington Corp. (Prep. *E*). Reducing sugar was determined by the Somogyi–Nelson method.

Glucose oxidase preparations from Squibb and Co. and the Nutritional Biochemical Corp. were compared for their effect on the formation of protein-bound iodine (origin radioactivity) in systems containing the oxidase, glucose, sucrose or no added substrate. The results are listed in Table 2. It can

Table 2

	No glucose oxidase mμmoles organic iodine per hr.	Prep. *A* glucose oxidase mμmoles organic iodine per hr.	Prep. *B* glucose oxidase mμmoles organic iodine per hr.
Particles	68	76	80
Particles + sucrose	86	47	202
Particles + glucose	59	256	197

Each flask contained particles from 0·1 gm. sheep thyroid, 2·5 ml. Krebs–Ringer phosphate medium *p*H 7·4, 10^{-4} *M* I^{-}. Concentrations were 1×10^{-3} glucose, 8×10^{-3} *M* sucrose and 0·5 mgm./flask glucose oxidase. Temp. 37° C.; duration 1 hr.

be seen that organic iodine formation by thyroid particulate preparations was enhanced by glucose oxidase (Prep. *B*) in the presence of both sugars but not without substrate. Preparation *A* stimulated synthesis only in the presence of glucose.

As glucose oxidase is inactive anaerobically the presence of β-fructofuranosidase was ascertained in the absence of oxygen. Glucose and fructose were allowed to stand anaerobically with glucose oxidase (Prep. *B*) and were found not to lose reducing power. Thus, the anaerobic technique used here appeared to be satisfactory for our purposes. A comparison of five glucose oxidase preparations was made, under aerobic and anaerobic conditions. Significant quantities of β-fructofuranosidase activity was shown in two of the preparations. The results are listed in Table 3. It is somewhat surprising that there was not a greater difference between anaerobic and aerobic experiments. This may be partly due to the relatively low activity of glucose oxidase at *p*H 7·3 and partly due to the fact that a portion of the reducing sugars is present as fructose.

Table 3. PRODUCTION OF REDUCING SUGAR BY CRUDE GLUCOSE OXIDASE

	Glucose oxidase preparation				
	A mμmoles*	*B* mμmoles*	*C* mμmoles*	*D* mμmoles*	*E* mμmoles*
Aerobic	0	612	484	52	26
Anaerobic	0	848	525	87	0

* Reducing sugar formed in 1 hr. at 24° C.

0·5 mgm. glucose oxidase, 3 mgm. sucrose in 1 ml. of 0·1 *M* sodium phosphate buffer *p*H 7·3.

Trehalose was found to be oxidized at 0·00028 of the rate of glucose in the glucose–oxidase preparation of Keilin and Hartree[1]. As some of the cruder preparations can form considerable quantities of reducing sugar anaerobically (Table 4), it is possible that such hydrolysis also occurred in the earlier work. Raffinose was also hydrolysed at a significant rate (Table 4). Bealing has reported formation of reducing sugar from trehalose and raffinose (as well as several other oligosaccharides) in crushed mycelium preparations of *Penicillium spinolosum* and certain *Aspergillus* species[4]. On the other hand, we found practically no hydrolysis of maltose, lactose or α-fructofuranoside under the same conditions. Maltase activity has been reported in samples obtained from several of these suppliers[6] but was found absent in yet another preparation[7].

Table 4. EFFECT OF CRUDE GLUCOSE OXIDASE ON THE HYDROLYSIS OF NON-REDUCING SUGARS

Sugar	mμmoles per hr. of reducing sugar produced
Trehalose	315
Sucrose	795
Raffinose	87

Trehalose (3 mgm.), sucrose (3 mgm.) and raffinose (4·5 mgm.) in 1 ml. of 0·1 *M* sodium phosphate buffer *p*H 7·3 were incubated anaerobically at 24° C. with 0·5 mgm. (Prep. *B*) glucose oxidase for 1 hr.

It has been known for some time that glucose oxidase preparations may be contaminated with catalase and mutarotase[5]. From the work of Bealing[4] on crushed mycelial preparations of *P. spinulosum* one might expect to find certain oligosaccharases in partially purified glucose oxidase preparations. This proved to be the case. Several commercial preparations of glucose oxidase are contaminated with β-fructofuranosidase and probably with other oligosaccharases. Such contamination must be kept in mind when glucose oxidase is used as a peroxide-generating system with cell fractions prepared with sucrose solutions. An example is given in which enough glucose is formed from sucrose to make the latter sugar equally as good a peroxide source as glucose for the formation of protein-bound iodine by sheep thyroid particles.

PERIPHERALLY EVOKED CORTICAL REFLEX IN THE CUNEATE NUCLEUS

By A. L. TOWE and I. D. ZIMMERMAN

School of Medicine, University of Washington, Seattle

THE anterior cerebral hemispheres of the cat can modify the excitability of subcortical neurones at various sites, including such sensory nuclei as those of the dorsal columns[1–4]. The excitatory influence of the cortex on neurones of the dorsal column nuclei is mediated largely, if not exclusively, by the pyramidal system[4]. Since cutaneous stimulation excites pyramidal tract neurones[5,6], it was suggested[4] that peripheral stimulation would produce a double discharge in the dorsal column nuclei, the first being due to the ascending afferent volley and the second to a descending, reflexly produced, pyramidal volley. The cortical outflow should be direct, for pyramidal tract fibres enter the hilus and ventral aspect of the cuneate and gracile nuclei and end on neurones within[7,8]. A gross potential change, recordable at the surface of these nuclei, could be expected, for Magni *et al.*[9] produced a gross potential in the cuneate nucleus by directly stimulating the pes pedunculi after destroying the remaining mesencephalic tissue.

A second, or late, surface negative wave has been observed in recordings from the cuneate nucleus[10]

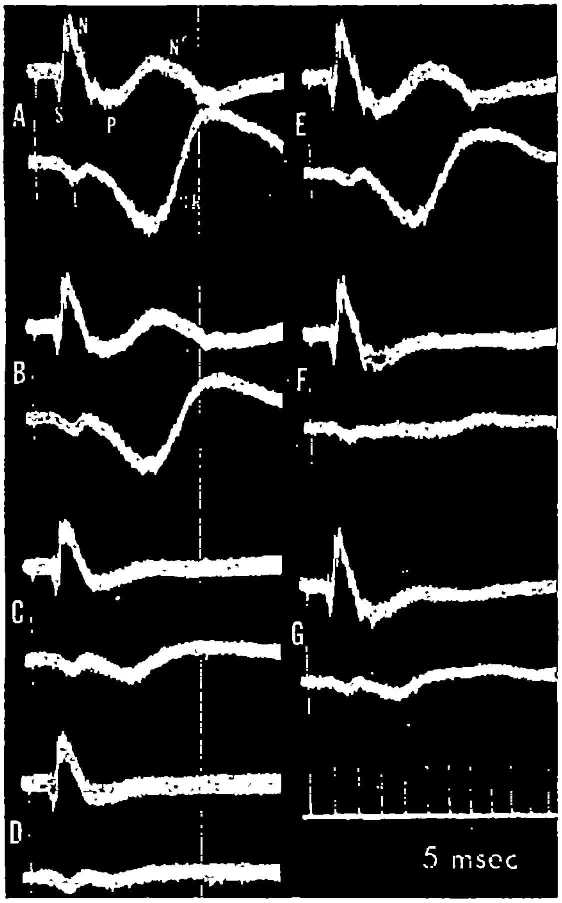

Fig 1. Upper trace of each pair, recorded with silver-ball electrode from surface of cuneate nucleus, shows 'normal' cuneate response, with second negative wave (*N*°) superimposed on a low amplitude positive wave (*P*). Lower trace of each pair, recorded with penetrating electrode about 0 5 mm. deep in medullary pyramid contralateral to cuneate electrode, shows killed-end recording of adjacent lemniscal response (*L*) and corticofugal reflex discharge in pyramid (*CR*). Time-scale applies to both traces of each pair. Responses produced by 0·1 msec. shock to forepaw ipsilateral to cuneate electrode. Superimposed traces throughout. *A*, 1 stimulus/sec., *B*, 2 stimuli/sec.; *C*, 4 stimuli/sec.; *D*, 6·25 stimuli/sec.; *E*, control response just before ice applied to anterior cerebral cortex; *F*, response 15 sec. after ice removed from both cortices (30 sec. application); *G*, response 10 min. after removal of ice, showing slight recovery

and is shown in the upper traces of Fig. 1. The more usual recording from the cuneate surface shown in the literature consists of a brief initial spike signalling the afferent volley, a longer negative wave and a very prolonged positive wave. The negative wave, 4–5 msec. in duration, presumably signals activity in cuneate neurones; concomitant activity occurs in the medial lemniscus (lower traces of Fig. 1). As suggested by Therman[11], the later positive wave has been regarded as a surface sign of activity in the underlying reticular neurones. However, this wave appears maximally over the dorsal column nuclei and reverses in sign within the cuneate nucleus; Anderson, Eccles and Schmidt[12] ascribed it to presynaptic inhibitory action of peripheral origin.

This prolonged surface positivity may be small in many preparations. Another phenomenon—the second surface negative response in the cuneate—is then clear. As shown in Fig. 1, this wave appears about 12–14 msec. after forepaw stimulation and lasts 18–20 msec. Like the late positive wave, this potential appears maximally over the dorsal column nuclei and reverses sign deep within the cuneate nucleus. It lags behind the underlying corticofugal reflex discharge[6] by about 3 msec. (5 msec. in Fig. 1, since the corticofugal reflex was recorded rostral to the cuneate nucleus). When the intensity or frequency of forepaw stimulation was altered the second negative wave and the corticofugal reflex varied together. Fig. 1 *A–D* show that the second wave disappeared just a little before the pyramidal discharge failed (rate of. 6·25/sec.). Similarly, when the stimulus intensity was decreased to near zero, the second cuneate wave disappeared just before the pyramidal reflex discharge; the latter failed when the first cuneate wave had diminished to about 7 per cent of its maximum amplitude.

The second negative wave could be eliminated by any method which stopped the corticofugal reflex discharge. Very deep anæsthesia or administration of small amounts of barbiturate to the chloralose-anæsthetized cat removed both the pyramidal reflex and the late cuneate response. The late wave is precluded by decerebration, and is also eliminated when both anterior cerebral hemispheres, from the ansate and coronal fissures rostromedially over the cruciate fissure to the anterior pole, are removed by suction. This is the tissue from which pyramidal tract fibres arise[13]. Transection of the pyramidal tracts alone at the olivo-trapezoidal level was sufficient to remove all trace of the response, even though activity in the adjacent medial lemniscus remained unaltered above the transection. The second negative wave of the cuneate thus appears to be a reflexly produced discharge descending from the cerebral cortex exclusively via the pyramidal tracts. The effect is bilateral. Fig. 1 *E–G* show elimination and partial recovery of the late wave following transient icing of both anterior cerebral hemispheres. When ice was applied directly to the exposed cortex, the second response disappeared in 4–10 sec.

Direct stimulation of a strand of dorsal column fibres isolated from the adjacent spinal cord except at its rostral connexion with the dorsal column nuclei (similar to the method used previously with pyramidal tract fibres[14]) produced a normal cuneate response and the second negative wave. The system appears to be a closed loop: cuneate nucleus–thalamus–cerebral cortex–cuneate nucleus. This positive feedback affects less than half the cuneate neurones[4]; the remaining neurones undergo a prolonged inhibitory effect[3] which is probably presynaptic in nature[12].

This work was supported by a grant (*B*396) from the National Institute of Neurological Diseases and Blindness, U.S. Department of Health, Education and Welfare.

INFLUENCE OF *p*H ON INTERFERON PRODUCTION AND ACTIVITY

By Dr. E. De MAEYER and Dr. P. De SOMER

Department of Virology, Rega Institute, University of Louvain

THE decreased growth of attenuated polioviruses in acid medium[1] led to the interesting suggestion by Lwoff that local acid production in inflamed areas could function as a homœostatic mechanism, limiting virus growth[2]. An alternative explanation for the different behaviour of attenuated and virulent viruses could be the increased interferon production of attenuated viruses, as recently described[3]. In order to investigate a possible correlation between these two phenomena, we examined the influence of bicarbonate concentration on the production and action of interferon.

The interferon used in this work was produced in a continuous line of rat tumour cells (*DE7R* cells), cultured in a medium consisting of Hanks's saline solution, enriched with 20 per cent inactivated calf serum and 0·5 per cent lactalbumin hydrolysate. The serum content of the medium was decreased to 3 per cent at the time of virus inoculation.

Interferon titrations were carried out in tube cultures of secondary rat embryo cells. Only embryos aged 18–20 days were used for preparing these cultures, all animals belonging to the highly inbred *R*-strain (originally obtained from Dr. Mühlbock, Amsterdam). Cultures at least 5 days old were used for the assay of interferon, since we found that younger cultures were less susceptible. The culture medium at the time of the titration of interferon consisted of Hanks's saline solution with 3 per cent inactivated calf serum and 0·5 per cent lactalbumin hydrolysate, enriched with choline, folic acid, nicotinamide, calcium pantothenate, pyridoxin hydrochloride, thiamine and riboflavin at a concentration of 1 γ/ml. Two different varieties of this medium were used; a low bicarbonate medium containing 0·1 per cent sodium bicarbonate and a high bicarbonate medium containing 0·3 per cent sodium bicarbonate. The *p*H's of the two media at the time of preparation were respectively 6·8 and 7·2.

The influence of the acidity of the medium on the yield of interferon was determined in cultures of *DE7R* cells inoculated with Sindbis virus. Three different multiplicities of infection were used, at both *p*H 6·8 and 7·2. In order to keep the *p*H as close as possible to its original value, bicarbonate was added several times. Culture fluids were collected when the cytopathological effect of the virus was between 75 and 100 per cent. The infectious virus was destroyed by overnight dialysis at *p*H 2. The interferon content of the dialysed fluids was then determined as follows: two-fold dilutions of the fluids to be tested, starting at 1/5, were carried out, using culture medium as a diluent. The interferon dilutions were added to tube cultures of rat embryo cells, inoculating 1 ml. into each tube and using 2 tubes per dilution. These cultures were then incubated overnight at 37° C. 500 $TCID_{50}$ of Sindbis virus were added the next morning as challenge virus. The interferon titre was read after 72 hr. as the highest dilution giving in both tubes at least 50 per cent protection against the cytopathological effect of this challenge virus. The results of this experiment show that, at each of the three multiplicities used, two- to four-fold higher yields of interferon were obtained in acid medium (Table 1).

Table 1. Interferon Titre obtained in *DE7R* Cells at Different *p*H and with Varying Multiplicity

Medium	Multiplicity of infection	Interferon titre
Low bicarbonate (*p*H 6·8)	10	1/5
	0·1	1/160
	0·001	1/80
High bicarbonate (*p*H 7·2)	10	None
	0·1	1/40
	0·001	1/20

The influence of the bicarbonate content on the action of interferon was determined, using Sindbis, vaccinia and herpes virus as challenging agents. Two titrations were carried out each time, one in low bicarbonate and one in high bicarbonate medium. The results of these experiments are summarized in Table 2.

Table 2. Titration of Three Different Interferon Batches in High and Low Bicarbonate Medium

Interferon batch	Challenge virus	Interferon titre: Low bicarbonate medium (0·1 per cent)	Interferon titre: High bicarbonate medium (0·3 per cent)
1	Sindbis	1/320	1/40
2	Sindbis	1/40	1/5
3	Sindbis	1/160	1/20
	Vaccinia	1/320	1/80
	Herpes	1/80	1/20

It can be seen that consistently higher titres were obtained when the interferon was assayed in low bicarbonate medium. Control experiments without interferon showed that the results obtained in the interferon titrations were not due to an inhibition of the challenge virus in the low bicarbonate medium.

The different titres obtained in high and low bicarbonate media were not due to a difference in interferon uptake by the cells under these two conditions, as shown in the following experiment. Two series of tubes were incubated overnight with two-fold interferon dilutions, one series in low bicarbonate medium, the other in high bicarbonate medium. The next morning the interferon was removed and every series was divided into two ; to one-half of the tubes, low bicarbonate medium was added, to the other half, high bicarbonate medium. The challenge virus was added afterwards. The interferon titre obtained in cultures incubated in high bicarbonate medium, but at the time of challenge changed to low bicarbonate medium, was approximately the same as the titre obtained in cultures where the bicarbonate content had always been low. On the other hand, cultures incubated in low bicarbonate medium, but at the time of challenge changed to high bicarbonate medium, gave the same low titre as was obtained in the series where the bicarbonate concentration was consistently high.

The possibility of using bicarbonate for reversing the cell-virus equilibrium obtained under the influence of interferon was studied in rat embryo cells infected with vaccinia virus. Rat embryo cultures were incubated with interferon in low bicarbonate medium and the next day 500 $TCID_{50}$ of vaccinia virus were added. After four days no sign of cytopathological effect was noticed in these cultures, whereas the control cultures were completely destroyed. On the fifth day the interferon was removed from the protected cultures and the cell sheets were washed twice with phosphate buffered saline. To half of these cultures fresh low bicarbonate medium was added; to the other half, fresh high bicarbonate medium. In four days the cultures with high bicarbonate medium were destroyed by the virus, contrary to the cultures with low bicarbonate medium, which showed very little sign of cytopathological effect. This clearly demonstrated that the protective effect of interferon obtained in acid conditions could be reversed by increasing the bicarbonate content of the medium.

These experiments show that the slightly acid conditions obtained in a low bicarbonate medium are favourable for the production, as well as for the activity, of interferon. This observation could explain the low plating efficiency of attenuated polio strains in low bicarbonate medium, since these viruses are characterized by an increased capacity to induce interferon production. Such interpretation is in agreement with the observations of Vogt, who found that this low efficiency of plating is caused by a reduced growth-rate of the virus, due to a decreased cell susceptibility which is only established after a preparatory period of several hours[1]. This preparatory period would correspond to the time necessary for the production of interferon and for the establishment of its protective action.

ANTIGENS OF *BRUCEI* TRYPANOSOMES

By K. N. BROWN and Dr. J. WILLIAMSON

National Institute for Medical Research, Mill Hill, London, N.W.7

THE antigenic variation which occurs in relapsing chronic infections with African trypanosomes was first recognized more than fifty years ago by Franke (1905) and by Rodet and Vallet (1906). This work, and much subsequent investigation by Ehrlich and others, has been reviewed by Taliaferro[1], and little has been added in more recent years. Agar-gel diffusion and immunoelectrophoretic techniques are now being applied to problems of trypanosomal immunity[2-4] and have been used to show a striking difference in precipitins between variants[5]; however, the precise nature of the antigens of African trypanosomes has remained indeterminate[4].

Some new observations are summarized here and will be described in detail in full elsewhere; a few preliminary results have already been briefly reported[4-6].

A syringe-passaged laboratory strain of *Trypanosoma rhodesiense*, originally isolated from man in 1923[7], was used for most experiments, including antigen fractionation. A recently isolated strain of *T. brucei*-group trypanosomes (*ANT* 32), kindly provided by Mr. M. P. Cunningham, East African Trypanosomiasis Research Organization, Uganda, was used for comparison. Relapse variants of each strain were isolated either after sub-curative arsenical drug treatment[8] or from chronically infected rabbits[9]. Trypanosomes were separated from heavily infected rat blood by centrifugation, washed three times in normal saline, lysed in water and broken ultrasonically or with ballotini in the Mickle disintegrator; this crude antigen source was usually freeze-dried. Rabbit anti-trypanosome sera were prepared by injection of crude antigen combined with Freund's adjuvant, followed by alum-precipitated antigen[10].

Nature of the antigens. At 37° C. the crude antigen source was stable in dilute mineral acid for at least 3 hr. and in dilute alkali (pH 9) for at least 18 hr., but at 100° C. reactivity with antiserum in agar gel was lost after 15 min. in acid or alkali; in neutral solution the major portion of the precipitin pattern was selectively lost after 30 min. at 100° C. Selective loss of the same major antigenic group was also produced by pepsin, 0·05 M sodium metaperiodate or by an acetylating mixture[11] (acetic anhydride in pyridine). The minor antigen group which resisted these procedures also differed from the larger group by its ability to pass through a dialysis sac and by its incomplete precipitability with cold 0·5 N trichloroacetic acid.

The separateness of the two groups was confirmed by an estimation of their molecular size[12] which correlated closely with that of macromolecular components separable in the analytical ultracentrifuge[4]. The major and minor groups (previously[4] called '*A*' and '*B*') which were present in both trypanosome strains, and in their variants, will therefore be referred to as the '4 S' and '1 S' antigens respectively. Capacity to react with antibody appeared to be insensitive to chymotrypsin, papain or carboxypeptidase treatment; but separation of the hydrolytic products by paper electrophoresis, partition chromatography or dialysis, showed that no antigenic peptides were present and that retention of antigenicity in the incubates was due to an unhydrolysed protein residuum. Inability to react with antibody after incubation of the antigen in 4 M urea may indicate the involvement of protein ternary structure in the precipitin reaction. Ribonuclease, deoxyribonuclease, ptyalin, β-amylase, lysozyme and acid and alkaline phosphatase pre-treatment had no effect on antigenicity.

Although this evidence indicated that the antigens were predominantly protein, the possible presence of a polysaccharide component was inferred from the sensitivity to metaperiodate and to acetylation, and from the persistence of antigenicity in the aqueous phase after trichloro-trifluoroethane (Imperial Chemical Industries, Ltd., 'Arcton 113') extraction[13]. The crude antigen preparation was also Molisch-positive[14], although the constituent responsible was afterwards found to be ribonucleic acid. Earlier analyses[14] had shown that the only detectable carbohydrate present in whole cell hydrolysates of *T. rhodesiense*, apart from nucleotide pentose, was a trace of glucosamine (0·2–0·3 µgm./mgm. protein), but a larger-scale fractionation was devised to investigate this point.

Analysis for possible polysaccharide and lipid antigens. Fractionation, based on a number of standard procedures for extraction of polysaccharide antigens from micro-organisms[15], consisted essentially of successive treatment of crude antigen with cold 0·5 *N* trichloroacetic acid[16] (TCA), extraction of the TCA-insoluble residue with 45 per cent aqueous phenol[17], separation, purification and further extraction with acid ether-ethanol[18] of the aqueous, phenolic and solid interfacial phases, and of the dialysed original TCA-soluble extract. Precipitin tests at all stages showed the absence of polysaccharide, lipopolysaccharide or phospholipid antigens, and the predominant association of antigenicity with a protein component.

Although lipid staining[14] (oil red *O*, fettrot 7*B*), and pre-staining (sudan black *B*), of electrophoretic separations on paper and on starch gel indicated that lipid or lipoprotein antigens were absent, crude antigen was fractionated with lipid solvents to check this aspect further. Serial extraction with chloroform-methanol at 0° C.[19], ether and ether–ethanol at $-70°$ C.[20], acid ether–ethanol at $-10°$ C.[18], and a final extraction of the residue with chloroform–methanol under reflux for 30 min., showed that antigen activity was not associated with unbound lipid, lipoprotein or phospholipid.

Separation of protein antigens. Zone electrophoresis at *p*H 8·6 of the crude antigen on Whatman 3 *MM* paper[14] showed at least three mobile proteins and an immobile residue, and at least four proteins were separated on starch gel, using a discontinuous buffer[21]. Analyses of eluates of electrophoretic fractions, chemically and by ultra-violet absorbance at 260 mµ and 280 mµ, determination of the sedimentation coefficient of crude antigen components (by courtesy of Dr. P. A. Charlwood), and electrophoresis of ultracentrifugal fractions showed the presence of a group of three nucleoproteins, mainly ribonucleoprotein, with S_{20w} values of 43, 54 and 72, and a group of at least two smaller proteins with S_{20w} values of 1 and 4. The latter group migrated anodically on electrophoresis at *p*H 8·6, whereas the nucleoprotein group was largely immobile.

Antigenicity was associated with 1 *S* and 4 *S* proteins, but predominantly with the latter. The nucleoprotein group appeared to be very feebly antigenic, as only one of four antisera tested gave a detectable reaction indicative of an antigen of corresponding molecular weight when determined by the gel-diffusion method[12]. The approximate molecular weight of the 1 *S* and 4 *S* proteins (1–2 × 10^4 and 4–8 × 10^4 respectively) from ultracentrifugal observations corresponds to estimates of about 10^4 and 5 × 10^4–10^5 determined by the gel-diffusion method[12] for the 1 *S* and 4 *S* antigen groups distinguished earlier.

Treatment of the crude antigen with non-denaturant ents used to indicate specific reactive groups in nes[22] showed that antigenicity was not affected rmalin-acetamide, formalin-alanine, *p*-chloro- ibenzoate or methanol-hydrochloric acid pretreatment, but was abolished by propylene oxide or diazobenzenesulphonic acid treatment.

The evidence thus far would therefore suggest that the antigenicity of *T. rhodesiense* is associated with at least two groups of soluble unconjugated proteins of molecular weight 10^4 and 5 × 10^4–10^5 approximately, principally with the latter, and that the haptens are probably ternary hydrogen-bonded structures involving, in the case of the larger 4 *S* proteins, phenolic or other hydroxyl-containing substituents such as the free side chains of tyrosine, serine and threonine, all which are present in trypanosomal protein[14].

Antigen location. The antigenic proteins are apparently mainly cytoplasmic, as the highest level of antigenicity per unit weight of trypanosomal protein occurs in the 'cell sap' fraction of centrifuged homogenates prepared in aqueous sucrose solutions. The centrifugal procedures conventionally used for the separation of nuclei, mitochondria, microsomes and cell sap in mammalian cell homogenates[23] were applied to trypanosome homogenates prepared by shaking with ballotini in a Mickle disintegrator. Three fractions which sedimented after 1·4 × 10^4*g*-min., 4·2 × 10^4*g*-min., and 6·3 × 10^6*g*-min. respectively, together with a final water-clear supernatant, were examined microscopically and chemically.

Separation of nuclear, microsomal and cell sap fractions corresponded to that observed in mammalian cells, but in the second fraction, which normally contains the mitochondria of mammalian cell preparations, some concentration of kinetoplast-containing fragments was observed. This is of interest in view of the unique mitochondrial-nuclear type of structure found in the kinetoplast of Trypanosomidae[24,25], and of some Bodonidae[26].

Aqueous 0·25 *M* sucrose–5 m*M* magnesium sulphate solutions gave better fractionation of cellular components than 0·44 *M* or 0·88 *M* sucrose solutions, as judged by microscopic appearance and distribution of protein and nucleic acids. Cell fractions were tested for antigenicity by serial dilution (times 5) in Ouchterlony gels; irrespective of the homogenization medium, antigenic activity in the cell sap was 10–50 times greater per unit weight of protein than in any other fraction (Table 1). After repeated washing, antigenicity was retained in the nuclear and microsomal, but not in the 'mitochondrial', fraction; incubation of the unwashed fractions in 0·4 *M* deoxycholate[30] did not release more antigen. Fractional precipitation of a 1 ml. sample of cell sap with ammonium sulphate in steps of 10 per cent saturation gave three protein peaks at 30, 50 and 80 per cent saturation respectively, with corresponding peak antigen titres, of which the last was the highest.

Table 1. ANTIGENICITY OF SUB-CELLULAR FRACTIONS OF *Trypanosoma rhodesiense*

Fraction	Protein[27] (µgm./ml.)	DNA[28] (µgm./ml.)	RNA* (µgm./ml.)	Antigenic titre/mgm. protein
Nuclear	1,570	420	0	3–15
(Mitochondrial)	780	0	70	6
Microsomal	610	0	290	8
Cell sap	1,310	0	35	100–500

Washing and suspension medium: aqueous 0·25 *M* sucrose–5 m*M* magnesium sulphate. Trypanosomes homogenized 40 min. with No. 12 ballotini in Mickle disintegrator and centrifuged 1·4 × 10^4*g*-min., 4·2 × 10^4*g*-min. and 6·3 × 10^6*g*-min. to separate nuclear, 'mitochondrial' and microsomal deposits respectively; the cell sap fraction is the clear supernatant which remained after 6·3 × 10^6*g*-min. The 'mitochondrial' fraction consisted mainly of kinetoplast-containing cell fragments. Antigenic titre is the reciprocal of the smallest dilution giving a visible precipitin reaction on an Ouchterlony gel.

* Determined by difference from total nucleic acid content[29] and DNA content.

Attempted detection of variant antigen synthesis. The almost complete restriction of trypanosomal antigens to soluble cytoplasmic proteins, and their highly specific nature, suggested that detection by gel-diffusion of selective antigen synthesis in a cell-free system might be possible, especially as the lowest limit of detection of precipitinogenic activity in our trypanosome preparations was of the order of 0·7 μgm. protein. Recent experiments[31] on the ribosomal control of specific hæmoglobin synthesis in cell-free reticulocyte preparations suggested a similar cross-over experiment. Microsomal and cell sap fractions of parent and relapse variant strains of *T. rhodesiense* were mixed and tested with corresponding homologous antisera after 1 hr. incubation at 37° C. in phosphate-buffered Krebs saline *p*H 7·4 containing 5 mM Mg^{++}, 17·4 μM 3-phosphoglycerate and 4·4 μM adenosine triphosphate. No formation of heterologous antigen was detectable in mixtures of heterologous microsomal and homologous cell sap fractions, but this may have been due to lack of sensitivity of the test method.

Antigen specificity. The 4 S group contains at least four proteins with very similar antigenic determinants which are, however, distinguishable by immunoelectrophoresis. These are present in varying proportions relative to each other in washed nuclear and microsomal fractions and in cell sap.

The specificity of reaction of rabbits immunized with different variant trypanosome homogenates was tested with mixed antisera[32] against crude antigen. Some produced antibodies which were clearly variant-specific, but antibodies common to, or cross-reacting with, a number of variants, including some of another strain, were present in all animals.

Further analysis of this apparently non-specific response showed that a quantitative difference also existed. When cell sap fractions from two antigenic variants were tested against antiserum to one or other of them, the concentration of 'common' antigen was found to be about 10 times greater in the homologous than in the heterologous fraction. The trypanolytic power of immune serum was completely variant-specific. It was abolished by absorption with cell sap but not by absorption with a 1 S antigen preparation; this suggests that lysis may be associated with the 4 S antigen.

A comparison of sera from rabbits, either infected, or immunized with crude antigen, showed that in both cases the 4 S antigens were the main precipitinogens; the washing of trypanosomes during the preparation of crude antigen did not appear qualitatively to alter their antigenic character[4]. Variants isolated from the infected rabbits were in some cases identical with those obtained from rats, suggesting that antigenic variation may be independent of the host species. A variant can also appear more than once in the same infection, and this may reflect the short interval (1–2 weeks) during which specific precipitins to a variant could be detected.

Discussion

Our investigation has shown that at least three groups of precipitinogens in *Brucei*-group trypanosomes can be separated and characterized; their probable distribution within the cell has also been established. This information could now provide a consistent terminology for trypanosomal antigens and a coherent basis for further work on the immunology of African trypanosomiasis. For example, the variant changes in trypanosomal antigens established as cytoplasmic proteins should be susceptible of analysis in terms of present knowledge of the intracellular control of protein biosynthesis. In many ways, this antigenic variation resembles the changes in phase in the free-living ciliates *Paramecium* and *Tetrahymena*[33]; a similar mechanism may contribute to the chronic relapsing nature of other parasitic protozoal infections where parasites can survive in the presence of protective antibody[34,35].

The association of antigenicity with the bulk of the proteins of the trypanosome cytoplasm also suggests that antibody interaction with glycolytic, respiratory or other soluble enzymes could occur; respiratory inhibition has in fact already been used as an index of antibody action in trypanosomiasis[36]. In this context, a relation of antigenicity with drug-sensitive enzyme loci may be reflected in the reported association of suramin- and antrycide-resistance, and 'antibody-fastness' in trypanosomes[37]. Some confirmation of this report is provided by our *T. rhodesiense* strain which, on maintenance in a series of chronically infected rabbits, became significantly less sensitive to suramin, but not to mapharside, pentamidine, antrycide or ethidium. Preliminary experiments with trypanosomes taken from rats several hours after drug treatment suggest that suramin, unlike ethidium, can affect the 4 S antigens.

EFFECTS OF VI ANTIGEN ON BACTERIAL HÆMAGGLUTINATION AND HÆMOLYSIS

By Prof. E. NETER

University of Buffalo Medical School, Statler Research Laboratories,
Children's Hospital, Buffalo, N.Y.

It has been known for many years that Vi antigen interferes with agglutination by O antibodies of typhoid bacilli containing both antigens. Other bacterial antigens, too, have similar effects, such as certain K antigens of *Escherichia coli*. Spaun[1] reported that this inhibitory effect of Vi antigen can be demonstrated also on red blood cells which had been artificially coated with both O and Vi antigens—an observation that was confirmed by Ceppellini and Landy[2,3]. Recently, it was shown that Vi antigen interferes with O agglutination of latex (polystyrene) particles as well[4]. At the present time, the mechanism whereby Vi antigen inhibits these and other agglutination reactions has not yet been fully elucidated. Several possibilities present themselves. (1) Because of spatial arrangement of the two antigens, Vi antigen interferes with the reaction of O antigen and homologous antibodies. (2) Treatment with two antigens of passive carriers, such as latex particles or erythrocytes, may result in competition between the antigens for surface areas or in the replacement of one by the other. This explanation, however, does not apply to bacteria naturally containing both antigens. (3) The Vi antigen may inhibit agglutination *per se* rather than interfere with the combination of O antigen and antibody. The present investigation was undertaken in an attempt to elucidate the mode of action of Vi antigen as inhibitor of agglutination.

Bacterial hæmagglutination and hæmolysis tests were carried out as described previously[5,6]. Briefly, sheep red blood cells (2·5 per cent) were washed three times. Bacterial antigens, alone and in combination, were added to the sediment in amounts sufficient to make a 2·5 per cent erythrocyte suspension. The cells were then kept in a water-bath at 37° C. and washed three times. For the hæmagglutination tests, these modified erythrocytes (0·2 ml.) were added to bacterial antisera in serial dilutions (0·2 ml.); the mixtures were incubated at 37° C. for 30 min. and then centrifuged at 1,300*g* for 3 min. The resulting hæmagglutination was read grossly. For the hæmolysis tests, guinea pig serum (Carworth Laboratories, New City, New York, in a dilution of 1 : 10; 0·1 ml.) was added to the above-mentioned mixtures of antisera and modified red blood cells. The suspensions were incubated at 37° C. and the resulting hæmolysis read grossly. The following antigens and antisera were used. Crude antigens of *Escherichia coli* 0111, *Salmonella enteritidis*, *Shigella sonnei*, and *Staphylococcus aureus* were prepared as described previously[5,7]. In addition, highly purified lipopolysaccharides from *Escherichia coli* 0111, *Salmonella enteritidis*, and *Shigella sonnei* were kindly made available by Prof. O. Westphal, Freiburg, Germany. Vi antigen was prepared according to Schubert, Edwards and Ramsey[8] and kindly supplied by Dr. A. H. Harris, Division of Laboratories and Research, New York State Department of Health, Albany, New York. All antisera were obtained from rabbits. Vi antiserum was kindly supplied by Dr. P. R. Edwards, Communicable Disease Center, Atlanta, Georgia; *Shigella sonnei* antiserum from Division of Laboratories and Research, New York State Department of Health, Albany, New York; *Salmonella enteritidis*, *Escherichia coli*, and staphylococcal antisera were produced in this laboratory. Phosphate hæmagglutination buffer of *p*H 7·3 (Difco) was used as diluent in all experiments.

It was reasoned that, if Vi antigen inhibits agglutination *per se* rather than interfering with the attachment of O antibody to O antigen on the surface of the erythrocyte, then immune hæmolysis by O antibodies and complement should not be similarly inhibited, for hæmolysis does not depend on aggregation of the red blood cells. Accordingly, repeated experiments were carried out on the effect of Vi antigen on agglutination and hæmolysis of sheep erythrocytes which had been modified with enterobacterial O and Vi antigens. Using standard amounts of both antigens, it was found that Vi antigen inhibits hæmagglutination but not hæmolysis. In view of the fact that fewer O antibodies per red blood cell are needed for hæmolysis than for agglutination, the effects of Vi antigen (1 : 100) on these two immunological reactions were determined with sheep erythrocytes which had been modified with varying amounts of O antigen. The results of a typical experiment are recorded in Table 1. It can be seen that Vi antigen reduces the agglutinating titre of the O antiserum more than four-fold and up to sixteen-fold. In contrast, the hæmolytic titre of the identical O antiserum, even with minimal amounts of O antigen on erythrocytes, is reduced only two-fold, and this reduction is irregular both with regard to amounts of O antigen on the erythrocyte surface and time allowed for hæmolysis. Similar results were obtained with other enterobacterial O antigens, both crude and highly purified, and with heterogenetic staphylococcal antigen as well. In all these experiments the presence of O

antigen on the surface of the erythrocytes did not affect the agglutinating or lytic titre of the Vi antiserum.

A second series of experiments was carried out to determine whether Vi antigen inhibits O hæmagglutination after O antigen-modified red blood cells had interacted with the corresponding O antibody. Accordingly, erythrocytes which had been treated with O antigen were added to O antiserum in serial dilutions in duplicate. After incubation at 37° C. for 30 min., Vi antigen (1 : 100; 0·1 ml.) was added to one series and buffer to another. The mixtures were again incubated for 15 min. at 37° C. and centrifuged. It was found that a definite reduction in the agglutinating titre of the O antiserum was effected by Vi antigen. Centrifugation of antigen-modified red blood cells after incubation with the corresponding antiserum strikingly enhances agglutination. It is unlikely that the attachment of O antibody to the antigen-modified erythrocytes is enhanced by centrifugation; rather, the aggregation of antibody-sensitized erythrocytes is facilitated. Therefore, the results of the foregoing experiment suggest that Vi antigen inhibits aggregation of red blood cells rather than the attachment of O antibodies to the erythrocytes.

Finally, experiments were undertaken to determine whether Vi antigen reverses agglutination effected by O antibodies. To this end, erythrocytes which had been modified with O antigen were added to O antiserum in serial dilutions in duplicate; the mixtures were incubated for 30 min. at 37° C., and the resulting agglutination was read after centrifugation. Vi antigen was added to one series, and buffer to the other. The mixtures were again incubated for 30 min. at 37° C. and centrifuged. It was found that Vi antigen reverses moderate agglutination effected by the higher dilutions of the O antiserum.

The results of these experiments, taken together, suggest that the major effect of Vi antigen as inhibitor of agglutination consists of interference with aggregation by O antibody of O antigen-modified erythrocytes—and possibly of bacterial cells as well—rather than with attachment of O antibody to the corresponding antigen on the cell surface. This inhibitory effect on aggregation may be due to interference, by steric hindrance, with the reaction of O antibody fixed to one cell with O antigen attached to another cell and/or with the non-immunological factors responsible for agglutination. A degree of specificity appears to be associated with the inhibitory activity of Vi antigen, for this antigen seemingly does not interfere with agglutination by its own homologous antibody.

EFFECTS OF PHYTOHÆMAGGLUTININ ON THE MORPHOLOGY OF CULTURED LEUCOCYTES

By MICHAEL W. ELVES and JOHN F. WILKINSON

Department of Hæmatology, University of Manchester and Royal Infirmary

RECENTLY interest has been taken in the mitosis-stimulating phytohæmagglutinin. This substance is a hæmagglutinin extracted from beans of the genus *Phaseolus*, and it was first used in the production of anti-serum for hog cholera[1], and later for the separation of viable leucocytes by Li and Osgood[2], who also described the preparation of a crude extract. A more refined product is now obtainable, prepared by the more elaborate method of Rigas and Osgood[3]. It is non-toxic *in vivo*[4] and has been used to separate leucocytes from marrow[5] and blood[6] for cultures, in which neither mitoses nor motility of the cells were affected. Its potentialities as a mitogenic agent were first realized by Hungerford *et al.*[7], who used a modified version of the Li and Osgood method to culture cells for examination of their chromosomes; this method of chromosome examination is now widely used. As a result of our studies of the cells during culture in order to determine the effect of phytohæmagglutinin on the cells we are able to record the following observations.

Leucocytes from peripheral blood were separated by the use of dextran, and cultured by a method slightly modified from that of Hungerford *et al.*[7]. Eight cultures were set up in which no phytohæmagglutinin was used, and ten set up with the addition of phytohæmagglutinin. Samples were withdrawn at intervals by means of a sterile needle and centrifuged in a Wintrobe tube sufficiently to sediment the cells but not to pack them. The bulk of the supernatant medium was removed, and the cells, resuspended in a small drop of medium, were spread on slides. Films were stained with: (1) Jenner–Giemsa, (2) the Feulgen reaction to check nuclear detail and (3) Washburn's per-oxidase stain.

A differential count of 200 cells was made on the Jenner–Giemsa films.

In these experiments phytohæmagglutinin-*M* (Difco) was used. The batch used (No. 450506) gave reasonably good yields of mitoses, but a previous batch (No. 448242) had no mitogenic properties. Slides made from cultures showed only two types of cell: polymorphonuclears and lymphocytes. A few monocytes were present initially in both cultures with and without phytohæmagglutinin, but were not present after 20 hr.

Changes in cell types during culture (Fig. 1). The rates of increase in the percentages of lymphocytes are shown in Fig. 1. It will be seen that in the presence of phytohæmagglutinin the rate of increase

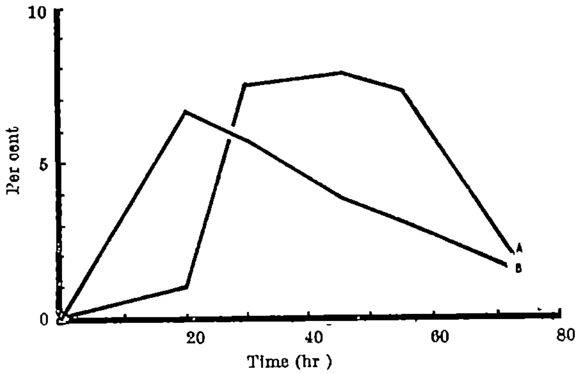

Fig. 1. Mean rate of increase in percentage of lymphocytes. *A*, culture without phytohæmagglutinin; *B*, culture with phytohæmagglutinin

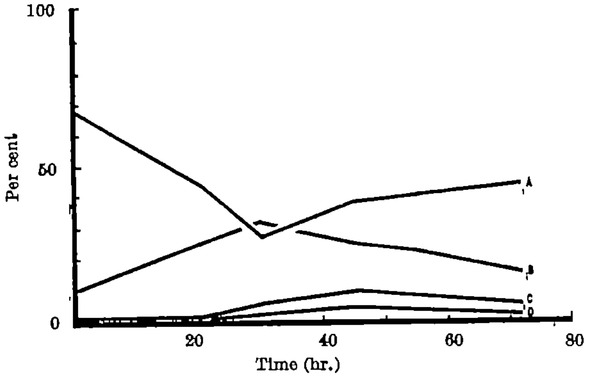

Fig. 2. Mean variation in the percentage of the lymphocyte types present in cultures with phytohæmagglutinin. *A*, normal lymphocytes; *B*, nucleoli possessing lymphocytes; *C*, 'blast' cells; *D*, mitotic cells

in the percentage of lymphocytes was rapid over the first 20 hr., and then gradually diminished during the remainder of the period of the culture.

In the case of cultures incubated without phytohæmagglutinin the initial rate of increase of lymphocytes was slow during the first 20 hr., rising rapidly in the next 10 hr., thereafter falling quickly.

These trends may be partially accounted for by the degenerative changes observed in the polymorphonuclear cells, which show two methods of degeneration; by vacuolation of the cytoplasm, and by nuclear pyknosis. The predominant degeneration in cells cultured without phytohæmagglutinin was by the pyknotic method, which appears to be the slower of the two methods, and so cells remain intact for a longer period of time, with a consequent slower initial rate of disappearance. In cultures with phytohæmagglutinin the predominant type of degeneration is by vacuolation, which, being faster, may cause the rapid initial rate of increase of lymphocytes already observed.

Change in morphology of cell types. The polymorphonuclear cells did not show changes other than the degenerative ones mentioned here. The lymphocytes, however, did show some changes in cultures with or without phytohæmagglutinin. Initially the lymphocyte population could be divided into three groups of large, intermediate and small lymphocytes respectively, the majority comprising the intermediate type. In non-phytohæmagglutinin cultures the population remained as such except for some degeneration by cytolysis until near the end of the period of culture when degenerative changes appeared in the nuclei. Although a few cells in these cultures did seem to develop nucleoli at various times no mitoses were seen. In the phytohæmagglutinin cultures a number of other types of lymphocytes were observed in addition to the normal lymphocytes. The percentages of these types present at the times of sampling are shown in Fig. 2. It will be seen that the first type to appear was the nucleoli-possessing cells. These were at first about the same size as the normal cells, but grew in size as the period of culture went on, showing increasingly basophilic cytoplasm, and the nuclei became larger and lighter in colour. From the graph it will be seen that these cells are most probably derived from the initial normal lymphocyte population.

After 20–30 hr. a new type of lymphocyte appears and these cells are very much larger than the initial cells, resembling primitive 'blast' cells, with deep blue cytoplasm, large nuclei and a number of nucleoli. Coincident with the appearance of this type is the appearance of mitotic cells, which reach a peak at about the same time, or slightly after the blast cell peak. Some mitotic figures do appear before the blasts, but these are smaller and are probably derived from the larger nucleoli-possessing cells, which are therefore probably capable of division. As the numbers of these more primitive cells decrease, the numbers of normal lymphocytes increase, presumably due to the new cells formed by the dividing cells. Some lymphocytes degenerate by cytolysis at all stages, the peak of degeneration being between 20 and 30 hr.. and the main cell types involved are the intermediate lymphocytes, the nucleoli-possessing cells and the blast forms. There is now some evidence that this type of degeneration may be a response to decreasing amounts of metabolites present in the medium due to increased metabolism of the more primitive cells. Larger lymphocytes which were present initially degenerated rapidly by vacuolation while the small lymphocytes become pyknotic.

The results presented here show that some of the lymphocytes in phytohæmagglutinin cultures undergo regressive changes, almost the reverse of the normal maturation sequence (Fig. 3). It seems probable that

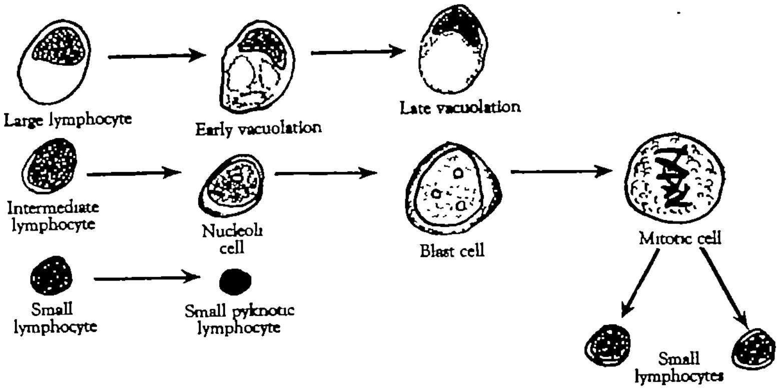

Fig. 3. Diagrammatic representation of morphological changes occurring in lymphocytes during culture with phytohæmagglutinin

concentrations of 0·2 mgm. per cent gave the best results in terms of sharply defined lines (Fig. 1). It was later found that incorporation of the antigen in agar layer over gelified antibody-charged agar gave still better results (Fig. 2). This change was adopted in our routine.

Horse immune sera and their γ-globulins against antigens from human tumours[4] were assayed by this method. Titres obtained by the described method were consistently the same as those obtained by the Ouchterlony method. Pre-immune and other non-immune control sera or γ-globulins did not form lines of precipitation.

Overnight standing of charged tubes results in the same pattern found after 1 hr. centrifuging, indicating that the effect of the gravity field is to accelerate diffusion.

CHEMISTRY

Chemiluminescence and Oxidation

Most chemiluminescent reactions are known to involve molecular oxygen or other compounds (peroxides, ozonides) liberating oxygen[1]. This striking correlation between chemiluminescence and oxidation was first established three centuries ago by Robert Boyle, who performed experiments with shining wood, fish and flesh, and found that their light disappeared on removing the air[2]. However, no satisfactory theory of the phenomenon has been offered so far.

We suggest that this action of oxygen on chemiluminescence may be explained on the basis of the following considerations.

(1) Many oxidation processes (oxidation of fats, lubricants, fuels, oxidative destruction of polymers, etc.) are chain reactions. The active radicals are the peroxy-radical RO_2 and radical R containing no oxygen, the former being a product of oxidation of the latter:

$$R + O_2 \xrightarrow{k_2} RO_2 \qquad (1)$$

(2) A weak luminescence has been detected recently in various chemical reactions at moderate temperatures[3]. It was shown that in liquid-phase radical reactions excitation occurs by the elementary processes of radical combination (or disproportionation). Immediately after recombination the energy of this exothermal process is concentrated on the newly formed molecules of a product, and a small portion of them emits energy in the form of light while the remaining molecules lose it by collision. The quantum yield (the ratio of photons emitted to the number of recombinations) is extremely low, namely, 10^{-8}–10^{-15}.

(3) The products of recombination of RO_2 and R radicals are compounds of different spectroscopic properties. The former are oxygen-containing molecules (for example, ketones, alcohols, aldehydes, etc.) which are luminescent in the visible and in the near ultra-violet. The latter show no luminescence in these spectral regions. Hence the former should transform the energy of the reaction into radiation more efficiently than the latter do.

(4) In the absence of oxygen only R radicals exist and recombine:

$$R + R \xrightarrow{k_4} \text{products } (+\text{ light}) \qquad (2)$$

Admission of oxygen results in the appearance of RO_2 and in new modes of recombination:

$$R + RO_2 \xrightarrow{k_5} \text{products } (+\text{ light}) \qquad (3)$$

$$R + RO_2 \xrightarrow{k_6} \text{products } (+\text{ light}) \qquad (4)$$

The higher $[O_2]$ the greater $[RO_2]$ and the contribution of reaction (4) to the total light intensity which results in brighter chemiluminescence. At a certain oxygen concentration all R-radicals are replaced by RO_2 and a further increase in $[O_2]$ does not lead to increasing of $[RO_2]$ and of the luminescence intensity.

Our hypothesis has been verified in experiments on oxidation of hydrocarbons initiated by thermally decomposing substances[4]. At a gradual consumption of dissolved oxygen and after $[RO_2]$ and intensity

Diffusion of Antigen into Antibody-charged Agar in Wintrobe Hæmatocrit Tubes accelerated by Centrifugation

THE methods of immunodiffusion and precipitation in gel media offer, over precipitation in fluid media or in interfaces, the advantage of creating automatically self-diluting gradients of concentrations of one or the two reactants, and thus, in a single tube or plate, the optimal conditions for reaction and aggregation (zone of equivalence). The chances of detecting a reaction in a single tube by the ring precipitation method are dependent on the pre- or post-zonal conditions since excess of one reactant dissolves the precipitate of antigen–antibody complex. Hence the need for serial dilutions even for qualitative evaluation.

Abandoned to the spontaneous forces that govern diffusion of the reactants in gel media, both single[1] and double[2], considerable time is required before the final reading of each test. With agar-diffusion Ouchterlony plates, lines of precipitation may appear as late as 14 days. This required recharging the reservoirs with reactants three times or more with consequent need for larger amounts of the reactants.

Given the dependence of the diffusion process on temperature (2°–3° C.) it becomes difficult to control this factor over long periods of time.

The factors that affect immunodiffusion are well known[3]. Some are of general nature such as temperature, pH, ionic strength of the solvents, trace elements and viscosity of the gel. These affect both the primary stage, that is, the antigen–antibody reaction, and the secondary stage, that is, the formation of the visible, light-scattering aggregates or precipitates. These can be controlled. Other factors are particular to each system, such as the nature, molecular weight and charge of the reactants, their relative concentrations and the presence of non-reacting proteins. These can only be controlled to an extent and they affect primarily the second stage.

For the simple detection and quantitation of an antibody, when identification of different antibodies is not required, such as in routine evaluation of immunization procedures, single diffusion in tubes was adequate. To reduce the time element it was decided to use Wintrobe hæmatocrit tubes providing constant dimensions and applying an increased gravity field by centrifuging.

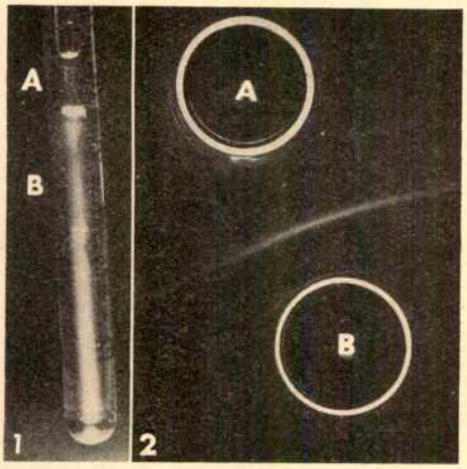

Fig. 1. 1, Modified Oudin method. Wintrobe tube after centrifugation for 1 hr. at 1,500g. 2, Ouchterlony agar plate. *A*, Antigen: mixture of purified antigens from human tumours (ref. 4); *B*, horse immune γ-globulin prepared against *A*. In 1 the γ-globulin solution is incorporated in the agar. In 2 it is deposited in the reservoir

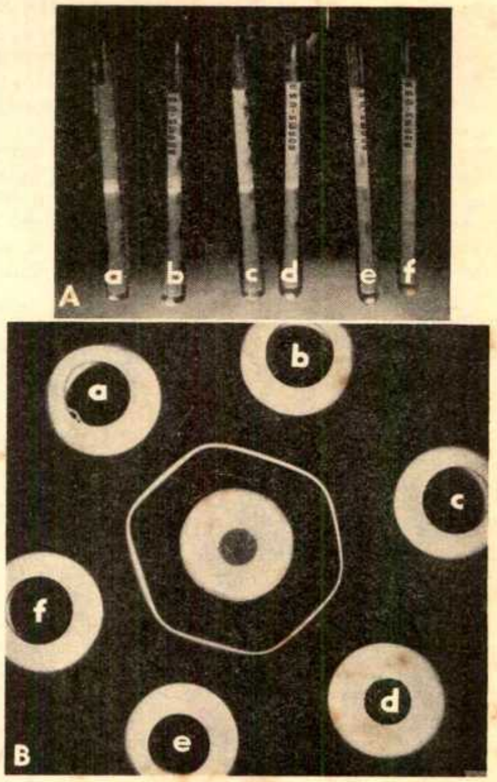

Fig. 2. *A*, Modified Oudin technique. The γ-globulin (Fig. 1) and its dilutions (10^0, *a* to 10^{-5}, *f*) are incorporated in agar in the lower half of the Wintrobe tube. After centrifuging for 1 hr. at 1,500g the lines of precipitation appear at, or near, the interface. In *B* the same system in Ouchterlony double diffusion show the correspondence of the dilutions (10^0, *a* to 10^{-5}, *f*). The titre was $10^{-5\cdot5}$, as determined in extrapolating tubes

The application of a gravity field to expedite diffusion has been suggested by Crowle[3]. It finds application only when a single antigen–antibody system is being tested, but not when separation of antigens in a mixture due to their differential diffusion-rate is expected. In this case the centrifugation would force the precipitate to move down and upset the resolution provided by the different diffusion-rates of each antigen.

In a single antigen–antibody system centrifugation can accelerate the collision of antigen–antibody molecules thus contracting the time otherwise required by simple diffusion forces.

'Ionagar' (Colab) was dissolved at 1·5 per cent in the following mixture of pH 7·6: 0·8 per cent sodium chloride, 9 parts, 0·15 M phosphate buffer, 1 part. Cadmium sulphate was added to make a 0·0005 per cent solution. Merthiolate was used as preservative at 0·01 per cent. Melted, sterile agar is cooled at 45° C. All equipment is kept at 37° C.; reagents at 25° C. Antibody (γ-globulin solutions and sera) dilutions are added to an equal volume of melted agar, mixed well without bubbling and added to Wintrobe hæmatocrit tubes up to mark 5. Agar is allowed to gel at 25° C. Agar surface must be smooth and free of air bubbles. Antigen and its dilutions overlayed on to the agar up to the 5·5 mark. Tubes are capped and centrifuged at 25° C. for 1 hr. at 1,500g. Antigen dilutions corresponding to protein

I thank, Dr. E. L. Fireman for providing the five-year-old samples used for this work.

BIOPHYSICS

Proof that the Replication of DNA involves Separation of the Strands

IN their description of the specific pairing of the nucleotides of deoxyribonucleic acid (DNA), Watson and Crick[1] proposed that this pairing was the basis for a mechanism of duplication: if unwinding occurred at the time of replication, each strand of the double helix could act as a template for the creation of a new molecule so that each daughter molecule would be a 'hybrid' of a parental strand and a new strand. Since then there have been several demonstrations that DNA replication does indeed result in an equal division of the parent molecule between the two daughters[2,3]. This, however, has not put the hypothesis beyond the realm of cavil. The DNA which divides between the two daughters might, the argument goes[4,5], consist of a pair of double helices : if so, no unwinding of the strands would be necessary to produce the observed result, and the mechanism of replication could be radically different from that proposed by Watson and Crick.

Decision could be reached if some DNA were found which (*a*) becomes hybrid on replication and (*b*) can be isolated intact in its entirety and, in this state, shown to be two-stranded. Bacterial DNA is unsuitable; it becomes hybrid[2], but it has not yet been isolated intact and so there is no unambiguous estimate of its native length-to-mass ratio (that is, strandedness). Conversely, *T*2 bacteriophage DNA is known to be largely or totally two-stranded[6], but the transfer of parental *T*2 DNA to the progeny is accompanied by so much fragmentation that only small sections of the recipient molecules are known to be hybrid[7]; these small hybrid sections could conceivably be four-stranded without markedly disturbing the ratio of total length to total mass. However, the case of λ-bacteriophage DNA appears to be straightforward. Parental λ-DNA is transferred to progeny particles which, though typical in other respects[8], contain DNA which is half parental and half new (that is, is manifestly hybrid)[9]. Further, the entire DNA of λ resides in a single molecule which can be extracted intact[10,11]. If this molecule can be shown to have the ratio of total length to total mass of two-stranded DNA, then strand separation must occur.

To prepare labelled λ DNA for autoradiography, lysogenic *E. coli CR*34 (λ) thy$^-$ was induced by irradiation with ultra-violet light and then incubated in *A* medium[9] supplemented with 2 μgm./ml. tritiated-thymine (11·2 c./m*M*). After 100 min., the bacteria were lysed with chloroform. The resulting phage was sedimented with 10,000-fold excess of unlabelled λ. resuspended and extracted with phenol[12]. This preparation of λ-DNA was diluted to a total concentration of 5 μgm./ml. in *M*/100 phosphate buffer *p*H 7, heated at 75° C. for 20 min.[11], and collected on glass microscope slides for autoradiography. Though most labelled molecules were seen to be folded or tangled, some could be measured. These ranged up to 23μ in length (Fig. 1). This estimate of length, when combined with the reported value of 46×10^6 for the molecular weight[11], gives a ratio of about 2×10^6 mol. wt./μ. This is the expected ratio for a DNA double helix in the *B* configuration[13]. Further support for the conclusion that λ-DNA is two-stranded came from the finding that the density of grains per unit length along these molecules was approximately the same as that along *T*2 DNA, labelled with the same tritiated-thymine and exposed under film for the same time; if *T*2 DNA is largely two-stranded so must be λ-DNA.

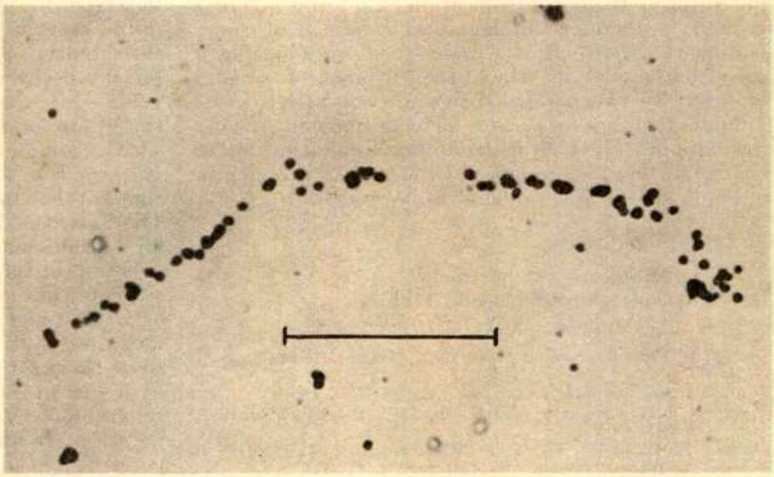

Fig. 1. Autoradiograph showing two molecules of λ-bacteriophage DNA, labelled with tritiated-thymine and exposed under Kodak '*AR* 10' stripping film for 56 days. The scale represents 10μ

In short, λ-DNA is known to form hybrids on replication. It is shown here to have the ratio of total length to total mass of two-stranded DNA. Therefore the replication of DNA must involve separation of the polynucleotide strands and the Watson–Crick model for DNA replication seems to be correct.

evidence for formation of dislocation loop after irradiation. Both copper and gold have stacking fault energies[4-6] which are considerably lower than for the other four metals[6,7]. These results would therefore seem to be consistent with the conclusion that stacking fault energy is an important factor in dislocation loop formation.

A second important factor in the formation of dislocation loops during irradiation is the rate of production of point defects since it is this which determines the dynamic equilibrium concentration of point defects in the lattice during irradiation. The rate of production of point defects would depend on the flux density and the nature of the bombarding particle. Recently, for example, Beevers and Nelson[8] have observed dislocation loops in molybdenum after bombardment with hydrogen and helium ions at rates of production which were estimated to be about 10^6 higher than for the neutron irradiations.

There are many factors, including dislocation density and distribution, specimen shape and size, and grain structure, as well as irradiation conditions such as flux density and irradiation temperature, which influence the size of dislocation loop in a neutron-irradiated metal. The development of a quantitative theory of dislocation loop formation and growth is therefore difficult. The effect of these factors can, however, be understood by adopting a simplified model in which the surfaces of a solid bounded by two parallel planes are considered to be unfillable sinks for point defects created during irradiation. The sink distribution is assumed not to change during irradiation and the rate of production of point defects is considered to be constant.

A Room-Temperature Diffusion Constant for Hydrogen in Proton-irradiated Steel

Recent measurements of hydrogen diffusion-rates in α-iron by Johnson and Hill[1] gave approximately 2×10^{-7} cm.^{2}/sec. for the value of D at room temperature; and in steel by Frank, Lee, and Williams[2] gave approximately 1×10^{-7} cm.^{2}/sec. Johnson and Hill measured re-emission of hydrogen from cylinders previously soaked in hydrogen at high temperatures and pressures, while Frank *et al.* used a mass spectrometer to measure the emission of hydrogen and deuterium from thin sheets. Frank, Swets and Fry[3], observing the build-up of hydrogen permeating through thin sheets of steel, obtained for D at room temperature values about an order of magnitude higher.

Because a knowledge of hydrogen diffusion-rates and mechanisms is important both for scientific and for technical problems, it is desirable to obtain measurements by as many independent methods as possible. I have made a determination of hydrogen diffusion at room temperature by studying the retention of tritium in proton-irradiated steel, which gives a value for the diffusion coefficient of about 10^{-10} cm.^{2}/sec. This number is believed reliable within a factor of 2.

Samples of mild steel were obtained which had originally been used for measurements of tritium and argon-37 production cross-sections by high-energy protons[4] and that had since been stored at room temperature for five and a quarter years. Tritium was originally produced throughout the bulk of the samples by irradiation with a beam of 1 BeV. protons, having a total flux of about 4×10^{12} protons/cm.^{2} The original tritium concentration, as determined approximately one month after the irradiation, varied with depth in the 10-in. long target from about 3×10^8 to about $2{\cdot}5 \times 10^9$ atoms/gm. The mild steel had been subjected to no special preparation, and presumably contained hydrogen, carbon, and other impurities in the amounts typical of non-vacuum-cast commercial steels.

From a slice selected from a known depth in the original target, the tritium was extracted and measured by techniques similar to those used for the initial determination of the tritium concentration in the samples[4]. The slice was 0·84 cm. thick. Correcting for the decay of tritium (12·4 year half-life) in the years since the original measurement, I determined the approximate fraction of tritium retained in the slice. Assuming an infinite slab, I then calculated a value of D of about 10^{-10} cm.^{2}/sec. Using the actual shape of the samples would lower this value somewhat. The difference between the diffusion-rate determined for tritium and the rate for hydrogen in the same sites is probably less than a factor of 2.

There thus exists a difference of about three orders of magnitude between D at room temperature as measured by tritium retention and what are believed to be the most reliable recent measurements of D for hydrogen in iron and steel. At present, the tritium-retention method has been used to determine only the values of D for room temperature. Until the temperature dependence of D is measured by this method, it is premature to attempt to explain the reasons for the smallness of our result. There are at least three important considerations to be borne in mind in comparing our determination with those made by more classical methods:

(1) The tritium the retention of which I measured is unequivocally introduced interstitially in the bulk of the iron or steel as the result of high-energy nuclear reactions of protons with the atoms of the metal. This is one great advantage of this technique compared with other methods of charging samples with hydrogen, which may preferentially introduce it into the structure of the metal at those locations from which it is most easily re-emitted.

(2) The same irradiation which produces the tritium produces simultaneously other radiation-damage to the metal.

(3) The concentration of tritium measurable in this way is extremely low—in this experiment, atom concentrations of about 10^{-13}. The over-all hydrogen concentration, however, is probably typical of ordinary commercial steels, and hence in a region of maximum metallurgical interest. This concentration may be low compared with that introduced by soaking samples in a hydrogen atmosphere at high temperature or pressure and then quenching them.

Neutron Capture in Tin Isotopes at Stellar Temperatures

THEORIES of stellar nucleosynthesis have emphasized the importance of neutron capture (s- and r-processes occurring in giant stars and supernovæ respectively) in producing the heavy elements[1,2]. For the s-process, cosmic isotopic abundances are predicted to show an inverse proportionality to the neutron capture cross-sections. While some nuclei can be produced by only one process or the other, the abundances can be most accurately measured for isotopes of a single element. Thus the many isotopes of tin provide the best opportunity to test the theories and to determine such parameters as the relative contribution of supernovæ to the material of the solar system. Tin-116 cannot be formed by the r-process, whereas tin-122 and tin-124 can only be so formed. In addition, the r-process is expected to be only a minor contributor[2] to the production of tin-117, -118, -119, and -120.

Stellar temperatures corresponding to neutron energies of 10–60 keV. have been suggested as typical for nucleogenesis. We have measured radiative capture cross-sections for seven of the tin isotopes by use of neutrons having an energy distribution of 18–46 keV. (mean energy, 30·4 keV.; full width at half maximum, 16 keV.), using the Oak Ridge National Laboratory 3-MV. pulsed Van de Graaff accelerator and the ^{7}Li(p,n) reaction near threshold[3]. We plan to extend the measurements to several energies from 10 to 60 keV. with better resolution, but as the neutron energy distribution in a star already covers many resonances in each isotope no significant change in the conclusions derived from the present results is anticipated.

The capture cross-sections were measured with a Moxon–Rae detector[4], using two *RCA*-7046 fourteen-stage photomultipliers and graphite converters 1 in. thick. The overall time resolution was 3–4 nanosec., permitting excellent neutron discrimination by time-of-flight, using an 8-cm. flight path to the isotope samples. Each sample weighed 30–35 gm. Corrections of a few per cent were made for resonance self-protection, average neutron path length in the sample, and isotopic impurities. The results are shown in Table 1.

The abundance attributed to giant-star nucleosynthesis, N_s, is found by subtracting an estimate of the supernovæ contribution, N_r (Table 1, col. 4), from the observed abundances N (Table 1, col. 3). The predicted inverse proportionality is shown by the approximate constancy of the product $N_s\sigma_c$ (Table 1, col. 5) for the s-process nuclei tin-116, -117, -118, -119, and -120. The increased relative importance of the r-process corresponding to these data is seen in comparing the ratio N_r/N_s (Table 1, col. 7) with the latest published estimates[2], which are shown in col. 8.

METALLURGY

Some Factors influencing Dislocation Loop Size in Neutron-irradiated Metals

THE nature of radiation damage in metals has mainly been inferred from changes in physical properties resulting from irradiation. This evidence cannot generally be interpreted unambiguously. A more direct experimental approach has recently been made possible with the development of the technique of transmission electron microscopy which makes possible the direct observation of dislocations in metals. The damage resulting from neutron irradiation has been examined in a number of metals using this technique. In some metals dislocation loops were observed while in others no structural changes were found subsequent to irradiation. The reasons for these differences in behaviour are not yet understood.

Dislocation loops in metals result from the aggregation of point defects into disks on close packed planes. These disks afterwards collapse to form a circular area of stacking fault bounded by a dislocation loop. The radius at which collapse occurs will depend on the energy of the disk relative to that of the collapsed configuration. Since the stacking fault energies of metals may differ by more than an order of magnitude, it seems reasonable to expect that the stacking fault energy would be an important factor in determining whether or not dislocation loops are observed in a particular metal.

Transmission electron microscopy investigations have been carried out on six metals, including copper[1], gold[1], aluminium[1], nickel[1], iron[2] and molybdenum[3]. Irradiation conditions were similar in all cases and total integrated fluxes were in the same range. Dislocation loops were observed only in copper and gold, while the other metals investigated showed no between solid and liquid and dependence on distance along the tube suggest that the effects will not be marked when particle collisions become frequent. The behaviour of suspensions of spherical particles in tubes has been satisfactorily explained in the past[9,10] by assuming, after Vand[11], that "the suspension behaves as though there were a layer of pure liquid at the tube wall". The thickness of this layer appeared to be independent of Reynolds number, length and diameter of tube, etc., and depended only on the particle diameter. Whitmore's "reduced concentration" theory[12] could also be considered in terms of the fluid layer hypothesis. The possible presence of particle migration complicates the issue in that such factors as tube-length, particle Reynolds number and particle concentration appear to be relevant. Until such time as particle migration effects at higher concentration are better understood, however, the behaviour of suspensions will need to be explained in terms of the simple models at present in use.

Packing of Equal 0-Spheres

A SPHERE can be defined as the locus of a point at a constant distance from a fixed point. A sphere in n dimensions is bounded by an $(n-1)$ dimensional envelope. This value $(n-1)$ can be used to define the sphere; thus an 0-sphere is a sphere in one dimension, that is a pair of points on a line[1].

Recent experiments[2,3] have confirmed that loose random packings of 2-spheres have densities of the order of 0·60. This value has been established by empirical methods only; no satisfactory theoretical treatment for a random pack has yet been found. The only alternative to direct measurement appears to be to produce a model packing with the aid of a computer and measure the density of that. Simulated random packings of 2-spheres have been produced by Monte Carlo methods[4]. Two methods have been used; the first involves placing spheres at random in a unit cube box, the second starts with a close packed array and gives each sphere a random move. This second method is useful when studying variation of distribution function in a sphere pack but not in estimating the density of a normal random arrangement. The first technique can be applied to the simple case of the packing of 0-spheres. In this case a computer is not required to generate the necessary random co-ordinates; random number tables serve equally well. A reference line is chosen and random numbers form co-ordinates on this line. These co-ordinates represent the centres of 0-spheres and the chosen diameter can be marked off. Spheres are placed until an overlap occurs, this one is rejected, more are placed, all overlaps being rejected until all the spaces left on the line are less than the chosen diameter. This represents the random packing, and the ratio of line covered to total length is the density. If part of a sphere overlaps either end of the reference line it is added at the other end.

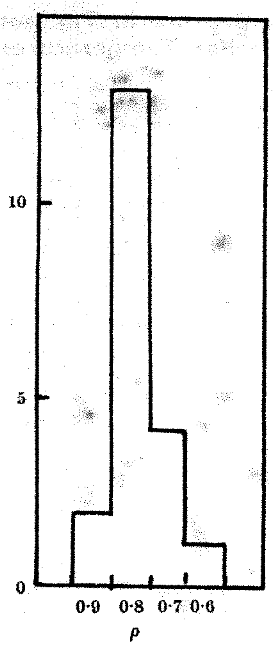

Fig. 1. Histogram for spheres of diameter 10 on 100 unit line

Since two digit random numbers were available a 100 unit line was chosen as the reference line. This means that diameters and positions can only be specified to an accuracy of 1 in 100. The edge effect which has to be considered when packings of 2-spheres are being investigated does not appear since there is no container to introduce it.

Table 1. RESULTS OF TRIALS WITH SPHERES OF DIAMETERS 10 AND 2

Diameter	Definition	No. of trials	No. of spheres on 100 unit line	Frequency N	Average density
10	1·0	20	9	2	0·78
			8	13	
			7	4	
			6	1	
2	0·01	5	40	1	0·75
			38	2	
			37	1	
			35	1	

The results of twenty trials with spheres of diameter 10 are shown in Table 1 and Fig. 1 shows the histogram of frequency N against density ρ. The mean value obtained for the density of the random pack is 0·78. To increase the definition on the reference line the tabled random numbers were taken in pairs giving random four digit numbers. With a 100 unit line this defines the position of the sphere to 0·01. Five trials with diameter 2 gave a value of 0·75.

I thank Mr. S. W. Twine, Mr. M. Clutton-Brock and Mr. R. E. Scraton, all of the Mathematics Department, Northampton College, for helpful discussion.

1·0–13·0. Despite the fact that the Reynolds numbers are some hundred times greater than those of Segré and Silberberg[1], the final positions adopted by rolling particles are in excellent agreement with the positions reported by these workers.

The apparatus consisted essentially of a vertical glass tube of length 42·0 cm. and internal diameter 0·94 cm., the upper end of which passed through the base of a glass cup and formed, in effect, a re-entrant mouthpiece. A rectangular water-filled 'Perspex' box surrounded most of the length of the tube to reduce optical distortion. The lower end of the tube was connected to a reversible variable-speed gear pump, the efflux from which was returned to the glass cup.

The methyl methacrylate spheres, of diameter 0·23–0·34 cm., were suspended in an aqueous solution of lead nitrate. The rotation of certain particles was prevented by drilling a fine hole in one side of the sphere, the offset centre of gravity counteracting rotation except when the largest hydrodynamic couples were present. A small quantity of ferric chloride sealed in the hole allowed the spheres to be moved in the tube with the aid of a magnet; a thin surface layer on the symmetrical particles served a similar purpose. Each run was started with a sphere about 8 cm. below the upper end of the tube, either close to the tube centre or in contact with the wall. After the sphere had been carried about 30 cm., a photograph was taken and compared with an equally enlarged photograph of a 'Perspex' graticule within the liquid-filled tube, this method giving the radial position of the sphere to within 0·01 cm. The sphere never moved radially during the brief period when the liquid was accelerating and, by the time the photograph was taken, radial movement had again effectively ceased.

Some typical results are given in Table 1.

It is apparent that the rolling spheres reach equilibrium when r/R is in the range 0·50–0·65, as previously reported[1], while all the non-rolling spheres move nearer to the tube axis. The initial position of the sphere has little influence on the final position, though it should be mentioned that if a sphere was located exactly on the tube axis, there was little tendency towards radial movement. For a symmetrical sphere, therefore, the axis of the tube corresponds to a position of unstable equilibrium; once the sphere is slightly displaced rolling starts and there is an increasing tendency for the sphere to 'run away' from the tube axis. In the case of some slightly asymmetrical spheres, a form of uneven rolling developed, and it is significant that as the roll-rate increased the particles moved away from the tube axis; when rolling was arrested they moved towards the tube axis.

In previous attempts to explain the behaviour of spherical particles in tubes in terms of a Magnus-type effect[1,4], it was necessary to assume that the spheres travelled with a velocity different from that of the liquid. A calculation of Simha[7] was used in order to show that the spheres lagged the liquid; the rotation of the spheres then carries them towards the tube axis if the Magnus force acts in the usual direction. In order to find the direction of the force for the current range of Reynolds numbers, the liquid density was changed a little so that symmetrical spheres had a slight tendency to rise (or fall) relative to the undisturbed fluid. A downward-settling sphere in downward-flowing liquid was found to behave much as before, though reaching equilibrium somewhat closer to the wall, but an upward-settling sphere in a downward-flowing liquid tended to drift gradually away from the wall and the rotation to die away. Thus the radial force resulting from an imposed axial translation is in the direction of the orthodox Magnus force, and if the results mentioned in this communication are to be explained in terms of the sphere's axial translation through the liquid, the sphere must lead and not lag the fluid.

Table 1. FINAL POSITIONS OF ROLLING AND NON-ROLLING SPHERES IN TUBE

R = tube radius = 0·47 cm.
d = final distance between tube wall and sphere surface.
r = final distance between sphere centre and tube axis.
W = indicates that sphere started on tube wall and C close to tube centre.

All spheres, irrespective of density or asymmetry, tended to move inwards if initially placed close to the tube wall; this also applied to a slowly settling sphere in a stagnant liquid. It is therefore clear that a short-range hydrodynamic force of repulsion is present between the particle and wall, even in the presence of particle rotation. The interplay between this inward-directed 'wall effect' and the outward-directed 'Magnus effect' produces the phenomenon observed by Segré and Silberberg, though both effects are little understood at the present time. Thus, Goldsmith and Mason[8] have recently quoted a theory, backed by experiment, which shows that spherical particles should migrate radially in Poiseuille flow only if the particles are deformable; no movement should occur with rigid spheres. It is probable, however, that these workers observed no migration with rigid spheres because of the very low particle Reynolds numbers used ($< 10^{-6}$), much lower than those used by Segré and Silberberg (10^{-3}–6×10^{-2}) or in the present work (1·0–13·0). Conversely, Rubinow and Keller[4] have accepted the findings of Segré and Silberberg regarding the annular concentration of particles and attempt to make their theory fit the facts by the introduction of an arbitrary function having the property of reversing the sign of the radial force at a fixed value of the radius. The mathematical complexity of the system seems to be largely responsible for the current slow rate of theoretical progress.

The influence of particle migration on the behaviour of concentrated suspensions is a matter of conjecture. However, the weak nature of the radial forces involved, their susceptibility to small density differences

GEOLOGY

Carbonatitic Lavas

RECENTLY, von Knorring and du Bois[1] described a vesicular lava of high carbonate content from western Uganda which shows close geochemical affinities with intrusive carbonatites. They stated: "It must be emphasized that the lavas examined are fresh and unaltered and that the carbonated nature cannot be attributed to alteration after solidification". Descriptions of extrusive equivalents of carbonatites are rare, but two other examples have been reported recently from Africa. Bailey[2] concluded that certain carbonate-rich tuffs in Northern Rhodesia were primary, and not alteration products of more normal rocks. On p. 58 of his report, he wrote: "Indigestible though the fact may be to some philosophical systems —the pyroclastics around the Rufunsa vents are effusive carbonatite". Reference is made, in both papers, to the 1954 eruption of Oldonyo Lengai in Tanganyika, during which showers of dust and ashes, largely composed of calcium and sodium carbonates, were observed to fall on the flanks of the volcano[3].

We have presented experimental evidence for the magmatic origin of carbonatites elsewhere[4,5]. Evidence from the system $CaO—CO_2—H_2O$ indicates that simplified carbonatite magmas can exist through a wide range of pressure at moderate temperatures. The lowest pressure reached in these experiments was 27 bars. Since then, Wyllie and Raynor[6], at the University of Leeds, have confirmed the existence of these melts down to pressures of 10 bars, and the minimum pressure could be considerably less than this. Addition of other components would lower the pressure even further; alkali carbonates which melt at low temperatures without dissociation at 1 bar can be especially effective in this way. On the basis of the experimental evidence, therefore, it can be concluded that carbonatite magmas could reach levels very near to the surface (10-bars pressure is developed by a rock overburden of about 140 ft.), and such magmas could be erupted as tuffs. If the alkali-bearing carbonatitic magmas persist down to pressures approaching 1 bar, then the eruption of vesiculating carbonatitic flows appears to be a reasonable possibility.

Experimental studies of multicomponent systems related to carbonatites are now well advanced. Preliminary data for the system $CaO—MgO—CO_2—H_2O$ have already been reported[5]. Fluorine is known to be an important constituent in many carbonatites, and phase relations in the system $CaO—CaF_2—CO_2—H_2O$ have therefore been studied[7]. Apatite is ubiquitous in carbonatites and investigation of the systems $CaO—CO_2—H_2O—P_2O_5$ and $CaO—CaF_2—H_2O—P_2O_5$ has confirmed that calcite and apatite can be precipitated together from a melt through a wide pressure and temperature interval, extending to below 650° C.[8] In the system $CaO—CO_2—H_2O—SiO_2$, calcite is precipitated along with a silicate mineral (calcio-chondrodite) from a low-temperature melt[9]. More detail on the crystallization of alkali carbonate melts has been obtained in the systems $CaO—Na_2O—CO_2—H_2O$ and $CaO—K_2O—CO_2—H_2O$[10]. The significance of these systems is evident from the eruption of alkali carbonates at Oldonyo Lengai and from the widespread fenitization associated with carbonatite complexes.

Von Knorring and du Bois concluded that the existence of carbonatitic lava flows was evidence for the primary origin of carbonatite magmas. The problem of whether carbonatite magmas are primary or derivative is also being studied experimentally. Systems such as $CaO—CO_2—H_2O—NaAlSiO_4$, $CaO—CO_2—H_2O—NaAlSi_3O_8$, $CaO—CO_2—H_2O—KaAlSi_3O_8$, and $CaO—CO_2—H_2O—NaFeSi_2O_6$ are being investigated, and it is hoped that the data obtained will indicate which of these suggested origins is more likely. However, whatever the ultimate origin of carbonatites may be, the nature of the reactions involving alkalis and basic oxides, with either solid-vapour or solid-liquid-vapour equilibria, is of fundamental importance for understanding the processes involved in the development, emplacement, or eruption of carbonatites and carbonatitic rocks.

PHYSICS

Influence of Particle Rotation on Radial Migration in the Poiseuille Flow of Suspensions

Segré and Silberberg[1] recently observed that when an initially uniform dilute suspension of rigid spheres passes through a circular tube in laminar flow, the spheres tend to concentrate into an annular region about half-way between the tube centre and tube wall. It was suggested that the inward motion of the spheres resulted from a force, akin to the Magnus effect, which was present because the spheres rotated as they passed through the tube. Work by Tollert[2], Saffmann[3] and Rubinow and Keller[4] has also indicated the presence of an inward force of the above type, while the 'minimum energy dissipation' theory of Jeffery[5] shows that the spheres should move inwards and eventually travel along the tube axis. Unfortunately no satisfactory explanation has been given of the fact that, in the above experiment[1], the inner spheres moved outwards while the outer spheres ceased to move inwards when they reached the region of the annulus.

I have recently made observations with single particles which clearly indicate that the rotation of the spheres results in an outward movement and not inward as previously suggested[1-4]. In the absence of rotation, the spheres normally drift towards the tube centre. This behaviour is obtained when the densities of the sphere and liquid are equal, the tube Reynolds number is in the range 100–500 and the relative particle Reynolds number[6] is in the range high resolution the induced dipole spectrum shows some interesting features.

GEOPHYSICS

Origin of Sudden Commencements

Geomagnetic storms fall into two distinct categories: recurrent and sporadic. Recurrent storms are produced by continuous streams of particles issuing from the solar *M*-regions. Swept round by the rotating Sun, the corpuscular streams overtake the Earth in its orbit at monthly intervals. By contrast, a sporadic magnetic storm marks the arrival of a single cloud of plasma, ejected at the time of a solar flare.

Sudden commencements are more frequent among storms of the sporadic type. This has been known for some time[1], but the observation has not received a satisfactory explanation. Recent theories on the nature of sudden commencements seem to provide a key to the answer. According to these theories[2], a sudden commencement results when the velocity of the solar plasma exceeds the ambient Alfvén velocity, thereby creating a hydromagnetic shock wave. A shock wave of this kind could form at the stream boundary, either in interplanetary space or in the region of impact at the Earth[2]. On the latter hypothesis it follows that the solar plasma must advance into the Earth's field with a velocity exceeding the local Alfvén velocity:

$$V_A = \frac{B}{\sqrt{\mu_0 \rho}} \quad (\text{M.K.S.})$$

Fig. 1 gives the values of V_A calculated for the Earth's exosphere in the plane of the magnetic equator ($B = B_0\,(R_E/r)^3$) out to a distance of 10 Earth-radii. Beyond that point the calculations become uncertain because of field irregularities. The ion-density was taken to be:

$$\rho = 2{\cdot}58 \times 10^9\, m_H \left(\frac{R_E}{r}\right)^3 e^{3{\cdot}03\, R_E/r}\ \text{kgm./m.}^3$$

in accordance with recent results obtained by the study of nose whistlers[3].

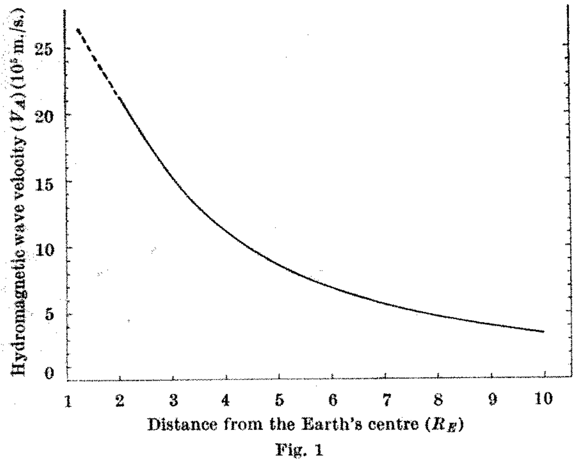

Fig. 1

A plasma cloud ejected at the time of a solar flare is propagated towards the Earth with a mean velocity of ~ 6 × 10^5 m./sec. (ref. 4). The cloud front probably reaches the Earth with a speed of 7 × 10^5 m./sec. In extreme cases (great magnetic storms) the velocity of approach may exceed 2 × 10^6 m./sec. Because of the low value of the Alfvén velocity near the boundary of the geomagnetic field (Fig. 1) a shock wave is likely to develop in that region (~ 10 R_E), particularly when the velocity of the incident plasma is higher than usual.

As regards the corpuscular streams which produce recurrent magnetic storms, the situation is quite different. In this case the velocity of approach of the stream surface (v_1) is no longer equal to the velocity of individual stream particles (v). Instead the relation:

$$v_1 = \left(\frac{1}{\omega^2 a^2} + \frac{1}{v^2}\right)^{-\frac{1}{2}}$$

holds, where ω is the solar (synodic) angular velocity of rotation and a the astronomical unit. The maximum possible value of v_1 is 4 × 10^5 m./sec. (as $v \rightarrow \infty$). Adopting the most probable value of v (6 × 10^5 m./sec.) (ref. 4) we obtain $v_1 = 3{\cdot}3 \times 10^5$ msec. Comparison with Fig. 1 shows that the velocity of the advancing stream surface could easily be less than the critical value necessary for the creation of a shock wave. This would explain the absence of sudden commencements among recurrent storms. The margin is narrow, however. Variations in field strength and density in the exosphere must inevitably lead to fluctuations in the hydromagnetic wave velocity. As a consequence, we should expect to find some recurrent storms with sudden commencement-characteristics, as well as some sporadic storms with gradual onset, a prediction which is amply confirmed by observation.

In principle the hydromagnetic shock could develop ahead of the solar plasma long before it reaches the Earth. The comparative rarity of sudden commencements among recurrent storms indicates that, as a rule, $V_A > 3{\cdot}3 \times 10^5$ m./sec. in the interplanetary medium. Since $V_A = 2{\cdot}2 \times 10^{16} \frac{B}{\sqrt{n}}$ m./sec., where n is the number of protons/m.^{3}, we deduce that $n < 4{\cdot}4 \times 10^{21} B^2$. This relation gives an upper limit to the ion-density when the field strength is known. Measurements obtained from satellite *Explorer X* (1961 κ) showed B = 1–2 × 10^{-8} w/m.^{2} at a distance beyond 30 R_E (ref. 5). Assuming this to be a representative figure, we conclude that the density of interplanetary gas near the Earth's orbit does not exceed 10^6 particles/m.^{3} under normal conditions.

LETTERS TO THE EDITOR

ASTROPHYSICS

Optical Echoes from the Moon

Experiments have been conducted to focus pulsed optical radiation on to the surface of the Moon and to detect the echoes.

A ruby optical maser radiating pulses of approximately 50 joules energy, 0·5-msec. duration, at 6934 Å. was used as the source. The transmitting optical system included a Cassegrainian telescope of 12-in. diameter. The echoes were received on a Cassegrainian telescope of 48-in. diameter, passed through an interference filter of 7 Å. band-width and were detected with a photomultiplier tube of spectral response type S-20, cooled to liquid nitrogen temperature. The field of view of the receiving telescope was 0·2 milliradians.

The photoelectron count obtained in a 0·5-msec. interval at the expected time-delay was compared with the counts obtained in 0·5-msec. intervals where no echoes would be expected and where the only relevant contributions to the count were those due to noise, that is, to Earthlight and scattered light (photoelectric dark current was negligible).

Table 1

	1 Eastern standard time	2 Region of the Moon	3 No. of flashes	4 No. of intervals	5 Average noise	6 *S.D.*	7 Average count in expected interval
May 9, 1962	21.56–22.07 hr.	Albategnius 15° S., 8° E.	11	15	1·11	0·28	1·91
May 10, 1962	21.52–22.34 hr.	Copernicus 10° N., 20° W.	23	16	1·39	0·22	1·74
May 11, 1962	21.57–22.50 hr.	Tycho 43° S., 10° W.	30	22	1·42	0·16	1·83
	22.54–23.15 hr.	Longomontanus 50° S., 20° W.	16	17	1·52	0·19	2·32

The experiments, conducted at Lexington, Massachusetts, on May 9, 10 and 11, gave positive results as indicated in Table 1. Column 3 indicates the number of consecutive flashes utilized; column 5 is the average number of photoelectrons due to noise in a 0·5-msec. interval column; 6 is the standard deviation of the noise count; column 7 is the average count in the 0·5-msec. interval where an echo was expected. The expected time delay of the signal was computed from ephemeris data and the position of the illuminated area on the Moon. Column 4 gives the number of range-intervals per trace used to obtain the data in columns 5 and 6.

I thank J. Daley, jun., of Lincoln Laboratory, for help in setting up and operating the telescopes, and G. Hardway and S. Kass, of the Raytheon Co., for help in the use of the maser. The work was supported in part by the U.S. Army Signal Corps, the Air Force Office of Scientific Research, and the Office of Naval Research.

Fundamental Band of the Quadrupole Spectrum of the Hydrogen Molecule

The application of interferometric techniques to astrophysical problems in the near infra-red shows considerable promise. The abundance of hydrogen in planetary atmospheres is probably of major importance.

Herzberg[1] observed the 2–0 and 3–0 bands of the quadrupole spectrum of hydrogen using pressures of 10 atmospheres and optical paths of 10–55 km. atmospheres. In addition, an induced dipole spectrum of hydrogen has been found by Chisholm, MacDonald, Crawford and Welsh[2] by making measurements in the pressure-range of hundreds to thousands of atmospheres.

We have observed the 1–0 band of the quadrupole spectrum of hydrogen. The spectrograph used was of the echelle type described previously[3]. An 8-metre 'White' multiple reflexion absorption tube allowed the optical path to be varied from 32 to several hundred meters. The pressures of hydrogen gas used varied from 1 to 12 atmospheres. The lines observed were $Q(1)$, $S(0)$, $S(1)$ and $S(2)$. The wave numbers of these lines have been measured to a precision of a few thousandths of a wave number. The results are $Q(1) = 4{,}155{\cdot}243$, $S(0) = 4{,}497{\cdot}830$, $S(1) = 4{,}712{\cdot}895$ and $S(2) = 4{,}916{\cdot}990$ all expressed in wave numbers *in vacuo*.

The intensities of the quadrupole lines have been observed to depend only on the mass of gas in the absorbing path (pressure independent). We have been unable to see any pressure shift or appreciable pressure broadening in the pressure-range of 1–12 atmospheres. The quadrupole lines are exquisitely sharp. The breadth of the lines closely approaches the breadth expected from the Doppler effect.

Probably the most surprising feature of the 1–0 quadrupole spectrum is its relatively high intensity. The intensities of the lines is 10–100 times as great as might be expected from the observations of Herzberg[4] on the overtones and the calculations of James and Coolidge[5]. We have been able easily to observe $S(1)$ with atmospheric pressure and an optical path of less than 100 metres.

In addition to the quadrupole spectrum we have also observed the induced dipole spectrum, which consists of extremely broad features underlying the quadrupole spectrum. The intensity of the dipole spectrum has been observed by Hare and Welsh[6] to depend on the square of the pressure. We have been able to verify this last observation. Furthermore, at as equivalent to 10–20 per cent of the major component, of a substance having an R_F value similar to that of DL-inositol. The R_F value of the minor component in three different solvent systems[3] and its electrophoretic mobility on paper in borate buffer[4] were found to be identical with that of an authentic specimen of DL-inositol. A positive reaction with the Scherer test for inositols, as adapted by Nagai and Kimura[5] for use on paper chromatograms, was also obtained.

By hydrolysis of a 'ferric phytate' preparation from several kilograms of soil, sufficient for the mixture of the two inositols was obtained for preparative chromatography on a cellulose powder column[6]. The minor component was isolated and found to be optically inactive; its hexabenzoate had a melting-point of 213° C., not depressed by admixture with authentic DL-inositol hexabenzoate.

A sample of component VI, inositol hexaphosphate, was isolated as the barium salt, converted to the free phosphate by treatment with a cation exchange resin ('Zeo-Karb 225'), the solution adjusted to *p*H 4·0 and heated for 4 hr. at 110° C. The resulting mixture of unchanged hexaphosphate and lower esters was fractionated on 'Dowex-1(*C*1)' as before and the various components hydrolysed. The unchanged hexaphosphate and each of the lower esters produced by the hydrolysis at *p*H 4·0 contained DL-inositol.

It is known that boiling 95 per cent acetic acid saturated with hydrogen chloride brings about the reversion of *myo*-inositol to DL-inositol[7,8]; but no such change has been reported when aqueous acid is used. It was found that hydrolysis of inositol hexaphosphate (Ciba, Ltd.) under the conditions used for hydrolysis of the soil preparations gave rise to *myo*-inositol only. Addition of inositol hexaphosphate to soil phytate preparations before hydrolysis did not increase the amount of DL-inositol present in the hydrolysate, as judged by visual examination of the paper chromatograms.

Reversion of *myo*-inositol hexaphosphate to DL-inositol hexaphosphate during extraction from soil was considered to be very unlikely. However, a sample of *myo*-inositol hexaphosphate (Ciba, Ltd.) was put through the extraction procedure and hydrolysed. Only *myo*-inositol was detected in the hydrolysate.

Although *myo*-inositol occurs to a considerable extent in Nature in the form of phosphate esters, none of the other inositols has previously been found in combination with phosphate. The fact that DL-inositol hexaphosphate has now been shown to occur in soil organic matter but is apparently absent from plant and animal tissues[9] suggests that it is of microbiological origin.

Scyllo-Inositol Hexaphosphate

Hydrolysis of component VII with 6 *N* hydrochloric acid at 110° C. for 40 hr. liberated material which gave a positive Scherer reaction for inositols. Paper chromatography in acetone–water (4 : 1) and *n*-butanol–acetic acid–water (4 : 1 : 1) of the hydrolysis product showed that its R_F value in these systems was identical with that of *myo*-inositol (preceding communication). A mixture of the inositol derived from component VII and *myo*-inositol failed to separate in these solvent systems.

When sufficient of the inositol from component VII became available its hexa-acetate was prepared. This had a melting-point of 301° C. which was not depressed by admixture with authentic *scyllo*-inositol hexa-acetate. The identity of the inositol with *scyllo*-inositol and the absence of other inositols were confirmed by: (1) Paper chromatography in phenol–water (4 : 1)[3]. This system distinguished between *myo*-inositol and *scyllo*-inositol provided that chromatograms were irrigated for at least 24 hr. This is contrary to the observations of Hawthorne[10] but in agreement with those of Angyal, McHugh and Gilham[3]. (2) Comparison of the infra-red spectra. The absorption band at 873 ± 11 cm.$^{-1}$ attributed to deformation of equatorial C—H bonds is shown by all the inositols except *scyllo*-inositol[11].

Scyllo-inositol has long been known to occur free in certain plant and animal tissues, but there is no record of its occurrence in combination with phosphate[9]. Recently, Hawthorne[10] examined lipids extracted from the liver of *Raia clavata* (the common ray) and also from the seeds (acorns) of *Quercus robur* (the common oak), both of which contain free *scyllo*-inositol, but found only *myo*-inositol in the hydrolysates of the phospho-inositide fraction.

Caldwell and Black[2] found that organic phosphates accumulated in soil parent materials (for example, clay–sand mixtures) if organic and inorganic nutrients were added, the whole inoculated with a water extract of surface soil, and incubated for several months at 30° C. The presence of *myo*-inositol hexaphosphate, and material apparently identical with what has here been shown to be *scyllo*-inositol hexaphosphate, was demonstrated in these materials after incubation. This investigation gives no indication which of the many types of micro-organism present in soil are responsible for the build-up of inositol phosphates.

Examination of organic phosphates extracted from yeasts[12–15] and *Penicillium chrysogenum*[16] has shown that although in one case[12] a material referred to as 'phytin' was isolated, later workers[13,14] either failed to repeat the preparation or considered that the 'phytin' was not inositol hexaphosphate. It is obviously necessary to carry out further investigations of groups of micro-organisms likely to be present in soil, with the view of determining which of them possess the ability to synthesize inositol hexaphosphate.

I thank Prof. S. J. Angyal, University of New South Wales, Sydney, for his advice, and for the preparation of the hexabenzoate derivative and its comparison with an authentic sample of DL-inositol hexabenzoate, and also for samples of *scyllo*-inositol and *scyllo*-inositol hexa-acetate.

are shown as percentages of the applied nitrogen. They may be converted to parts of inorganic nitrogen per million parts of dry soil by multiplying by 5·6.

In the first week after urea application, the average *p*H value and contents of ammonium, and hence of free ammonia, in the urea-treated soil were high and the dry-matter yield was only 57 per cent of that of the nil-nitrogen control. The urea-treated soil smelt of ammonia during this first week, and the results of daily analyses showed a rapid accumulation of ammonium ion, with a maximum on the fourth day after urea application. In the second week, both the *p*H value and the ammonium content fell and the yield rose to 92 per cent of the control. In the following three weeks the *p*H value and the ammonium content decreased further, but little or no nitrate was formed. The nitrite-ion content, however, increased and reached a maximum of 24 per cent of the applied nitrogen in the fourth week. In this and the subsequent week the dry-matter yields fell to 32 per cent of those of the nil-nitrogen controls. In the fifth and sixth weeks after urea application, the nitrite-level fell and nitrate contents increased sharply. The dry-matter yield also increased in the sixth week to reach a value of 82 per cent of that of the nil-nitrogen control. The total inorganic nitrogen accounted for only half the applied nitrogen; the other half was lost probably as gaseous products.

Throughout the experiment, visual symptoms of damage to the plants growing in the urea-treated soil were recorded. During the first three weeks of bioassay, visible damage was confined to necrosis at the leaf tip accompanied by some loss of turgidity. In the fourth and fifth weeks, the leaves rapidly lost their bright sheen and became flaccid, and at harvest many of the plants appeared to be dead. During the sixth week of bioassay the plants in contact with the urea-treated soil appeared to be as healthy as the controls.

These results confirm that phytotoxicity to seedlings can occur soon after the application of urea to soil, due, at least in part, to the accumulation of free ammonia produced by the hydrolysis of urea. They also show that nitrite can accumulate in urea-treated soil under conditions similar to those of this experiment. This nitrite accumulation is accompanied by marked phytotoxicity and reduction in plant yield. The later phase of urea-induced plant damage is thus probably due to toxic levels of nitrite.

FORMS OF INOSITOL HEXAPHOSPHATE IN SOILS

By D. J. COSGROVE

Division of Plant Industry, C.S.I.R.O., Canberra

DL-Inositol Hexaphosphate

An investigation of the 'phytate' fraction of soil organic matter by Smith and Clark[1], using a step-wise elution with increasing concentration of hydrochloric acid from an anion-exchange resin column, showed that in addition to small amounts of lower inositol phosphates there was present an organic phosphate which was eluted from the column after the main fraction, inositol hexaphosphate, had been removed. This material was referred to as an "isomer of inositol hexaphosphate". A further examination of this by Caldwell and Black[2] showed that on hydrolysis a substance was released which gave positive Scherer and Salkowski reactions but did not support the growth of *Saccharomyces carlsbergensis* or of a *myo*-inositol-requiring mutant of *Neurospora crassa*. The 'isomer' was therefore considered to be the hexaphosphate of an inositol other than *myo*-inositol.

In an investigation of the 'phytate' fraction of some Australian soils the following techniques have been used. The soil is first washed with 0·2 *N* hydrochloric acid, then extracted for 4 hr. at 60° C. with *N* sodium hydroxide. The extract is made strongly acid (*p*H 0·5) and the precipitated humic acid removed by centrifuging. Sufficient solid sodium hydroxide is added to neutralize the resulting fulvic acid solution, followed by excess sodium hypobromite. Oxidation is continued at 5° C. overnight and completed next day at 60° C. for 1 hr. The solution is acidified, extracted with ether to remove bromine, adjusted to $pH \simeq 2{\cdot}0$ and concentrated ferric chloride solution added until no further precipitation takes place. The precipitate is suspended in water and converted to the sodium salt by addition of sodium hydroxide solution.

Examination of material prepared in this way from four soils of widely differing characteristics was made by gradient elution, with 0–1·5 *N* hydrochloric acid, from a column of anion-exchange resin, 'Dowex-1(*Cl*)'. Aliquots of the fractions collected were analysed for total phosphorus by the method used by Caldwell and Black[2]. The results indicated the presence of seven components. Comparison with results obtained in an identical separation carried out on a mixture of inorganic phosphate and commercial phytin (Ciba, Ltd.) showed that component I was inorganic phosphate, IV and V were apparently identical with material present in commercial phytin, that is, presumably lower phosphates of inositol, VI was inositol hexaphosphate and VII the material described by Smith and Clark[1].

Hydrolysis of components II–VII was carried out in 6 *N* hydrochloric acid at 110° C. for 40 hr., the hydrolysates evaporated, de-ionized and examined by paper chromatography[3]. Components II and III contained no inositol; VII, *myo*-inositol only; but IV, V and VI contained in addition to the major component, *myo*-inositol, a smaller amount, estimated

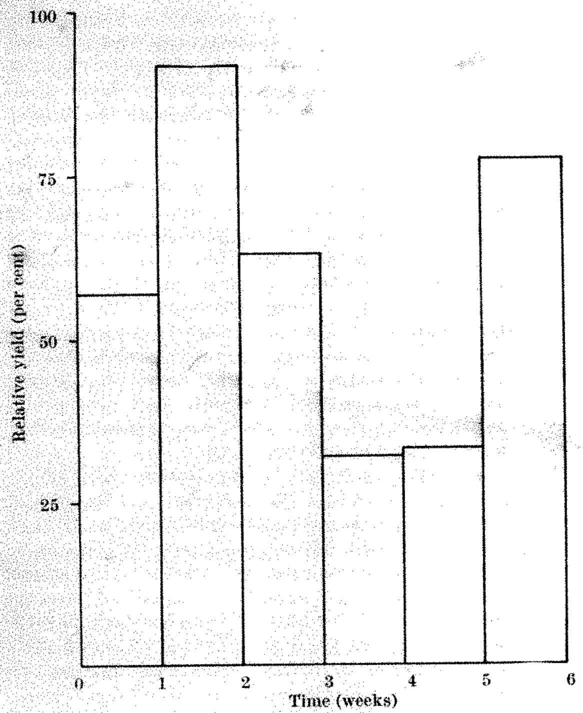

Fig. 1. Dry-matter yields from urea-treated soil at each weekly bioassay as percentages of yields from nil-nitrogen control

mixed throughout the soil there was little or no loss of seedlings at the germination stage. Two or three weeks later, however, in the urea-treated soil the plants lost their healthy appearance and many died. There was no adverse effect on the plants in the same soil treated with equivalent ammonium nitrate. The following is an account of an investigation into the possible cause of this later phase of urea-induced phytotoxicity, which cannot be ascribed to the presence of biuret.

The effects of the successive transformation products arising from addition of urea to soil were bioassayed at weekly intervals over a six-week period. The technique used was a modification of that of Stanford and DeMent[2] which has proved valuable for making determinations of short-term crop responses to nutrients or toxic materials applied to soil. The test soil, a sandy loam (*p*H 7·4), was sieved to pass ¼-in. mesh. Half the sieved soil was mixed mechanically with crystalline urea containing 1 per cent biuret at a rate equivalent to 0·6 gm. nitrogen per pot. The other half of the soil was also mixed mechanically, though no nitrogen was added. The treated and untreated soils were placed in 5-in. diameter plastic pots with two replicates of each treatment at each time of bioassay. The pots, placed on saucers in a heated glasshouse, were given a uniform overhead watering and were then covered with saucers to reduce loss of moisture. Further watering was given when necessary. At weekly intervals, 12 maize seeds, var. John Innes Hybrid, were sown in a 50:50 (w/w) mixture of silver sand and sandy loam in bottomless 3½-in. plastic pots standing on Petri dish bases. One week after sowing, by which time the seedlings were 2–3 in. high and had developed a root system, the 3½-in. pots were removed from the Petri dishes and placed on the urea-treated and untreated soils in the 5-in. pots. Water was applied to the saucers under the 5-in. pots to encourage rapid downward growth of the roots into the soil. A week after the transfer to the urea-treated and untreated soils, the foliage was cut at the level of the sand–soil mixture and oven-dried at 105° C. The dry-matter yields of the crop from the urea-treated soil are shown in Fig. 1 as percentages of those from the untreated soil for each week of the six-week experiment. Thus, the changing fertility of the treated and untreated soil was assessed over each separate weekly period for a total of six weeks.

At intervals of 2 or 3 days, the soils in the 5-in. pots were sampled for chemical analysis of inorganic nitrogen. The samples were extracted with *N*/calcium chloride and the ammonium, nitrate and nitrite contents of the extracts were determined by colorimetric methods. Frequent *in situ* measurements of the *p*H values of the soils in the 5-in. pots were made. The results, averaged over each week of the bioassay, are presented graphically in Figs. 2 and 3. The results of the analyses for inorganic nitrogen

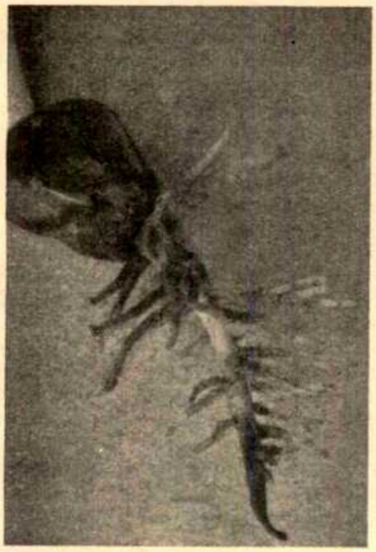

Fig. 1. Maize root damaged by urea

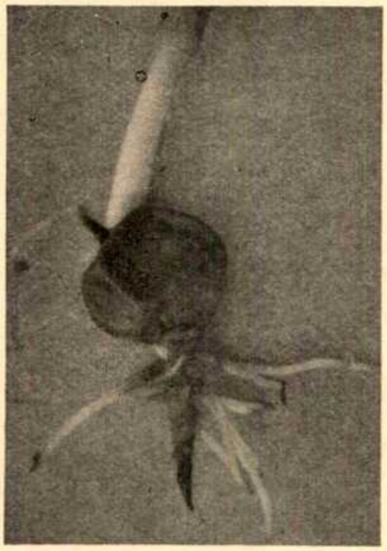

Fig. 2. Maize root damaged by anhydrous ammonia

8-in. diameter pot, equivalent to 70 or 700 lb. nitrogen per acre, were applied as urea or anhydrous ammonia. The former rate was a normal field rate; the latter was considered to give a not unrealistic concentration in the context of combine drilled fertilizer and seed, and had been shown to produce very severe urea damage. The urea was mixed with the soil immediately prior to sowing; anhydrous ammonia gas was injected into the centre of the pot by means of a hand lance either at sowing or two or five days later, spanning the period of ammonia release from the urea. In a ninth treatment no nitrogen source was applied (control). There were six replicates of each treatment. Germination occurred in 5 days, and 7 days after sowing the plants from 4 replicates of each treatment were separated from the soil and the roots washed clean for examination.

At the low nitrogen-rate urea caused no obvious signs of root damage, but about 20 per cent of the seeds showed delayed germination. At the high nitrogen-rate urea produced severe root damage; the roots were very short (mostly less than 1 cm.) and ended in a scorched brown tip (Fig. 1). Damage caused by the anhydrous ammonia was much more severe at the centre of the pot than at the edges, showing that there was little movement of ammonia through the soil. When applied at the high rate at sowing or 2 days later germination was reduced by about 50 per cent; but those plants which did germinate showed damage visually identical with that caused by urea, namely, a shortened root curtailed abruptly with a scorched tip (Fig. 2). At the low rate, only the seedlings near the centre of the pot were damaged. When anhydrous ammonia was applied 5 days after sowing, that is, after the seeds had germinated, damage occurred along the whole length of the roots, which became thin and limp; it was most marked at the high rate of application where some of the plants were killed.

The other two replicates of each treatment were allowed to grow on until the forty-second day after sowing when the roots were washed clean for examination as before. Plants which had not been killed but had had their roots damaged by the anhydrous ammonia treatment had recovered and their growth was similar to that of the control. Of the plants which had received urea, those with the low nitrogen-rate were slightly smaller than the controls but not markedly different, while at the high rate the plants were very small with much-reduced root systems. The lack of recovery from the early damage in the urea-treated plants compared with the recovery of those which received anhydrous ammonia suggests that another factor in addition to ammonia is active in urea toxicity[4].

These observations support the hypothesis that the roots of seedlings can be damaged by the ammonia produced by the hydrolysis of urea in the soil, but they also indicate that at least one other factor may be operative in urea toxicity.

Nitrite Toxicity arising from the Use of Urea as a Fertilizer

In a series of pot experiments with maize as the test crop the fertilizer value of commercial urea containing 1 per cent biuret was compared with that of ammonium nitrate.

The nitrogen sources were either uniformly mixed with the soil at the time of sowing, or placed with the seed ¼ in. below the soil surface. At low rates of applied nitrogen, urea gave a crop response equal to that from ammonium nitrate. At high rates of application, however, the response to urea was much lower than that to ammonium nitrate and the foliage yields were often less than those of the nil-nitrogen controls. The lower yields obtained when urea was placed near the seed were often due to a reduction in the number of germinating seedlings. This damage has been attributed to high concentrations of free ammonia near the seed (ref. 1 and preceding communication). When the nitrogen sources were

this tissue was formed as a result of plaques having undergone further differentiation and organization. Amniotic plaques have been reported in a wide variety of animals, including ruminants[1-4] and horses[4,5]. Amoroso describes them in the horse as "local heapings-up of amniotic ectoderm", while Hammond, Amoroso and Naaktgeboren and Zwillenberg report that they contain large quantities of glycogen. Hammond observed, significantly, that the plaques "had an appearance very similar indeed to that of the fœtal skin epidermis; distinct layers were present as in the skin; the base adjoining the mesoblast was thrown into papillæ and in the mesoblastic portion of these blood vessels were numerous". In our experience with sheep, amniotic plaques are limited in distribution to the umbilical cord and to a variable area around it. Rarely are plaques found farther than 15 cm. from the point of reflexion of the amnion from the cord. Plaques vary in shape from flat plates, 1–2 cm. in diameter, to small masses of the same area but from which project several club-like projections (up to 2 mm. in length).

Histological sections of fibre-producing tissue (Fig. 2) were similar to those of normal skin. The epidermis and dermis were clearly defined, and follicles were of normal basic structure, although they appeared somewhat shortened. The dermal papillæ were well defined. Sebaceous glands were associated with nearly all follicles, but sudoriferous (sweat) glands were rarely seen. Neither arrector pili muscles nor melanin pigment were observed.

These observations indicate the competence of the amniotic ectoderm to differentiate in a manner similar to that of the normal fœtal epidermis—given adequate inductive stimulus. Further evidence in this direction comes from the recent observations of Payne and Payne[6], who report the occasional production of epidermoid cysts (some of which contained hair follicles and sebaceous glands) from transplants of amnion to the maternal omentum in rats.

In the embryological sense, the primary requirements for the differentiation of the ectoderm with consequent formation of follicle and fibre growth are the presence of an inductive stimulus from the mesoderm and the competence of the ectoderm to react to this stimulus. Both prerequisites must have been met in the present cases, and yet, judging from the apparent rarity of the phenomena, either or both requirements must usually be absent from the amnion, or the time-relationships of their occurrence disturbed. From the point of view of development, the amnion has an origin similar to that of fœtal skin and comprises both ecto- and meso-dermal tissue, a homology which has been emphasized by Naaktgeboren and Zwillenberg. The frequent occurrence of amniotic plaques, their epithelial nature, and the fact that they rarely undergo further differentiation to produce fibres, suggest that the ectodermal component of the amnion is normally competent but that the inductive stimulus of the mesoderm is usually absent during the period of competence.

TOXIC EFFECT OF UREA ON PLANTS

Damage to Plant Roots caused by Urea and Anhydrous Ammonia

DAMAGE caused to seedlings by urea of low biuret content is often attributed to the ammonia released by the hydrolysis of the urea in the soil[1-3]. If this is so, anhydrous ammonia should cause damage similar to that from urea.

To investigate this hypothesis maize seedlings (J.I. Hybrid, 10 per pot) were grown in a glasshouse in Mitscherlich pots on a sandy loam soil, *p*H 7·4. Nitrogen dressings of 0·25 or 2·5 gm. nitrogen per protein) sometimes seen in the fibroblast cytoplasm. In view of the changed appearance of the surrounding intercellular tissue it can be presumed that the fibroblasts are contributing to the ground substance, producing new (argyrophilic) collagenous fibres or precursor substances, and splitting up the existing bundles of fibres, possibly by secreting an enzyme. Eosinophils have been shown to have considerable chemotactic properties[1] so it is likely that these cells are attracted into the tissues by the fibroblast secretions, to perform a necessary function by acting on or with the secretions so that a pathological condition cannot develop; in extreme cases (for example, œstrous ferret vulval skin) they are attracted right to the source of secretion so that the cells are in contact with each other. In tissues in which the fibroblasts are constantly stimulated to synthesize and secrete, some such regulatory mechanism is essential. The fact that in some of these structures eosinophils are especially numerous during the involutionary process strengthens the idea that they are involved in the removal of substances not required by the organism. Since the eosinophils contain relatively little RNA they are unlikely to be contributing to the extracellular protein themselves.

Although many different suggestions for the function of eosinophils have been put forward from time to time, several authors[1,9,10] have considered that protection against foreign protein is the chief reason for an abnormal accumulation of eosinophils. The ideas suggested by the present findings are thus an extension of this theory to include the regulation of extracellular protein produced under certain normal conditions by the cells of the animal itself.

COMPETENCE OF THE AMNIOTIC ECTODERM TO DIFFERENTIATE IN SHEEP

By P. G. SCHINCKEL

Division of Animal Physiology, Ian Clunies Ross Animal Research Laboratory, C.S.I.R.O., Prospect, New South Wales

DURING a routine examination of placentæ from parturient ewes, Mr. R. Edols of this Laboratory observed one in which he thought that wool fibres were growing on the membranes. Closer examination showed that fibres were growing on the amnion. These were distributed on the distal part of the umbilical cord and the adjacent area of amnion, in a definite but interrupted row, and as isolated islands, along blood vessels passing between the two layers of the amnion. The exact origin of the blood vessels could not be determined because of damage to the cord at parturition. The row was 11 cm. long and rarely more than 3 mm. wide. The fibres were produced from small masses of tissue, in which the general outline of follicles was readily seen (Fig. 1).

Since the discovery of this case, a further 50 placentæ from the same group of experimental ewes have been examined and, in two, fibres (about 1 cm. in length) were found. In these, the number of fibres was much smaller and all were produced from scattered islets of tissue. A fourth case was found in the membranes of one of 40 ewes examined in another group. In this instance only two fibres were found in one isolated amniotic plaque. The phenomenon was not observed in any membranes removed from a third group of 49 ewes, 80–145 days pregnant. All positive cases have been subject to histological examination. The ewes in the first group above were involved in one of Mr. G. Alexander's experiments in which a number of cotyledons were surgically removed from the uterus some months prior to mating. Of the three cases showing fibre growth on the amnion, one ewe had had 12 cotyledons removed, one 36 and one 60. I have been unable to locate any other references in the literature to the presence of fibre-producing follicles on the amnion.

Macroscopically, the fibre-bearing tissue resembled amniotic plaques and there seems little doubt that

methods. Samples of vulval skin from one spayed and one œstrous animal were also prepared and sectioned for electronmicroscopy.

In the spayed animal (Figs. 1 and 2) the microscopical appearance of the vulval skin resembles that of skin from the rump. The collagenous fibres are dense and show little argyrophilia, the fibroblast cells consist of small nuclei only, with no visible cytoplasm, and there are no eosinophils. In early pro-œstrus the nuclei of some fibroblasts are slightly enlarged, a few having a small amount of basophilic cytoplasm; some eosinophils are present, but confined to the patches in which the fibroblasts are changed. In pro-œstrus (Fig. 3) all fibroblasts have basophilic cytoplasm, some only a small amount, but in others the obviously enlarged nuclei with prominent basophilic nucleoli are surrounded by much basophilic cytoplasm; many eosinophils are present, occasionally seen in contact with fibroblasts. In full œstrus (Figs. 4 and 5), when the vulval skin is enormously swollen and the amount of ground substance among the loosened and more argyrophilic fibres greatly increased, the fibroblasts are dramatically enlarged, with big nuclei and nucleoli and conspicuous negative Golgi images (demonstrable also positively by silver or osmic acid methods) in their strongly basophilic cytoplasm. Many fibroblasts are in contact with one or more eosinophil. Electronmicrographs of such associated cells show that the contact between the apposed cell membranes is indeed exceedingly close (Fig. 6). By contrast there were no such changes in the rump skin from pro-œstrous and œstrous animals.

Experimental histochemical studies of the changed fibroblasts in the ferret vulval skin, also in the modified connective tissue of œstrous, pregnant and post-partum animals of other species[4], indicate that these cells contain much ribonucleic acid. This has been confirmed by electronmicroscopy of ferret vulval skin, which shows that the cytoplasm of the enlarged fibroblasts contains an extensive rough membraned endoplasmic reticulum[6]. Some of the fibroblasts contain periodic acid–Schiff-positive substance in the cytoplasm. It appears that in all these various tissues an enlarged negative Golgi is visible in the fibroblast cytoplasm only when the cells have reached a considerable degree of enlargement.

The changes of eosinophils are more obviously numerical than morphological. Both microscopically and ultramicroscopically, however, they do not appear to contain much RNA. Some, but not all of them, are periodic acid–Schiff-positive, a few being brilliantly coloured, but the majority are a less intense shade.

The close contacts between eosinophils and fibroblasts appear to be much more frequent than to be expected from a random distribution. A mathematical test (which will be described in detail elsewhere) shows that the number of eosinophils in close proximity to fibroblasts is significantly in excess of the expected random distribution. This is so not only in the œstrous condition when many of the cells are in contact, but also in pro-œstrus when the eosinophils are near the fibroblasts but seldom actually touching.

The evidence for a definite association between eosinophils and enlarged fibroblasts in the modified connective tissues of œstrous and pregnant animals which have been examined thus seems fairly clear. Since these tissues are from various sites in the pelvic and perineal region of animals from a number of different species, it can be postulated that, in such structures closely concerned with the reproductive process and specifically sensitive to sex hormones, an association between active fibroblasts and eosinophils may be characteristic of mammals generally. The actual purpose of this association is at present less clear; but a theory can be advanced which fits both currently observed and already known facts about each type of cell.

The high RNA content of the fibroblasts is evidence that they are actively engaged in protein synthesis[7], while their enlarged Golgi suggest that they are actively secreting[8], probably this protein, which may be also partly related to the periodic acid–Schiff-positive substance (? mucopolysaccharide or glycophytohæmagglutinin exerts its mitogenic effect due to its ability to cause rejuvenation of the lymphocytes. Not all lymphocytes, however, are able to respond to the stimuli of phytohæmagglutinin, otherwise the percentage of blasts might be considerably greater. It would seem that not all the cells which develop nucleoli are destined to become blasts; but this may be due to deficiencies in the culture medium caused by the increased metabolism of the cells, rather than the inability of the cells to respond.

These results are in agreement with those reported by Cooper, Barkham and Hale[8], from their studies on the incorporation of thymidine into deoxyribonucleic acid (DNA). The increase in DNA synthesis they observed is probably due to the metabolism of the nucleoli-possessing type of cells, and later the blast cells. These cells show morphological features of active metabolism, namely, the presence of nucleoli, the increasing size of the nuclei and increasingly basophilic cytoplasm.

Our studies have also indicated that the appearance of blast formation coincides with the maximum uptake of amino-acid from the medium.

Phytohæmagglutinin therefore seems to act by rejuvenating the normal intermediate lymphocytes, probably the younger cells, causing a general increase in metabolism, particularly in respect to increased DNA synthesis, which ultimately results in the division of some cells.

INFILTRATION OF EOSINOPHILS INTO THE MODIFIED CONNECTIVE TISSUE OF ŒSTROUS AND PREGNANT ANIMALS

By E. G. BASSETT

Medical Research Council of New Zealand, Endocrinology Research Department, Medical School, Dunedin

THE accumulation of eosinophils in tissues in which they are not always present is usually regarded as pathological[1,2]. The purpose of this article is to describe the behaviour of eosinophils in tissues in which they are not always present but accumulate in association with the normal physiological conditions of œstrus and pregnancy.

Recent[3-5] and current investigations have shown that regionally specific changes occur in various pelvic and perineal connective tissues from a number of different species in both œstrus and pregnancy (also in diœstrus in animals such as the rat with very short cycles). The changes in œstrus are often, but not always, less marked than they are in the same tissues from pregnant animals. The evidence is in favour of the fibroblast cells being responsible for the characteristic changes in collagenous fibres and ground substance, as they are the only cells present in all the sites in all the species where such changes have been found; also the morphology of the fibroblasts becomes very different in œstrus or with the advance of pregnancy. It is fairly certain that these modifications are effected by endogenous hormones.

In many of these tissues, particularly those with the most markedly altered fibroblasts, eosinophils are distributed throughout the tissue, having presumably entered from the blood, as they are often seen in and surrounding sectioned small blood vessels. Eosinophils are absent or rarely seen in the same tissues from anœstrous or spayed animals, or in tissues from diœstrous animals with long cycles (for example, ewe).

Eosinophil infiltration has been seen in œstrus in the broad uterine ligament (ewe), uterus (ewe, rat, mouse, ferret), cervix (rat), vagina (rat), vulval skin (ewe, ferret). Eosinophils are also present in the uterus of diœstrous rats and mice and persistent œstrous rats.

Eosinophils have been seen in the following tissues from animals in late pregnancy or early post-partum involution: sacrosciatic ligament (ewe), broad ligament (ewe, cow, sow, rat, ferret), intramuscular connective tissue and tendon of origin of ischiococcygeus muscle (ewe, cow, sow), symphyseal ligament (mouse, hedgehog), sacro-iliac joint (ewe), retractor clitoridis muscle (ewe), uterus (ewe, rat, mouse, hedgehog), cervix (rat, hedgehog), vagina (ferret, rat, hedgehog), median canal (phalanger), vulval skin (ewe, rat). Involutionary stages for all these different structures have not been investigated, but in those which have (for example, broad ligament and sacro-iliac joint of ewe, symphyseal ligament and uterus of mouse), there are generally more eosinophils than in the same tissues from animals in late pregnancy.

Eosinophils have not been found in all the tissues in which fibroblast changes have been seen, and in the tissues in which they are present there is a considerable variation in the number of eosinophils. The differences appear to be related to the degree of change in the fibroblasts. In places in which eosinophils are numerous they are occasionally (for example, vulval skin of pregnant ewe, uterus of œstrous rat) or frequently (œstrous ferret vulval skin) seen in close contact with fibroblasts.

Since the grossly swollen vulval skin of the œstrous ferret represents the most extreme change in connective tissue of all the structures listed here, it has been made the subject of a special study. Altogether 10 ferrets were available (kindly supplied by Tasman Vaccine Laboratories, Lower Hutt) in several sexual states, including spayed, very early pro-œstrus, pro-œstrus and œstrus. Sections of vulval and rump skin were prepared by usual histological methods and stained with hæmatoxylin–azur II–eosin or periodic acid–Schiff or silver impregnation

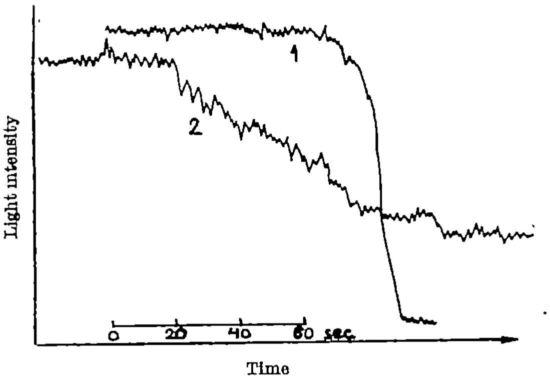

Fig. 1. Luminescence drop induced by substitution of *R* radicals for RO_2 in the oxidation of ethylbenzene (1) and methyloleate (2) at 60°. The rate of initiation is 7·5 × 10^{-7} mole $l.^{-1}$ $sec.^{-1}$. For ethylbenzene the drop is more sharp, as the reaction of this hydrocarbon with oxygen occurs more easily than in the case of methyloleate radicals

remained constant for a long period of time, a drop in the luminescence, caused by disappearance of RO_2, was observed (Fig. 1).

The higher the oxidation-rate and the lower the initial concentration of oxidation, the earlier the drop occurs. On the other hand, the shape of the drop itself should depend on kinetic parameters of the reaction. This was the basis for development of chemiluminescence methods for quantitative studies of oxidation reactions[4]. The correlation of results obtained by these and other methods is given in Table 1.

Vibrationally Excited Products of Bimolecular Exchange Reactions

Many observations of gaseous bimolecular exchange reactions in which vibrationally excited products appear have been interpreted[1–3] in terms of a simple model developed by F. T. Smith[4]. Smith's treatment, based on the kinematics of a collinear collision, predicts that the upper limit to the fraction of energy of reaction which may appear as product vibration is $\sin^2\beta$, where β is the angle between the skewed axes of the potential energy surface on which a sliding mass point represents the progress of the collision. Observed vibrational energies in excess of the amount calculated in this way have usually been interpreted as contravening Smith's model. It is the purpose of the present communication to point out that when the Smith treatment is generalized by lifting the restriction that collisions be collinear, it becomes apparent that the fraction being calculated is more nearly a lower limit than an upper. As a result certain changes in the interpretation of the experimental evidence are required.

Suppose the reaction being considered is $A + BC \rightarrow AB(\text{excited}) + C$. Let the masses of A, B, and C be m_1, M and m_2 respectively; let the AB distance be r_1, the BC distance r_2, and the angle between r_1 and r_2 be α. Smith's calculation in effect replaces the steeply rising portion of the potential surface at small r_1 and r_2 for $\alpha = \pi$ with a vertical plane normal to the r_2 direction. The component of momentum of the sliding mass point which is parallel to r_2 is supposed to be reflected by this plane; this leads to the result quoted here. Smith suggests that to the extent that reflexion of the mass point is not specular, the amount of energy appearing in product vibration will be less than that calculated in this way.

For a fixed value of α (not necessarily π) the kinetic energy of the system is[4]:

$$T = \tfrac{1}{2}(\mu_1 - \rho\mu_3^2 r_2^2 \sin^2\alpha)\dot{r}_1^2 + \tfrac{1}{2}(\mu_2 - \rho\mu_3^2 r_1^2 \sin^2\alpha)\dot{r}_2^2$$
$$+ (-\mu_3 \cos\alpha + \rho\mu_3^2 r_1 r_2 \sin^2\alpha)\dot{r}_1\dot{r}_2$$

in which $\mu_1 = m_1(m_2 + M)/(m_1 + m_2 + M)$

$$\mu_2 = m_2(m_1 + M)/(m_1 + m_2 + M)$$
$$\mu_3 = m_1 m_2/(m_1 + m_2 + M), \text{ and}$$
$$\rho^{-1} = \mu_1 r_1^2 + \mu_2 r_2^2 - 2\mu_3 r_1 r_2 \cos\alpha$$

In general, no two-variable potential surface can be constructed on which the motion of a sliding mass point represents the collision, unless r_1 and r_2 are constants. This is an approximation which may be made in the present case, since interest centres on what happens at the point on the surface where the mass point is supposed to be reflected. With this identification of r_1 and r_2, one may proceed with the standard method[5] of potential surface construction and arrive at:

$$\sin(\tfrac{1}{2}\pi - \beta) = \frac{-\mu_3 \cos\alpha + \rho\mu_3^2 r_1 r_2 \sin^2\alpha}{(\mu_1 - \rho\mu_3^2 r_2^2 \sin^2\alpha)^{1/2}(\mu_2 - \rho\mu_3^2 r_1^2 \sin^2\alpha)^{1/2}}$$

The fraction of energy converted to vibration is then:

$$\sin^2\beta = (\mu_1\mu_2 - \mu_3^2)/(\mu_1\mu_2 + x)$$

in which:

$$x = \rho\mu_3^2 \sin^2\alpha(\rho\mu_3^2 r_1^2 r_2^2 \sin^2\alpha - \mu_1 r_1^2 - \mu_2 r_2^2)$$

When α is 0 or π, x is 0 and $\sin^2\beta = 1 - \mu_3^2/\mu_1\mu_2$, which is precisely Smith's result. One discovers by algebraic manipulation (making use of the fact that ρ^{-1} is the instantaneous moment of inertia of A, B and C about a perpendicular axis through their centre of mass, and therefore always positive) that $x \leqq 0$ for $0 \leqq \alpha \leqq \pi$ and any choice of rs and μs. Thus collinear collisions lead to a smaller fraction of energy converted to vibration than do any other type. Furthermore, since β varies from less than to greater than $\pi/2$ as α changes from π to 0, there is some intermediate value of α (much more probable geometrically than the collinear value $\alpha = \pi$) for which the potential surface axes form a right angle. For the Smith model this configuration corresponds to all the energy of reaction appearing as vibration; in the generalized model one then says that the upper limit for the fraction of energy converted to vibration is always unity, as is suggested by the experimental evidence, and by theoretical arguments adduced by J. C. Polanyi[6].

The observations concerning these reactions must therefore be reinterpreted as follows. Appearance of vibrational energy in excess of the amount calculated from the one-dimensional Smith model is always to be expected if the reflexion approximation for the motion of the representative mass point is a realistic one. Appearance of vibrational energy less than the amount calculated may mean that the reflexion approximation is a poor one, or that not all the heat of reaction is released as kinetic energy during the approach of the reactants, or that the observations have been made after some vibrational relaxation of the observed species has occurred.

BIOCHEMISTRY

Structure of the Carbohydrate Moiety of Orosomucoid

Orosomucoid isolated from serum has been the subject of many investigations in recent years[1–4]. Popenoe[5] isolated an α_1-glycoprotein from the urine of patients with the nephrotic syndrome and showed it to be immunochemically identical to serum orosomucoid. More recently the glycoprotein has been isolated from the same source by means of cellulose ion-exchangers[6]. This glycoprotein was shown also to be identical to serum orosomucoid by immunoelectrophoresis and gel-diffusion techniques, and was found to be homogeneous by physical and chemical techniques[7].

The present investigations were concerned with the chemical structure of the carbohydrate portion of the latter glycoprotein by means of periodate oxidation.

Oxidation of the urinary orosomucoid in 0·04 *M* sodium metaperiodate (15 molar excess) at ambient temperature is complete after 10 days. Eighteen moles of formaldehyde and 36 moles of formic acid are liberated rapidly. During further slow oxidation an additional 54 moles of formic acid are liberated, but no additional formaldehyde. The final consumption of periodate is 190 moles per mole of orosomucoid (mol. wt. 46,500). The ratio formaldehyde/formic acid/periodate consumed after oxidation for 15 hr. is 2 : 4 : 9. Titratable non-dialysable acid increased from 18 equiv./mole of orosomucoid to 28 equiv./mole during the oxidation. The material contains no *O*-acetyl groups as determined by the method of Lipmann and Tuttle[8].

The urinary orosomucoid sample contained 18 *N*-acetyl neuraminic acid (NANA) residues per mole. When it was treated with 36 moles of sodium metaperiodate, 18 moles of formaldehyde and 18 moles of formic acid were liberated after 10 hr.

The carbohydrate residues remaining and fragments formed during the oxidation were investigated chromatographically after oxidation for 1 hr. and after total oxidation. The oxidized samples were reduced with sodium borohydride, hydrolysed (3 *N* H_2SO_4 for 4 hr.) and the amino-acids were removed by use of 'Deacidite *FF*' (carbonate).

Fucose and NANA were destroyed during the first hour of oxidation. After total oxidation appreciable amounts of galactose and mannose remained unoxidized, these substances being present in nearly equal quantities before and after oxidation, while the *N*-acetyl glucosamine residues appeared largely resistant.

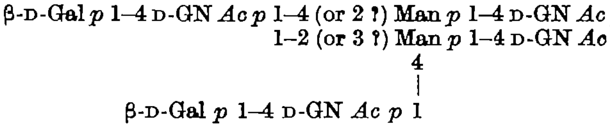
A spot migrating between galactose and mannose (butanol/ethanol/water, 5 : 1 : 4) was present in the hydrolysate of oxidized orosomucoid, and was shown to be glucose by oxidation to gluconic acid with the specific enzyme glucose oxidase. The absence of glucose in the hydrolysate of native urinary orosomucoid is consistent with the fact that it has not been reported by previous workers. One explanation for its release after oxidation is that its neighbouring unit(s) is oxidized, causing a weakening of an acid-resistant linkage, but the possibility of it arising by epimerization from mannose has not been excluded.

The fragments of the oxidized sugars contain, *inter alia*, appreciable quantities of glycerol and glycolaldehyde. The glycerol concentration appears to diminish during the slow stage of oxidation, indicating that oxidation of the activated carbon-5 hydrogen follows a cleavage between carbons-3 and -4, giving then additional formic acid with resultant loss of glycerol. Ionophoresis in molybdate buffer[9] showed the presence of a trace of threitol but no erythritol.

The amino-acid composition of the protein moiety remains qualitatively unchanged during the oxidation as shown by hydrolysis (5 *N* HCl for 17 hr.) and two-dimensional chromatography.

From these observations the following conclusions are indicated. *N*-acetyl glucosamine must be linked at position 3 or 4 or branched. The production of large amounts of glycerol and formic acid favours a 1–6 linkage for some of the galactose and/or mannose. The absence of erythritol proves that no mannose is linked at positions 1 and 4 alone, while the presence of a trace of threitol shows that only a small amount of galactose is linked at 1 and 4. Some of the mannose as well as galactose must be substituted at 1 and 3 or branched to account for that which resists oxidation.

In a recent paper, Eylar and Jeanloz[10] proposed the following structure for an octasaccharide obtained by mild hydrolysis of serum orosomucoid:



$$\begin{array}{rcl} \beta\text{-D-Gal}\,p\ 1\text{–}4\ \text{D-GN}\,Ac\,p\ 1\text{–}4\ (\text{or}\ 2\ ?) & \text{Man}\,p & 1\text{–}4\ \text{D-GN}\,Ac\,p \\ 1\text{–}2\ (\text{or}\ 3\ ?) & \text{Man}\,p & 1\text{–}4\ \text{D-GN}\,Ac \\ & 4 & \\ & | & \\ \beta\text{-D-Gal}\,p\ 1\text{–}4\ \text{D-GN}\,Ac\,p & 1 & \end{array}$$

(GN *Ac* is *N*-acetyl glucosamine)

The above findings are in accord with this structure first from the point of view of resistance of hexosamine units, and secondly, that only part of the mannose is susceptible to periodate oxidation.

This investigation was carried out during the tenure of a postdoctoral fellowship (grant No. *GF*–13485) from the Division of General Medical Sciences, United States Public Health Service.

Recovery of Microbial Polysaccharide B-1459 with a Quaternary Ammonium Compound

A new cyclic process has been developed for isolating a microbial polysaccharide from fermented broth. The usual method has been by addition of a water-miscible solvent in which the polysaccharide is insoluble, for example, methanol or ethanol[1,2]. Because of the high viscosity of most microbial polymers in water solutions, it is difficult to obtain concentrations greater than 1·5 per cent in the fermented broth; consequently, large amounts of solvent are required to isolate and purify the polysaccharide.

In the new process a polyanion polysaccharide was isolated from fermented broth with a quaternary ammonium compound, and the quaternary ammonium compound recovered and re-used in a cyclic procedure, thereby decreasing the amount of solvent required for isolation. The polysaccharide isolated was synthesized by the bacterium *Xanthomonas campestris NRRL B*-1459 by fermentation of a medium containing glucose, organic nitrogen, and inorganic salts. At the completion of fermentation, the broth had a viscosity of 7,000 centipoises (determined by means of a Brookfield viscometer); (mention of firm names or trade products does not imply that they are endorsed or recommended by the Department of Agriculture over other firms or similar products not mentioned) and a polysaccharide content of about 1·5 per cent.

Tests showed that the quaternary ammonium compound would be most effective for recovery of polysaccharide in dilute broth in the presence of an electrolyte, such as potassium chloride. Dilution of the broth also facilitated removal of cells and insoluble materials.

Percentages of potassium chloride and quaternary ammonium compound stated in the recovery procedure are based on the weight of undiluted broth.

The broth was diluted to a viscosity of 450 cp. by addition of two parts by weight of water, and the cells removed by centrifugation. Two per cent potassium chloride was added to the centrifugate and the polysaccharide precipitated with 2·75 per cent (v/w) of 'Arquad 16–50', an industrial grade quaternary ammonium compound, which consists primarily of cetyltrimethylammonium chloride. Electrolyte concentration was critical since addition of 1 per cent potassium chloride gave a voluminous gel-like precipitate; whereas with 3 per cent potassium chloride, no precipitate formed.

A fibrous, slowly settling, precipitate formed and was separated from the broth by centrifugation at 13,000*g*. The weight of the cake was about 8 per cent of the original broth weight. The centrifuged liquid contained about 2 per cent of the quaternary ammonium compound used, as assayed by the method of Colichman[3].

To remove the quaternary ammonium compound from the polysaccharide, the cake was agitated with four times its weight of methanol containing 0·05 per cent potassium chloride to prevent gelling in the methanol. The cake filtered easily on a vacuum filter. A total of three washes was made, after which the water-soluble polysaccharide was vaccum dried.

The combined filtrates from the methanol washes were concentrated under vacuum to recover methanol in the distillate and 'Arquad 16–50' in the concentrate. Distillate from the concentration contained 97 per cent methanol. Concentrate from the evaporation was assayed for the quaternary ammonium compound by determining the efficacy of precipitation on polysaccharide broth samples. The concentrate contained 80 per cent of the original quaternary ammonium compound. Consequently, 20 per cent of the original amount of fresh quaternary ammonium compound was added to the recovered concentrate for precipitation of polysaccharide from broth in the second cycle. A total of six cycles was made in this manner. Recovery of quaternary ammonium compound after each cycle was 80 per cent.

Table 1. Weight and Viscosity of Water Solutions of Polysaccharide recovered with Re-cycled Quaternary Ammonium Compound

Cycle No.	Polysaccharide (gm./100 gm. broth)	Viscosity (cp. at 25° C.) concentration 2 per cent	1 per cent	½ per cent
1	1·56	8,640	2,330	300
2	1·55	9,960	2,270	260
3	1·60	8,580	2,140	260
4	1·57	8,820	2,300	275
5	1·42	9,460	2,350	265
6	1·58	9,080	2,450	285

The weight of polysaccharide recovered from each cycle was uniform, except for an unexplained lower recovery on the fifth cycle; and viscosities of water solutions of the polymer showed little variation (Table 1). These viscosities compare favourably with those of polysaccharides recovered by methanol precipitation.

Urea Cycle and Cellular Deoxyribonucleic Acid Content

While preparing a manuscript on the metabolism of Amphibia to appear in a forthcoming book[1], I was struck by an interesting relationship between the occurrence of the ornithine-urea cycle[2] in the liver of vertebrates and the deoxyribonucleic acid (DNA) content of their somatic cells.

Vendrely[3] has tabulated the values of the DNA content per somatic cell for 73 species of vertebrates. Values ranged, for example, from 0·94 × 10^{-12} gm. DNA per somatic cell in the shad, *Eucinostomus gula*, to 168 × 10^{-12} gm. in the amphibian, *Amphiuma* sp. With several exceptions (wood turtle, snapping turtle, alligator, water snake, mouse, and the lamprey eel, all of which exhibited values of 5·0 ± 0·1 × 10^{-12} gm.) the urea cycle occurs in, and only in, those vertebrates[4,5] containing more than 5·0 × 10^{-12} gm. DNA per nucleus of somatic cell. That is to say, animals examined, the livers of which are capable of effecting a synthesis, *de novo*, of urea, that is, from carbon dioxide and ammonia, generally possessed nuclear DNA values above a cut-off value of 5·0 × 10^{-12} gm.; animals incapable of effecting this synthesis generally had values below the cut-off value (Table 1). Because of the difficulties in determining precise values for the DNA content per cell, it is not certain whether or not there is an overlap of cellular DNA content and the

Table 1

* Evidence for occurrence of urea cycle is presumptive.

occurrence or non-occurrence of the urea cycle in certain species of Agnatha, Squamata, and Chelonia. It is of further interest to note that invertebrates, none of which is known to possess a functioning urea cycle, have values below the cut-off value. It has been suggested elsewhere[4] that there has occurred a deletion of some of the urea cycle enzymes during the course of vertebrate evolution. In this regard, Mirsky and Ris[6], whose data make up a large portion of the values tabulated by Vendrely[3], suggested that in the course of vertebrate evolution there were decreases in the DNA content per cell. The data are consistent with the idea that there has been first a general upwards trend in the level of cellular DNA followed by a general decreasing trend during the course of animal evolution. In the evolutionary line leading from amphibian stock through the Cotylosauria (stem reptiles) the reduction probably did not fall to the cut-off value until after the appearance of the progenitors of turtles and mammals, for all species of these investigated possess an active urea cycle, while this is not the case with birds, lizards, snakes, and alligators (crocodiles).

It is offered as a working hypothesis that the reduction in DNA during vertebrate evolution involved at certain points the loss of information for synthesis of one or more enzymes of the urea cycle.

Mammalian Phosphoprotein Phosphatase

THE demonstration by Harris[1] and Barth *et al.*[2,3] of an enzyme in frog egg releasing phosphate from an endogenous phosphoprotein substrate was followed by the observation[4] that mammalian tissue preparations split the phosphate bonds of exogenous phosphoproteins such as casein and phosvitin, at acid *p*H, at rates of about 60 μmoles phosphoprotein phosphorus/gm. wet wt. tissue/hr. Both these enzymic activities were attributed to 'phosphoprotein phosphatases'. Studies on preparations from rat liver and spleen[4,5] described a Mg^{2+} and thiol-activated enzyme, labile to heat and salt fractionation, and active on casein and phosvitin but not on simple phosphate esters, thus distinguishing it from acid phosphomonoesterase. It was presumed to function by the splitting of the phosphoseryl bonds of phosphoproteins without accompanying proteolysis[4,5,21].

More recently, reports from a number of laboratories have described the extensive purification of a phosphoprotein phosphatase from rat, mouse and ox liver and spleen[6-16]. Like the earlier described enzymes, this preparation was active at acid *p*H, but in other respects it resembled them only slightly. Thus it was stable to the routine use of prolonged acid autolysis, salt fractionation, temperatures up to 70°, and dialysis, during purification; these procedures were all reported to partly or wholly inactivate the unstable enzyme[4,5]. It was activated by thiols and Fe^{2+}, but not by Mg^{2+}, and was inhibited by molybdate. But the major distinction lay in the specificity of the enzyme. Removing virtually all the phosphate of casein and phosvitin, it was also active with, *inter alia*, fructose diphosphate, acetyl phosphate, adenosine mono- and tri-phosphate, phosphoramidate, pyrophosphate and phenyl phosphate, splitting phosphate from some of these substrates at rates many times in excess of that for phosphoproteinase activity.

The low specificity of the enzyme suggests its original designation as 'phosphoprotein phosphatase' as fortuitous; indeed, Singer and Fruton[11] originally studied it as a phosphoramidase. It would appear to represent nothing else than a non-specific acid phosphatase of the type of β-glycerophosphatase.

I have examined, and purified 100-fold, the phosphoprotein phosphatase of guinea pig, rat and ox brain[17,18]. This enzyme, which represents the sole phosphoproteinase of these tissues, had in common with those earlier described an acid *p*H optimum, but differed from the stable liver and spleen enzyme[6-16] in being very unstable, losing activity on dialysis, salt and acetone fractionation, freezing and thawing and at *p*H's outside the range 5·0–7·5. It was activated by Mg^{2+} and Mn^{2+}, but not by thiols, and was inhibited by 0·1 m*M* Fe^{2+}. The enzyme was highly specific, releasing only a small percentage of the phosphate present in casein and phosvitin, but[19] quantitatively active with an endogenous phosphoprotein fraction from a variety of mammalian tissues. It showed no activity with β-glycerophosphate, phosphorylserine, fructose diphosphate, adenosine mono- and triphosphate, phosphoramidate, pyrophosphate or phenyl phosphate. It was present only in the heavy mitochondrial and soluble fractions from brain.

Thus the cerebral enzyme, in contrast to the stable spleen and liver enzyme, appears to represent a genuine phosphoprotein phosphatase, resembling in this the enzymes of frog and chick egg[1-3,20] and the unstable liver and spleen preparations of Feinstein and Volk[4] and Roche, Thoai and Pin[5]. Preliminary evidence suggests that the phosphoprotein phospha-

tases of kidney, intestinal mucosa, and human red cells, are also of this type[19].

Some of these differences are set out in Table 1. They point to the conclusion that mammalian tissue contains at least two classes of enzymes capable of splitting phosphoproteins, one being stable and non-specific, and present primarily in liver and spleen, and the other more widely distributed, labile, and highly specific. It is suggested that it is this latter enzyme which plays a part in the rapid *in vivo* metabolism of endogenous phosphoproteins.

'Soluble' Cysteine Desulphurase of Rat Liver as an Adaptive Enzyme

IN a previous communication from this laboratory, results were presented which show that the enzymatic formation of hydrogen sulphide from L-cysteine in the liver of the rat occurs through two pathways[1]. During the course of purification of the pyridoxal phosphate-dependent enzyme present in the non-particulate fraction of the liver (which we referred to as 'soluble' desulphurase), it has been observed that the purified enzyme which catalyses the formation of hydrogen sulphide and ammonia from L-cysteine is also responsible for the formation of ammonia from some other substrates and particularly from DL(+)-*allo*-cystathionine; the ratio of specific activities of the enzymatic preparations towards cystathionine and towards cysteine remained the same even after an approximately 300-fold purification. We concluded[1] that the soluble cysteine desulphurase was probably identical with the cystathionase-homoserine deaminase crystallized by Matsuo and Greenberg[3]; but, from the results of some inhibition experiments, we suggested that the mechanism of action of cystathionase appeared to consist of the deamination of substrates leading to the labilization of γ-substituents rather than the reverse mechanism proposed by Matsuo and Greenberg. Recently, Goswami *et al.*[4] observed that the L-cysteine desulphydrase activity in an homogenate of chick liver (where the two pathways demonstrated in rat liver are also present[5]) was increased if L-cysteine or L-histidine were injected to the animals for 4 days, while other amino-acids (DL-methionine, L-arginine, L-glutamic acid) were not effective.

In the investigation described here we studied the variations of the levels of soluble cysteine desulphurase and of some deaminases in rat liver under the influence of injections of various amino-acids, some of which (L-methionine, DL-homoserine) are related to cystathionine and cysteine while the others (L-alanine, DL-tryptophan) are without any apparent relation to these substrates.

We used Wistar male rats from the Centre de Sélection des Animaux de Laboratoire du C.N.R.S. with mean body-weight of 80 gm. The L-amino-acids were injected intraperitoneally into the rats in doses of 3·3 m.moles/kgm. according to Lin and Knox[6], the DL-amino-acids in doses of 6·6 m.moles/kgm. The animals were killed 4 hr. after the injection; the preparation of the supernatant fraction of the liver and the conditions of determination of formation of hydrogen sulphide have been described earlier[7], the only difference being that in the present experiments the final concentration of L-cysteine was 10^{-1} *M* instead of 10^{-2} *M*; pyridoxal phosphate was always added to the preparations of liver. The determination of the level of enzymatic deamination of various substrates by the supernatant was carried out according to a process analogous to the method employed by Matsuo and Greenberg[3]; in these experiments also pyridoxal phosphate was always added.

Table 1 presents the results obtained after injections of L-methionine. It can be observed that this treatment increases all the enzymatic activities, the increases being significant, in our experimental conditions, in the cases of desulphuration of L-cysteine and of deamination of DL-homoserine.

Table 1. RESPONSE OF ENZYME-LEVELS TO L-METHIONINE

	Desulphuration of L-cysteine	Deamination of L-cysteine	Deamination of DL(+)-*allo*-cystathionine	Deamination of DL-homoserine
Control	102 ± 4·5* (6)	7·5 ± 0 65 (8)	50·1 ± 8·8 (8)	9·8 ± 0·6 (7)
Injected	148 ± 11 (8)	8·1 ± 0·5 (8)	58·1 ± 2 7 (9)	13·5 ± 1·2 (7)
	$P < 0{\cdot}01$	$0\ 3 < P < 0{\cdot}5$	$P = 0{\cdot}1$	$P = 0{\cdot}02$

The activities are expressed, for the desulphuration, as μgm. hydrogen sulphide (mean of the group measured) formed in 30 min by 1 ml. of the supernatant, and for the deaminations as μgm. ammonia (mean of the group measured) formed in 15 min. by 0·1 ml of the supernatant. Figures in parentheses are number of animals.
* *S.E.*

Table 2 shows the response of some enzymatic activities to injections of DL-homoserine. After this treatment the level of cysteine desulphuration was significantly increased, the same type of results were obtained in the case of deamination of DL-homoserine. In these experiments, too, the deamination of cysteine was also increased, but not in a significant manner.

Table 2. RESPONSE OF ENZYME-LEVELS TO DL-HOMOSERINE

	Desulphuration of L-cysteine	Deamination of L-cysteine	Deamination of DL-homoserine
Control	66·5 ± 5·5* (15)	5·7 ± 0·65 (12)	9·5 ± 0·8 (11)
Injected	97 ± 3 (13)	7·1 ± 0·6 (12)	12·4 ± 0·9 (8)
	$P < 0{\cdot}01$	$0\ 1 < P < 0\ 2$	$0{\cdot}02 < P < 0\ 05$

* *S.E.*

It is noteworthy that after injections of L-alanine and of DL-tryptophan the level of cysteine desulphuration in the liver remained unchanged; the actions of L-methionine and of DL-homoserine thus appear to be specific. The injection of DL(+)-*allo*-cystathionine was not effected, due to the poor solubility of this substance. In experiments in which L-cysteine was administered, we observed no modifications of the level of desulphuration although L-cysteine is a substrate for the enzyme; even after administration of L-cysteine for 4 days according to Goswami *et al.*[4], the level of desulphuration remained unchanged; this fact is perhaps due to other reactions of L-cysteine and especially to rapid oxidation of this substance in the organism of the rat. Perhaps these results also show that cysteine is not one of the best substrates for the enzyme investigated.

From these results it appears that the soluble cysteine desulphurase of rat liver is an adaptative enzyme the level of which is controlled by the amount of some amino-acids related to the substrate. It has also been observed that this enzyme is regulated by hormonal influences: the level of the soluble desulphurase is significantly decreased in the liver of thyroxine-treated rats and increased in the liver of thyroidectomized rats[5]; in addition, the level of the enzyme, which is not modified after adrenalectomy, is nevertheless increased after injection of hydrocortisone[5].

The fact that the administration of L-methionine increases the level of the soluble desulphurase and increases also the levels of deamination of DL(+)-*allo*-cystathionine and of L-cysteine and, moreover, the fact that in the liver of DL-homoserine-treated rat the deamination of DL-homoserine and the desulphuration of L-cysteine are both significantly increased, strongly suggests that all these reactions are catalysed by the same enzyme.

Vitamin K_1 in Chloroplasts

THERE has been considerable speculation concerning the role of vitamin K in photosynthesis. Arnon[1] has shown that several water-soluble naphthoquinones stimulate photosynthetic phosphorylation, although vitamin K_1 is inactive as a stimulant in these reactions. Dam[2] has shown that material which shows the biological activity of vitamin K is contained in chloroplasts and is localized in the green parts of plants. On the other hand, vitamin K_1 has not been isolated from chloroplasts and has not been detected previously by chemical assay in extracts from chloroplasts[3]. In our laboratory we have not previously been able to observe vitamin K_1 in extracts from chloroplasts even though we could find the vitamin in extracts from whole leaves. We have now found chemical evidence for vitamin K_1 in extracts from spinach chloroplasts. The compound has been purified by silicic acid column chromatography and has shown absorption maxima at 269, 261, 249, 242 mμ in alcoholic solution. After treatment with potassium borohydride the absorption decreases in the 260–270 mμ region and increases to a new maximum at 244 mμ with an isosbestic point at 254 mμ. This material also gives a positive Irrevere–Sullivan test[4] as well as a positive Dam–Karar test[5] for vitamin K.

The compound from spinach chloroplasts shows an R_F identical to vitamin K_1 from alfalfa when chromatographed on silicone-impregnated paper[6] and chromatography reveals only one quinone-positive spot.

The amount of material obtained after chromatography on the silicic acid column corresponds to 0·01 mole of vitamin K_1 per mole of total chlorophyll. This value agrees well with the value reported by Dam[7] for other tissues.

We believe that two factors are of primary importance in the estimation of K_1 in spinach chloroplasts. First, the compound is difficult to extract and is often not removed even when plastoquinone is extracted. We find that extensive extraction is necessary with a mixture of polar and nonpolar solvents. For this extraction we use a mixture of chloroplasts having a chlorophyll content of approximately 1·73 mgm. chlorophyll/ml.; 0·2 *M* potassium phosphate buffer, *p*H = 6·5, a solution of 1 : 1 propanol to heptane and water in the v/v ratios of 1 0; 1·2; 3·0; 2·5. The mixture is then shaken on a reciprocal shaker for 3 hr., separated by means of a separatory funnel, and the aqueous phase re-extracted several times with petroleum ether until only a pale proteinaceous residue of the chloroplasts remains. Second, the borohydride reduction assay, when used to determine K_1, must be used with care, since K_1 is readily autooxidizable and the spectral changes associated with reduction of the quinone may not be observed.

Chloroplasts for these studies were prepared by differential centrifugation of a homogenate prepared by grinding spinach leaves in 0·5 *M* sucrose in a Waring blender at half the maximum speed for 1 min. as previously described[8].

We have checked our chloroplast preparations under the electron microscope and find no gross contamination with either small particles or fibrous material. There is also no significant amount of coenzyme Q in the preparation, indicating that there is no significant mitochondrial contamination.

Occurrence of Arachidonic and Related Acids in the Protozoon *Ochromonas danica*

IT is generally accepted that arachidonic acid is only found in animal lipids. However, similar fatty acids have been reported from several micro-organisms[1–3]. It is therefore of interest to search for the occurrence of arachidonic acid in the lipids of organisms close to the origin of flora and fauna. The composition of fatty acids of the protozoon *Ochromonas danica* has been investigated by us.

This phytoflagellate can be cultivated under photosynthetic conditions and in the dark. The sample used for detailed analysis came from cultures grown in light for 7–10 days on a synthetic medium which did not contain any lipid[4]. The cells were collected by centrifugation; their lipids were extracted by chloroform–methanol, saponified, and the acids esterified[5].

Table 1 gives results of gas-liquid chromatography of the methyl esters[6], but several other acids, some of them not yet identified, were detected in small amounts. The samples did not contain conjugated or *trans* double bonds but alkaline isomerization confirmed the presence of high unsaturation. The tentative identifications by gas-liquid chromatography retention times were confirmed by isolation of the unsaturated fatty esters and determination of their structure.

Isolation proceeded by the following steps: low temperature crystallization removed saturated and oleic acids; liquid–liquid chromatography[7] of the unsaturated fraction yielded essentially two peaks consisting of two and three components; preparative gas-liquid chromatography of 30–40 mgm. samples separated these peak fractions into the individual components, except linolenic and γ-linolenic esters, which were not separated from each other on a preparative scale.

The positions of the double bonds were determined by ozonolysis and subsequent hydrogenation to aldehydes and aldehyde-esters[8]. These products were identified by gas-liquid chromatography and/or thin-layer chromatography[9] of the 2,4-dinitrophenylhydrazones.

Methyl oleate was isolated from the more saturated fraction of the initial crystallization and its structure was verified by the above procedures.

Table 1. MAJOR FATTY ACIDS OF *Ochromonas danica* GROWN IN LIGHT AND CHEMICALLY DEFINED MEDIUM (percentage composition)

Myristic	15	Linolenic	2
Palmitic	10	γ-Linolenic	10
Stearic	3	Arachidic	1
Oleic	8	8,11,14-Eicosatrienoic	5
Linoleic	16	Arachidonic	11
		Docosapentaenoic*	2–4

* Probably 4,7,10,13,16-docosapentaenoic acid.

Methyl docosapentaenoate was isolated from another sample of *O. danica* lipids by preparative gas-liquid chromatography of the total esters. Ozonization-hydrogenation showed it to be 4, 7, 10, 13, 16-docosapentaenoate. Gas-liquid chromatography indicated the occurrence of this, or a very similar, acid in the sample described in Table 1.

As with other micro-organisms, the fatty acid composition of *O. danica* varies with the culturing conditions. On defined medium under light the organism produced linolenic and γ-linolenic acids at a ratio of about 1 : 4, and this was not drastically affected when the cultures were grown in the dark. In contrast, their ratio was found reversed when *O. danica* had been grown on a complex medium[10]. However, arachidonic acid represented 10–15 per cent of the total fatty acids at all conditions so far tested.

The discovery of arachidonic together with linoleic, γ-linolenic and 8, 11, 14-eicosatrienoic acids in *O. danica* is of great interest since, in the rat, these latter acids are precursors of arachidonic acid[11]. The occurrence of arachidonic acid in micro-organisms related to *O. danica* is likely. The finding may open a microbiological approach to the study of arachidonic acid metabolism and function.

PHYSIOLOGY

Œstrous and Ovarian Response of the Ewe to a Horse Anterior Pituitary Extract

MULTIPLE-OVULATION in the ewe can be readily induced by a single injection of pregnant mare serum gonadotrophin given on the twelfth–fourteenth day of the œstrous cycle[1]. However, little is known of the ovarian response of the cyclic ewe to other gonadotrophins.

In recent work[2], carried out in the autumns of 1960 and 1961, in which large numbers of fertilized eggs were required, merino ewes were treated with a horse anterior pituitary extract prepared from frozen anterior pituitaries. The frozen pituitaries were finely ground and then homogenized in a Waring blender with a 2 per cent solution of sodium chloride. The homogenate was centrifuged at 1,200 r.p.m. for 20 min., the residue discarded, and the supernatant precipitated with 4 vol. of ethyl alcohol. The precipitate was dried over phosphorus pentoxide and stored at room temperature. The extract was prepared for injection by suspending it in a finely ground state in sterile water at a concentration of 6 mgm./ml. Each ewe received a total of 100 mgm. of the extract administered as 6, equal, 12-hourly subcutaneous injections, commencing on the twelfth day after service by a vasectomized ram. During and after treatment the ewes were run with entire merino rams.

In the autumn of 1960, 50 ewes were treated with the extract. Eighteen of these were treated again in the autumn of 1961. Of the 50 treated in 1960, 49 were served within 96 hr. of the final injection of horse anterior pituitary extract, 31 (63 per cent) of these within 36 hr. of the cessation of treatment.

Table 1. RESPONSES TO HORSE ANTERIOR PITUITARY EXTRACT

Date of treatment	No. ewes		No.* corpora lutea		Eggs recovered		Eggs fertilized	
	Treated	Served	Total	Mean	Total	Percentage of eggs shed	Total	Percentage of eggs recovered
1960	50	49	583	11·9 ± 1·1	472	81·0	325	68·9
1960	18†	18	250	13·9 ± 1·9	205	82·0	136	66·3
1961	18†	12	117	9·8 ± 3·0	83	70·2	61	73·5

* Total and mean numbers of corpora lutea in only those ewes which were served.
† Ewes treated in both years.

Laparotomies performed for the purpose of egg recovery, 48–80 hr. after the onset of œstrus, revealed that 45 of the 49 ewes had ovulated, shedding a total of 583 eggs (Table 1). The 4 ewes which were served, but failed to ovulate, showed a marked follicular response to treatment. The ovaries of these ewes contained a total of 67 (mean of 16·7 ± 2·4) unruptured Graafian follicles greater than 5 mm. in diameter, while the 45 ewes which ovulated had only 84 (mean of 1·9 ± 2·1) unruptured follicles. 472 eggs were recovered from ewes which had ovulated, and 325 of these eggs showed normal cleavage and were considered to have been fertilized.

Of the 18 ewes treated with 100 mgm. horse anterior pituitary extract in 1960 and again in 1961, 18 and 12 respectively, were served within 96 hr. of the final injection of horse anterior pituitary extract (Table 1). Laparotomies showed that in both years, all ewes served had ovulated. Although significantly fewer ($\chi^2 = 5{\cdot}00$; $P < 0{\cdot}05$) of the ewes were served following a second treatment no significant difference could be found between the mean numbers of corpora lutea in those ewes which were served following the first and second treatments ($t = 1{\cdot}82$; $P > 0{\cdot}30$). Similarly the second stimulation by horse anterior pituitary extract did not appear to have any real effect on either the proportion of eggs recovered or the proportion of recovered eggs found to have been fertilized.

Similar horse pituitary extracts have been used to induce multiple-ovulation in the rabbit[3], and in this species a refractory condition, as illustrated by the ovulatory response to a second treatment, develops rapidly[3,4]. The results of the study reported here show that a similar refractory condition was not evident in the ewe when 12 months elapsed between successive treatments with a horse anterior pituitary preparation.

Plasma Fibrinolytic Activity in the Immature Animal

FOLLOWING the demonstration that hyaline membrane formation in adults[1] is related to upset of fibrinolysis and that pulmonary hyaline in new-born infants consists predominantly of fibrin[2], some of the recent work in this field has been directed to the investigation of possible abnormalities of fibrinolytic mechanisms in the lungs of these children. Lieberman[3], for example, has shown that extracts of lung contain a specific inhibitor of plasminogen activator in many of the children who have died from this condition and presents evidence that the placenta may release such inhibitors when undergoing degenerative changes. Briefly, the mechanism in the normal individual is that plasminogen activator, a tissue enzyme, converts plasminogen to plasmin, the active fibrinolytic enzyme of the body. An alternative hypothesis is that hyaline membrane fibrin has its origin in plasma fibrinogen which, because of circulatory disturbances, enters the alveoli as a transudate[4].

Many enzyme systems do not appear to be active late in fœtal life or after birth, and in prematurely born infants there may be an even greater delay[5,6]. If plasmin belonged to this group of enzymes, then the high incidence of hyaline membrane disease in prematurely born infants might, in part at least, be due to this delay in appearance of fibrinolytic activity in the plasma. This communication describes an experimental investigation of blood plasmin activity in the first five days of life. New-born kittens and rats were used and the method of plasmin assay used was a modification of that of Bidwell[7].

The blood was obtained by cardiac puncture and was immediately mixed with 3·8 per cent sodium citrate solution (nine parts of blood, one part of citrate). The plasma was separated by centrifugation.

Two sets of tubes were prepared, each containing 2·4 ml. of veronal–acetate-buffered saline *p*H 7·4, 0·1 ml. of plasma was added to all the tubes, which were then placed in a water-bath maintained at 37° C. After exactly 5 min., 0·1 of a thrombin solution (20 u./ml.) was added and the mixture stirred vigorously with a roughened cylindrical glass rod. The first set of tubes was removed from the water-bath, the fibrin clots wound on to the glass rod and transferred to test-tubes containing 6 ml. of isotonic saline which had been standing for about 30 min. in melting ice. The clot was then washed with two further lots of ice-cold saline, each washing taking 15 min. The fibrin clots in the second set of tubes were treated in a similar manner after 2 hr. incubation at 37° C. The last saline washings were poured away and 1·0 ml. of 0·1 *N* sodium hydroxide added down the rod. The test-tube was then placed in a boiling water-bath for 2 min., cooled to room temperature and 3·0 ml. of 12·5 per cent w/v sodium carbonate were added. 0·5 ml. of 0·01 *M* copper sulphate solution was then pipetted into the tubes, the mixture stirred with the glass rod and to this was added 0·5 ml. of Folin and Ciocalteau's reagent (diluted 1 in 3).

After 30 min. the density of the colour produced was read in a photoelectric colorimeter, using a red filter, against a blank prepared with 1·0 ml. of 0·1 *N* sodium hydroxide and the rest of the reagents as described. The results were expressed as the percentage lysis after 2 hr. of the fibrin clot which formed at zero time.

Table 1. PLASMIN-LEVELS IN THE INFANT RAT AND KITTEN COMPARED WITH THE ADULT RAT AND CAT (EXPRESSED AS PERCENTAGE LYSIS OF FIBRIN CLOT AFTER 2 HR.)

	Rat			Cat		
Age (days)	Mean plasmin level (per cent)	No. of observations	*S.D.*	Mean plasmin level (per cent)	No. of observations	*S.D.*
1	11·3	8	1·8	4 5	4	3·0
3	5·2	4	12·5	13·3	3	1·8
4	17·0	3	4·1	50·6	8	9·2
5	52·3	3	4 5	37·5	4	6·0
adult	61 5	7	11·7	46·2	4	6·2

Table 1 shows that low plasmin-levels are present in early post-natal life in both the rat and the cat. In the cat, plasma fibrinolytic activity comparable with that of the adult is attained in 4 days, while this does not occur in the rat until the age of 5 days. The difference in time at which the enzyme appears in the two animals may be attributed to the less-mature state of the rat at the time of birth compared with the kitten. These findings suggest that in these two animals plasmin belongs to the group of enzymes which appear to be inactive until after birth.

At the present time we are conducting a more extensive investigation of fibrinolytic activity in the blood of premature and full-term laboratory animals and human infants.

Effects of Stilbœstrol and Thiouracil on the Electrocardiograms of the Sheep

THE use of stilbœstrol and thiouracil in enhancing the fattening efficiency of livestock has emphasized the importance of undertaking the present investigation on the physiological effects of these drugs on sheep.

Table 1. EFFECT OF FEEDING STILBŒSTROL AND THIOURACIL ON THE ELECTROCARDIOGRAM OF SHEEP. (Mean value of three leads)

Group	Heart rate (beats/min.)	Intervals (sec.)			Potentials (mV.)				
		PR	*QRS*	*QT*	*P*	*Q*	*R*	*S**	*T*
Control *M*[1]	78 0	0·124	0 057	0·317	0·100	−0·330	0·220	−0·100	−0 290
±*S.D.*	8 5	0 001	0 020	0·084	0·030	0·110	0 120	—	0 100
Stilbœstrol *M*	75 0	0 127	0·059	0·322	0·110	−0·320	0·260	—	−0·710
±*S.D.*	11 2	0·001	0·021	0·036	0·030	0 080	0·140	—	0 290
Thiouracil *M*	65·0	0·134	0·062	0·335	0·075	−0·400	0·190	—	−0 660
±*S.D.*	12 8	0 001	0 023	0·038	0 030	0·100	0·120	—	0·220

*Figures are not sufficient.

1 *M* represents the average of four sheep with ±*S.D.*, standard deviation.

Electrocardiographic tracings were recorded fortnightly for 6 months on 12 adult sheep, divided into three identical groups of four each. They were fed daily on a ration consisting of groundnut cake (4 oz.), barley (12 oz.), salt (1 oz.) and oat hay *ad lib.* A capsule of 'Adoxiline' (Glaxo) was given as vitamin A and D supplement once a week. The first group served as control, in the second 20 mgm. stilbœstrol (M. and B.) in pellet form was implanted under the skin, and 1 gm. of thiouracil (B.D.H.) per 100 lb. live weight was supplemented daily in the third group. For electrocardiographic recording, the method described by Mullick[1] was followed.

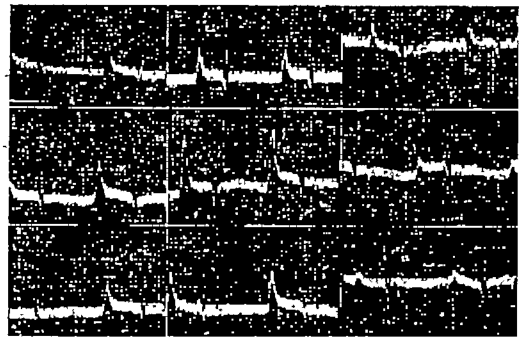

Fig. 1. 1, Control group; 2, stilbœstrol group; 3, thiouracil group

Table 1 and Fig. 1 show the summary of the electrocardiographic records.

Normal electrocardiogram: all the *P* waves were upright. Slight variation was recorded in the form of *QRS*. In all the tracings, *Q* and *R* waves were prominent, whereas very few *S* waves were noted. All *T* waves were inverted.

Electrocardiogram following stilbœstrol implantation: The heart-rate was slow and the interval and potential figures were higher. The significant change in the potential of the *T* waves indicated greater force of the heart output in each beat, whereas in other waves the changes were not appreciable. The absence of *S* waves was conspicuous.

Electrocardiogram following thiouracil feeding: The same trend of change in the heart-rate, intervals and potentials was noted as before but to a smaller extent.

It appears that the pharmacological action of these drugs may affect the normal physiological function of the cardiac cycle, and hence requires consideration in their administration.

Effect of Phenylalanine Diet on Learning in the Rat

The subject of phenylketonuria, an inborn error of metabolism, has been recently reviewed[1]. This defect in the homozygous individual is characterized by the lack of active phenylalanine hydroxylase and severe mental retardation. The heterozygous carrier of one defective gene is able to oxidize phenylalanine to tyrosine and is reported to appear normal. However, a slower rate of phenylalanine oxidation and slightly elevated plasma-levels of phenylalanine have been observed in these individuals. This communication reports the effect on the rate of learning of a dietary-induced heterozygous state in the rat.

Pregnant Holtzman rats were divided into two groups, one of which received an adequate purified diet (*P*–1), and the other, the *P*–1 diet supplemented with 1 per cent DL-phenylalanine (*P*–2). At four weeks of age the young were placed on the respective diets of the mothers. There was no significant difference in weight between groups *P*–1 and *P*–2 during the experimental period. At 16 weeks of age both groups were subjected to seven sessions of 160 trials each on the conditioned-avoidance procedure[2]. Caged rats were placed in a situation where failure to turn a small wheel, on presentation of a warning sound of seven seconds duration, produced a mild but aversive 0·6 m.amp. electroshock. The avoidance trials occurred after variable time-intervals which averaged 60 sec. in length. On completion of the test, blood was drawn from the tail for the determination of phenylalanine, and urine was collected under toluene for the determination of keto-acids.

The phenylalanine concentration in deproteinized blood was determined microbiologically with the phenylalanine-requiring *E. coli* mutant 83–5 (kindly supplied by Bernard Davis). A significantly higher ($t = 1\cdot83$, $P < 0\cdot1$) phenylalanine-level was observed in the experimental group (61 ± 5 μgm./ml.) than in the control group (50 ± 3 μgm./ml.). Total urinary keto-acids was estimated by a modification of the method of Penrose and Quastel[3]. The average amount of keto-acids excreted in the urine by the control group was 2·2 ± 0·34 mgm./24 hr., which is not significantly different from the amount excreted by the experimental group, 2·5 ± 0·35 mgm./24 hr. Figs. 1 and 2 graphically depict the marked difference between groups *P*–1 and *P*–2 on the conditioned-avoidance test. The control group developed the conditioned-avoidance behaviour quite rapidly. The phenylalanine-fed rats failed to develop the appropriate behaviour and their avoidance failure was both widely distributed and erratic from day to day.

Forty-five days following the first test on the conditioned-avoidance procedure the rats were re-run for another 7 sessions. Twenty days prior to the second test, both groups were fed the *P*–1 diet. At the end of the test the average concentration of blood phenylalanine in the experimental group had fallen to 52 ± 2 μgm./ml. Fig. 3 shows the improvement in performance of 4 of the animals of this group. By the fourth session their performance curves were down within the limits shown by the control rats (Fig. 4).

Our results are in accord with the findings recently reported by Yuwiler and Louttit[4]. It is apparent that a high dietary intake of phenylalanine may be correlated with the failure to develop

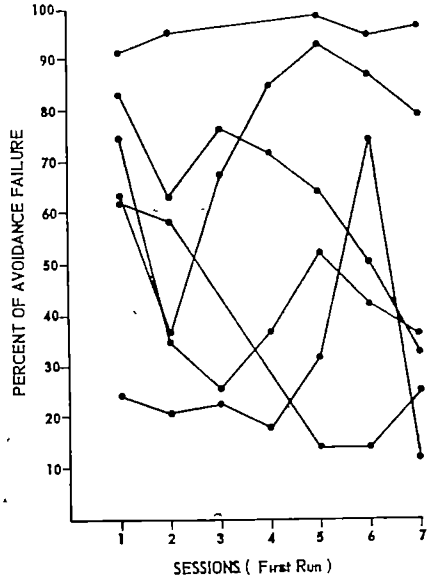

FIG 1 SIX RATS ON PHENYLALANINE DIET (P-2)

HÆMATOLOGY

α-Chain of Rabbit Hæmoglobin

HUMAN hæmoglobin, the structure of which has recently been determined[1], consists of two pairs of homologous amino-acid chains—the α- and β-chains. The work reported here was concerned with the species differences between the α-chains of rabbit and human hæmoglobins.

Rabbit hæmoglobin (prepared by Drabkin's method[2]) consists of two electrophoretically distinct components (Müller, C. J., private communication), which differ in the presence or absence of bound glutathione. This is supported by our finding that oxidation of rabbit hæmoglobin with performic acid splits off glutathione. During the acetone–hydrochloric acid treatment used to remove hæm from hæmoglobin[3], glutathione is also split off, and the resulting rabbit globin thus represents a single protein. After the α- and β-chains of rabbit globin had been separated by counter-current distribution[4], the α-chain was denatured with urea and split by trypsin. The resulting α-'core', a large insoluble peptide, was precipitated at pH 6·4, oxidized with performic acid, and split by chymotrypsin. The soluble tryptic peptides and chymotryptic core peptides were separated by column chromatography over 'Dowex 1X2' (ref. 5), purified by paper chromatography, and quantitatively analysed[6]. In Table 1 the rabbit peptides are compared with the corresponding human and horse[7] peptides with regard to amino-acid composition.

It follows from these results that the peptides of rabbit, horse, and man are quite similar but in most cases not identical. The α-chains of all three species are of the same length—141 amino-acids. However, no more than 114 amino-acids in human and rabbit α-chains can be identical; that is, one must assume

R, rabbit, *M*, man, *H*, horse.

The peptides are listed in their order in the chain, beginning with the N-terminal peptide No. 1. Peptides 13–16 form the so-called 'core'.

that at least 27 positions in the chains are occupied by differing amino-acids. For example, in peptide 2, lysine, asparagine, and threonine are common to all species, but valine appears to have been replaced by isoleucine in the rabbit. Of particular interest are the peptides 9 and 10, which contain seven and twenty-two residues, respectively. In man this region occurs as a single tryptic peptide with twenty-nine residues, of which only one, the C-terminal residue, is lysine. In the rabbit an additional lysine stands in place of an asparagine twenty-two residues further, and since trypsin cleaves peptide bonds at the carboxyl end of each lysine or arginine, one obtains two tryptic peptides instead of one. It should be noted that the same variant—asparagine replaced by lysine at this locus—occurs in the pathological human hæmoglobin Hb *G* (ref. 8).

The twenty-seven or more exchanges in the rabbit α-chain are not confined to a small region but are distributed over the whole chain, that is, in eleven of the seventeen peptides. Nevertheless, the structurally critical amino-acids—cysteine in peptide 13, the hæm-stabilizing phenylalanines of peptide 6, the accumulation of basic residues in peptides 7 and 8, and the histidines of peptides 7 and 10, which bind the hæm group—remain unaffected by exchanges in all three species.

The α- and β-chains of hæmoglobin are thought to have evolved from a single-chain myoglobin-like precursor, and to have become differentiated from each other as well as from myoglobin itself by successive mutations giving rise to exchanges of amino-acids. These mutations are clearly illustrated by the differences described here between α-chains from various species. Thus, in peptide 7 a glycine residue in man appears as alanine in the horse and rabbit, and the human β-chain also has alanine at this locus[1]. Presumably alanine represents the more primitive condition, and the mutation alanine to glycine occurred here in the α-chain at a stage of evolution later than that represented by the horse and rabbit. The α-chains from different species resemble each other more nearly than do different chains from the same species: that is, horse and rabbit α-chains share about 126 and 114 residues, respectively, with human α-chain, whereas human α- and β-chains have only 66 residues in common. Rabbit and human α-chains are thus evolutionary more distant than horse and human α-chains.

Finally, studies of protein mutations and species variations have made it clear that the same primary amino-acid transitions appear again and again, that is, any one amino-acid can mutate directly into only a few other amino-acids. For example, the transition isoleucine–valine, which was mentioned here in connexion with rabbit peptide 2, has also been observed as a species variant of insulin[9] and hypertensin[10,11] and arises as a nitrite-induced mutant of tobacco mosaic virus[12]. Such a recurrence of certain primary mutations is to be expected from considerations based on the genetic 'code', by which the nucleotide sequence of DNA determines the amino-acid sequence of proteins. For example, if a certain amino-acid were determined by a given nucleotide triplet, then this amino-acid would be able to mutate directly into at most nine other amino-acids (there are four different nucleotides, and any one of three sites in the triplet might thus mutate into any one of three other nucleotides). In practice, the number of possible transitions may be less, since not all triplets may be genetically meaningful. From the peptide compositions reported in this article, the differences between rabbit and human α-chains provide at least 27 such transitions, most of which are probably direct and the exact identification of all of which will require sequence analysis. It is thus clear that species variants in protein structure will provide important evidence concerning the genetic code.

We thank Prof. A. Butanandt for his advice, and Miss K. Haselhorst and Mr. H. Schäfer for performing analyses. This work was performed during the tenure of a National Science Foundation fellowship held by one of us (J. M. D.).

Failure to elicit a Delayed Hypersensitivity Reaction against Blood Group Substance from Erythrocytes

IN some recent work[1], we have explored the antigenicity in guinea pigs of the secreted human blood group substances A (ref. 2) and Le^a (ref. 3). There was a delayed hypersensitivity response to A and Le^a, and to other human blood group substances, showing a very marked degree of cross-reactivity, irrespective of the immunizing antigen. This cross-reaction and other evidence were taken to indicate that the polypeptide part of blood group mucopolysaccharides was the entity chiefly concerned in producing and eliciting delayed hypersensitivity to these substances. The reaction of A and Le^a substance with circulating antibody was much more specific than was the delayed hypersensitivity reaction. The small degree of cross-reactivity of circulating antibody could be attributed to a small amount of Le^a activity in A substance. The more precise nature of the circulating antibody was explained in terms of a response to the specific polysaccharide entity of blood group substances. Thus, it was postulated that the secreted blood group substance macromolecule was capable of evoking separate immunological responses to its two main chemical components, the polypeptide and the polysaccharide.

Blood group substance obtained from human group A erythrocytes, unlike secreted blood group substance, is a glycolipid without any appreciable content of amino-acids; in a recently reported sample[4], the sum of sphingosine and hexosamine nitrogen represented 98·8 per cent of the total nitrogen. Through the kindness of Dr. J. Kościelak, who prepared this material, we were able to test the immunological activity of such erythrocyte-derived blood group A substance. We tested guinea pigs for evidence of delayed hypersensitivity as well as circulating antibody. Each of a group of 8 guinea pigs was immunized by the intracutaneous injection of purified human A substance[2], obtained by Prof. W. T. J. Morgan from ovarian cyst fluid. The antigen was emulsified in saline with an equal volume of Freund's complete adjuvant (Difco). Four of the animals received 10 μgm., the other 4 were given 50 μgm. A substance. Ten days later, the guinea pigs were tested for delayed hypersensitivity by intracutaneous injection of 0·1 ml. test doses of antigens. The reactions were read 24 hr. later. The immunizing A substance, at a test dose of 10 μgm., gave delayed skin reactions with diameters ranging from 8 to 20 mm. A test dose of 1 μgm. gave a 5–6 mm. reaction. Two samples of the erythrocyte-derived A substance were similarly tested in the same guinea pigs at the same time, in doses of 1, 10 and 100 μgm. Reactions were negative throughout. A sample of erythrocyte-derived B substance was also tested. At a dose of 100 μgm., this gave some slight immediate, but no true delayed, responses ; similar reactions to B substance were found in control animals which had been immunized with adjuvant only.

Table 1. Cutaneous anaphylaxis in guinea pigs immunized with ovarian cyst blood group substance (A 401), and tested with this, with two samples of erythrocyte-derived A substance, and with erythrocyte-derived B substance

* Reactions measured by diameter in mm. of area coloured by intravenous Evans blue at site of challenge injection.

Circulating antibody was tested for in six other guinea pigs which had been immunized by the subcutaneous injection of 2 doses of 100 μgm. of the purified human A substance (A 401), derived from ovarian cyst fluid, as in the previous experiment. The animals were tested by the direct cutaneous anaphylaxis method using Evans blue, as described in a previous publication[1]. Results are given in Table 1. All animals reacted with the immunizing antigen. They also reacted with the erythrocyte-derived A substances—strongly in the case of animals 1–4, more weakly in Nos. 5 and 6. There was no reaction to B substance in 4 animals and a very weak, probably non-specific one, in the other 2. No reaction to any of the test substances occurred in control guinea pigs injected with complete adjuvant only.

We may conclude that circulating antibody induced against secreted blood group substance is capable of giving cross-reaction with a substance of similar group specificity, but obtained from erythrocytes. This contrasts with the findings with respect to delayed hypersensitivity, where no such cross-reaction was seen. These results are in agreement with the concept derived from our earlier work[1]. Delayed hypersensitivity, being chiefly attributable to the polypeptide moiety of the blood group substance macromolecule, cannot be elicited with erythrocyte-derived A substance, since it does not possess this component. Cross-reaction occurs, however, with the circulating antibody, since this depends chiefly on the group-specific polysaccharides, which secreted substance shares with erythrocyte-derived material.

IMMUNOLOGY

Acceptance of Tumour Homografts by Thymectomized Mice

Recent experiments in guinea pigs[1], rabbits[2] and mice[3,4] indicate that the thymus plays an important part in the development of immunological competence. Although the observations that patients with acquired agammaglobulinæmia often have a benign thymoma[5,6] suggested a role for the thymus in immunological reactivity it was only very recent investigations which led to consideration of the thymus in immunological development. Glick *et al.*[7] and Mueller *et al.*[8,9] showed that removal of the bursa of Fabricius, a lymphoid organ developing as an outpouching of the posterior gut and an organ homologous to the thymus in several ways, interfered with the ultimate development of full immunological competence. Mueller *et al.*[9] showed further that prevention of development of this lymphoid organ by treatment of chick embryos with progestational hormones, for example, 19-*nor*testosterone, provided potent inhibition of the development of immunological capacity.

In the examination of the inhibiting effect of neonatal thymectomy on the development of the capacity to reject skin homografts it was observed that significant prolongation of skin graft survival was achieved only in strains of mice isogenic at the *H*-2 histocompatibility locus but homologous with respect to other 'weaker' histocompatibility genes as described by Counce *et al.*[10]. In the present communication it is established that even the *H*-2 histocompatibility difference may be overcome by thymectomy performed in the neonatal period when a mammary adenocarcinoma is used as the homotransplanted tissue.

In one group of experiments mice of the $Z(C_3H)$ strain were thymectomized, sham-thymectomized or splenectomized at 0–24 hr. of age. Thymectomy was performed by gentle suction of both thymic lobes through a longitudinal thoracic opening in the midline and traversing the manubrium sterni. 1–2, 22 or 50 days after surgery mice were subjected to the subcutaneous transplantation of a piece of a mammary adenocarcinoma spontaneously arising in a breeder female mouse of the *A* strain. Incidence of 'takes' as well as progressive growth of the transplanted tumours resulting in death of the host were determined in the different groups.

In a second set of experiments groups of 35 to 40-day-old $Z(C_3H)$ mice were prepared as follows: (*a*) thymectomized, (*b*) splenectomized, (*c*) thymectomized and splenectomized, (*d*) sham-thymectomized, (*e*) non-operated controls. Twelve or 55 days after surgery mice of all groups were transplanted subcutaneously with a bit of homologous tumour tissue of the same kind as before.

The results of the first experiment were as follows (Table 1): (1) In the group grafted 1–2 days after the operation, 62 per cent of the sham thymectomized controls and 100 per cent of the thymectomized animals were growing the tumour at the time of weaning (30 days of age). (2) In the group grafted at 22 days, 5 per cent of the sham-operated controls, 8 per cent of the splenectomized and 87 per cent of the thymectomized mice accepted the tumour. (3) In the group grafted at 50 days, none of either the sham-operated controls or the splenectomized mice accepted the tumour, whereas 57 per cent of the thymectomized animals grew it successfully. In all groups mice accepting the tumour homograft were killed by the progressive growth of the malignant tissue. In the second set of experiments in which thymectomy, splenectomy or both operations were performed in 35- to 40-day-old mice the results showed that the tumour homografts were rejected in all instances.

Table 1. Incidence of Successful Transplantation of an *A* Strain Mammary Adenocarcinoma in $Z(C_3H)$ Mice splenectomized or thymectomized at Birth (0–24 hr. after Delivery)

Group	Days between operation and grafting 1–2	22	50
Sham thymectomized	13/21*	1/20*	0/10*
Splenectomized	—	1/13	0/10
Thymectomized	11/11	13/15	4/7

* No. of mice accepting tumour/No. of animals grafted.

Although in the group of mice operated at birth and grafted 1–2 days after surgery a high percentage of the sham-operated controls accepted the homologous tumour (62 per cent), due in all probability to the immunological immaturity of the hosts at that age (1–2 days)[11,12], the incidence of successful takes in thymectomized mice receiving similar tumour transplants was significantly higher (100 per cent) the difference being statistically significant ($P < 0{\cdot}01$). On the other hand, it is interesting to note that the thymectomized mice were killed faster by the progressive growth of the tumour (47 ± 1·6 days) than the sham-operated controls (63 ± 4·0 days). The results of this experiment as well as those in which grafting was performed at 22 and 50 days following surgery demonstrate that thymectomy in new-born mice allows the acceptance and growth of tumour tissue originally developed in a mouse differing at the *H*-2 histocompatibility locus. In contrast, neither thymectomy in young adult mice nor splenectomy at birth or in older animals was capable of affecting the development of the usual homograft reaction. Previous experiments had shown that thymectomy performed in neonatal mice does not lead to an immunological depression of sufficient degree to overcome the strong histo-incompatibility conditioned by a difference at the *H*-2 locus[3,4]. In those experiments skin homografts were used to test the immunological capacity of thymectomized mice, whereas in the present experiments a spontaneous mammary adenocarcinoma was utilized. The different results might perhaps be explained either on the basis of a difference in the antigenicity of the tissues grafted, the tumours being less antigenic than skin, or on the basis of greater growth potential of neoplastic as compared with normal tissues. These observations add strong support to the concept that the thymus plays an important part in transplantation reactions and tumour immunity in early life.

It is postulated that the lymphoid tissue of the gut and the thymus gland in particular are important sources of origin of immunological competent cells during late gestational and early neonatal life. The thymus, indeed, may represent the 'fertile crescent' of greatest importance as a centre of origin and centrifugal distribution of cells possessing immunological competence in neonatal mammals.

Induction of Partial Acquired Tolerance to a Carcinogen

GREEN[1] postulated *inter alia* in his immune theory of cancer, that the chemical induction of cancer might produce a specialized immune response in which antibody attack on the protein-bound carcinogen in the cells masked or deleted the tumour-specific antigens.

In this investigation an attempt has been made to induce acquired tolerance to a chemical carcinogen, and to note its effect on skin tumour induction in adult life.

Wistar rat embryos were inoculated by injection with 0·1 mgm. 20-methylcholanthrene (20-MC) in the last week of intra-uterine life. Another small group of rats were given 1 mgm. of the carcinogen by intramuscular injection within 3 hr. of birth. They were challenged by bi-weekly painting with 0·5 per cent 20-methylcholanthrene to the shaved abdomen, starting at the sixth week and continuing until tumours developed or until death.

Table 1 shows the time of appearance of skin tumours. At 52 weeks all the controls bore tumours,

Table 1

No. of surviving rats	Dose	Skin appearance of tumours (weeks)
12	20-MC 0·1 mgm. intra-fœtal	52, 55, 57, 58, 62, 77, 77, 78 (mean 64)
7	1·0 mgm. 3 hr. after birth	56, 61, 66, 72 (mean 64)
12	Controls	36, 39, 41, 47, 47, 52, 52, 52, 52 (mean 46)

but only one of the experimental animals. All surviving rats eventually developed carcinomata on the painted area, but the average time of appearance was 17 weeks later in the pretreated group, and this suggests a state of partial acquired tolerance.

A second experiment was designed to increase this tolerance by giving a series of follow-up injections during the neonatal period. Five groups of rats were given an intra-uterine injection of 0·5 mgm. 20-methylcholanthrene followed by a varying number of subcutaneous injections during the first four weeks of life.

Table 2

No. of rats surviving	Fœtal injection 20-MC (mgm.)	Postnatal dose of 20-MC (mgm.)	No. with sarcomas	Time to development of last tumour (weeks)
7	0·5	7·5	7	46
10	0·5	6	10	36
4	0·5	4·5	4	49
6	0·5	4	6	60
9	0·5	3	8	35

They were all challenged by painting the unshaven abdomen bi-weekly with a 2 per cent suspension of 20-methylcholanthrene in 'Trex', from the age of six weeks until tumours appeared or until death intervened.

All the rats developed sarcomas at the site of subcutaneous injection, and only one rat survived long enough to develop a skin tumour on the painted area. The postnatal injection of carcinogen did not boost acquired tolerance, but appears to have broken it down.

In a third experiment rats in two groups were each injected with 1·0 mgm. of 20-methylcholanthrene, the first group within 3 hr. of birth, the second group at four weeks of age. They were painted as before with 2 per cent 20-methylcholanthrene in 'Trex' during adult life.

All the rats injected at four weeks developed sarcomas by fifty weeks, but none of the group receiving the same dose immediately after birth had developed any sarcomas by seventy-eight weeks, though four of these seven had skin tumours.

Although immune responses have been shown to occur in the fœtuses of several mammals by Silverstein[2], Uhr[3], and Kalmutz[4], who attribute acquired tolerance as described by Dixon and Maurer[5], to an immunological paralysis similar to that demonstrated by Felton[6] in adult mice given large doses of pneumococcal polysaccharide, it appears that a single intrafœtal or early neonatal injection of 20-methylcholanthrene in rats can induce a partial suppression of antibody formation to the protein-carcinogen complex as shown by the delay in the appearance of skin tumours when the animal is painted with the carcinogen. When, however, intrafœtal injection is followed by subcutaneous injection of the weanlings, this non-response is broken down and the animals behave like the control group.

BIOLOGY

Preservation of Bull and Human Spermatozoa by Freezing in Liquid Nitrogen Vapour

My work on factors involved in low-temperature preservation has favoured the design of a simple and efficient freezing method for the preservation of spermatozoa of the bull and the human. I have used this method successfully for more than three years and find it as good as, or superior to, present methods, including those requiring expensive automatic freezing equipment. It uses liquid nitrogen and is an improvement over 'dry ice' methods.

Briefly, this work with spermatozoa has revealed the following as to low-temperature factors.

(1) *Glycerolation temperature.* Freeze–thaw survival of bull spermatozoa decreases as temperature of glycerolation increases from 5° to 21° to 37° C. (ref. 1), while human spermatozoa are independent of such a glycerolation temperature–freezability relationship[2].

(2) *Rate of cooling above freezing.* Egg yolk (lecithin) protects bull spermatozoa from temperature shock while human spermatozoa show little or no susceptibility to temperature shock[2,3] naturally.

(3) *Rate of cooling below freezing.* Average rates of 16°–25° C./min. result in post-thaw motilities at least as high as the best of present methods, better than those realized with rates of 1° and 2° C./min.

(4) *Final temperature.* Cooling from −77° to −196° C. and rewarming from −196° to −77° C. has no effect on post-thaw motilities of frozen samples.

(5) *Time at final temperature.* During frozen-storage for one year at −77° C. there is a post-thaw percentage motility loss of 26 for bull spermatozoa and 10 for human spermatozoa, while at −196° C. the loss is only 4 and 0 per cent respectively for bull and man[2].

(6) *Rate of rewarming.* Both bull and human spermatozoa show no differences in post-thaw motility when rewarmed from −77 or −196° C. at rates of from 1°–60° C./min.[2].

The essential steps in the method as devised for spermatozoa from man and from both dairy and beef (Santa Gertrudis) bulls are:

(1) *Pretreatment of semen.* Bull semen is diluted with a suitable extender[4]. Human semen is not diluted[5].

(2) *Glycerolation.* Glycerol is added to bull semen at 0° or 5° C. in stepwise fashion to a final concentration by volume of 7 per cent[4]. Human semen is glycerolated (stepwise) at room temperature to a final concentration of 10 per cent by volume.

(3) *Packaging.* Following glycerolation, 1 ml. volumes of semen are placed in labelled glass ampoules (Kimball 2020 *s* 28 or equivalent) the tips of which are sealed by flame (*HS*-1 sealer, Popper and Sons, New York) and clipped on a fibreglass or metal cane.

(4) *Freezing.* Canes with ampoules are suspended from a 'Styrofoam' cover over the surface of liquid nitrogen in half (or less) filled Linde Co. (Long Island, New York) *LNR*-*25B* liquid nitrogen container. The nitrogen vapour temperature above the liquid is −172° to −194° C. Average rate of cooling to −75° C. is ± 25° C./min. for one cane, slower with more canes in boxes, etc. The *LNR*-*25B* container is best for combined freezing and storing with liquid nitrogen.

(5) *Storing.* After as little as 5–10 min., canes in vapour can be quickly transferred to a storage canister which hangs partially immersed in liquid nitrogen of the same container.

(6) *Thawing.* Frozen-stored semen is rewarmed by dropping ampoules into a water-bath at either 0°, 5°, 21° or 37° C., whichever is best suited to the investigator's needs.

I have used the basic steps in this liquid nitrogen vapour method to preserve cells other than spermatozoa. These include ascites tumours, sarcomas and three parakeet tumours. I suggest that this method will prove applicable to the preservation of many other cells. However, I must stress the necessity for evaluating each cell type from each animal on the basis of those factors mentioned here before following the technique exactly.

The Placenta as a Homotransplant

There has been increasing interest during the past decade in the immunological aspects of pregnancy. Since the placenta is of fœtal origin, it has been postulated that the former is antigenically different from the mother and thus representes a homotransplant in the uterus[1,2]. Recently it has been shown[3] that human syncytiotrophoblast cells can bind a γ-globulin, possibly an antibody, which is present in *postpartum* serum. The remarkable findings of Douglas *et al.*[4] that relatively large numbers of such trophoblastic cells enter the maternal circulation during normal human gestation has added impetus to speculations concerning the mechanism by which the mother is able to tolerate presumably foreign tissue. That the rabbit fœtus is antigenic for the rabbit was clearly demonstrated by Woodruff[5], but to our knowledge the only report concerning the capacity of placenta itself to immunize the mother is that of Hašková[6]. She found that F_1 placentæ, although less antigenic than F_1 fœtal tissues, readily stimulated transplantation immunity in mice of the paternal but not the maternal strain. In this work, however, we have shown that the F_1 murine placenta contains antigenic determinants which are capable of inducing homograft immunity in mice isogenic with the mother. Douglas and Dancis have reached similar conclusions[7]. Our investigations, utilizing the entire placenta, do not necessarily indicate, however, that these determinants occur in the portion of the placenta which is in direct contact with maternal tissues or circulation.

C3H virgin female mice were mated with *C57* male mice. At 15–17 days of gestation, laparotomy was performed under 'Nembutal' anæsthesia and blood was removed from the fœtal heart with a fine Pasteur pipette rinsed with heparin. The corresponding placenta was stripped off the uterine wall, trimmed of visible fœtal membranes, minced with scissors and passed through a stainless steel sieve into physiological saline. The cell suspension was centrifuged at low speed, washed once with 5 ml. saline and after resuspension in saline, a cell count was performed using 1 per cent acetic acid as the diluent. A suspension of F_1 adult spleen cells was prepared in a similar manner. Groups of 12 virgin female *C3H* mice 6–8 weeks old were injected intraperitoneally with 0·1 ml. of either placenta, adult spleen or fœtal blood cells three times during a 9-day period. Three days after the last immunizing injection, all the mice were grafted on their backs with *C57* female skin, each graft measuring approximately 1 cm.^{2}. The plaster bandages were removed at six days, the animals were killed and the entire graft removed and fixed in Carnoy's formalin. One section was taken from each graft for histological study. The criteria used for evaluating graft survival were those of Billingham *et al.*[8].

Table 1 summarizes the results of two experiments. In experiment 1, it can be seen that previous injection of the placental cell suspension immunized the recipients for an accelerated homograft rejection. Thus, none of 10 non-immunized animals showed severe epithelial damage at 6 days, in contrast to the severe or moderate reaction of all of 7 animals previously injected with a placental cell suspension. As expected, all animals previously immunized with spleen cells showed either severe or complete epithelial destruction. No attempt had been made to use equal amounts of placenta and spleen for immunization. Fœtal blood cells in the small amounts injected exhibited virtually no antigenicity. Twelve isograft controls not shown in Table 1 showed absence of epithelial damage. Thus, a suspension containing F_1 (♀ *C3H* × ♂ *C57*) placental cells can induce transplantation immunity to *C57* skin in virgin *C3H* mice. These results are not necessarily in conflict with those of Hašková[6], in which a different strain combination of mice was utilized and only one injection of placenta was used for immunization.

A second experiment was carried out to confirm this conclusion and also to test the possibility that the antigenicity of the placental cell suspensions was due solely to the presence of contaminating fœtal blood cells. As shown in Table 1, the antigenicity of placental cell suspensions was confirmed. Four of 7 placental-injected mice showed severe epithelial damage in contrast to none of 6 control animals. Both the suspension of fœtal blood cells and the

Table 1

Exp.	Cell suspension injected	No. of nucleated cells per mouse			No. of mice grafted	Epithelial damage		
		Day 1	Day 5	Day 9		Total or severe	Moderate	Mild or none
1	None	0	0	0	10	0	3	7
	Placenta	$3·5 \times 10^5$	$1·1 \times 10^6$	$1·2 \times 10^6$	7	4	3	0
	Spleen	3×10^7	$2·5 \times 10^7$	$1·5 \times 10^7$	7	7	0	0
	Fœtal blood	4×10^5	$1·5 \times 10^4$	3×10^6	7	0	3	4
2	None	0	0	0	6	0	2	4
	Placenta	$3·5 \times 10^6$	$1·6 \times 10^5$	7×10^4	7	4	2	1
	Diluted placenta	5×10^4	$6·5 \times 10^4$	$3·5 \times 10^4$	8	2	4	2
	Fœtal blood	5×10^4	$6·5 \times 10^4$	$3·5 \times 10^4$	8	1	3	4

placental suspension diluted to contain the same number of nucleated cells appeared to show slight antigenicity. Of these two, the placental suspension appeared more antigenic, although the difference may not be significant. It would appear unlikely, however, that the antigenicity of the placental cell suspension could be entirely accounted for on the basis of fœtal blood cells, since the latter represents only a small fraction of the nucleated cells in the placental cell suspension (the vast majority are either placental cells or maternal blood cells). Nevertheless, the second part of this experiment, the attempt to define the cells which caused the antigenicity of the placental suspension, should be interpreted with caution, because of the lack of sensitivity of the assay system used. Since the dose-response curve in homo-transplantation immunity is rather flat[9], this system is particularly insensitive for the assay of antigen.

Twilight Transitions and Biological Rhythmicity

IN laboratory investigations of biological rhythmicity, changes in ambient illumination are usually brought about by turning lamps on and off[1]. The responses of deer mice to artificial bright–dim light cycles with simulated twilight transitions are at present being examined in this laboratory.

Mice are particularly resistant to the imposition of unnatural periodicities. Previous investigations led to the conclusion that activity cycles deviating by more than 3 hr. from 24 cannot be imposed on them by on–off light régimes[2]. The results recorded here indicate that utilization of simulated twilight transitions allows a greater degree of control over periodicity.

Enclosures[3] and recording techniques[3,4] are described elsewhere. Enclosures were housed individually in isolated light-proof and sound-proof cabinets in an air-conditioned dark-room (20°–22° C.). Animals were 1-ft. distant from the source of light; results do not depend on the presence or absence of nesting quarters or shade.

Five individuals have been examined so far. Detailed results (Figs. 1c–e and 2) are presented for a mature *Peromyscus maniculatus* female which gave the most clear-cut response. Activity was assessed from records of the time of wheel-running, instantaneous values of rate and direction of running, and revolutions per 10-min. intervals.

Transitions between bright daylight and minimum light of night last for several hours, depending on latitude and season. Light intensity roughly halves

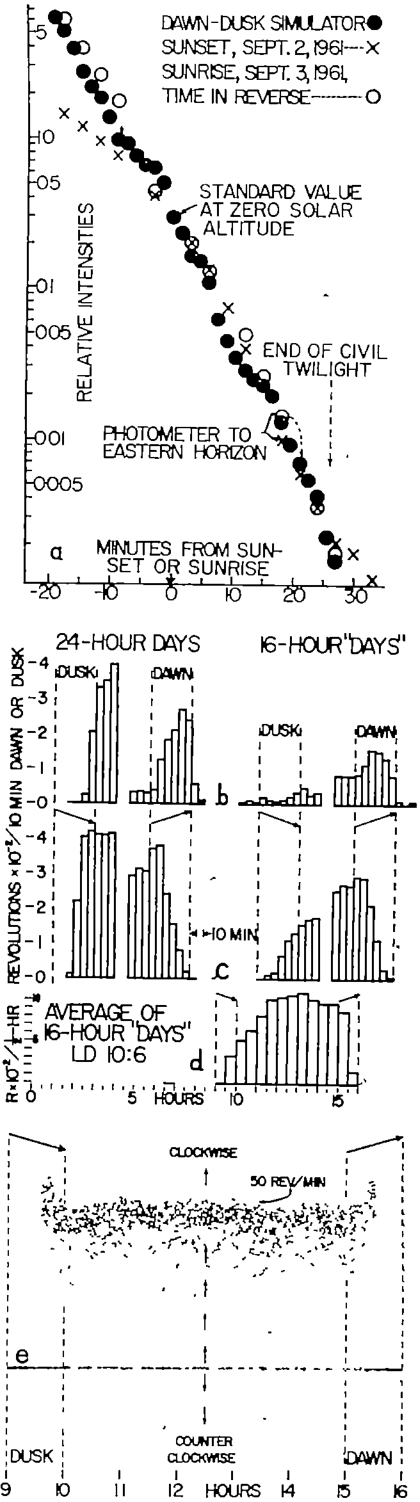

Fig. 1. *a*, Simulated twilight changes compared with those of local sunset and sunrise. The limbs of the sunrise curve (open circles) have been reflected about the ordinate of zero solar altitude to facilitate comparisons. *b*, Revolutions run per 10-min. interval during dawn and dusk by the most poorly synchronized mouse. The plots extend 30 min. before and after the 60-min. twilight transitions. *c*, Same as Fig. 1*b* but for the best synchronized animal. *d*, Revolutions run per 30-min. intervals by the female on a 16-hr. (L : D 10 : 6) periodicity plotted on a 16-hr. grid. *e*, Reconstruction of 'Speedomax *G*' record (points at 4-sec. intervals) of instantaneous speed and direction of wheel-running during a 16-hr. period (L : D 10 : 6)

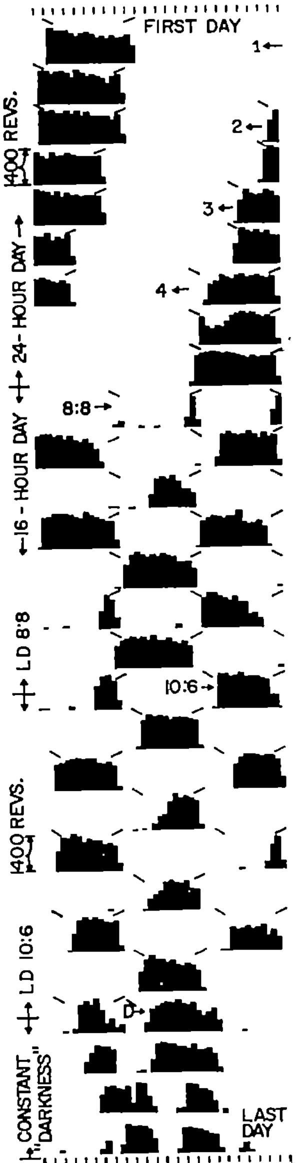

Fig. 2. Revolutions run per 30-min. intervals by the female for the 28-day period covered by the experiment, plotted on a 24-hr. grid. Dawn and dusk periods are indicated as in Fig. 1. Changes in programme are marked

(or doubles) every 3 min. during twilight. Design of the dawn–dusk simulator was guided by determinations of local sunset and sunrise transitions. The curves of Fig. 1*a* are in arbitrary units of intensity relative to a value of 0·3 at zero solar altitude. As a first approximation, only the relative changes in intensity occurring in the hour before (and after) the end (and beginning) of local civil twilight have been simulated. The intensities encompassed range from about 1/2,500th that of bright sunlight to about 1/25th that of the full moon[5].

Changes in light intensity were effected by continuously varying the d.c. voltage applied to 4 General Electric No. 44 incandescent bulbs through the range 1–6·5 V. The light intensity changes[4] by a factor of 5,000, roughly from 0·0008 to 3·96 foot-candles. Deer mice are very active at the lower intensity, which approximates conditions on a clear moonless night[6].

The dawn–dusk simulator consists of a motor-driven 15-ohm rheostat (Ohmite No. 0146) provided with travel-limiting microswitches tripped by cams. A reversible motor rotates the rheostat contact-brush through 180° in a 1-hr. period. The rheostat is connected in series with 8 bulbs in parallel, 4 per enclosure. The relative intensity changes are plotted (solid circles) in Fig. 1*a*. The midpoint of the rheostat movement is set to coincide with the time of zero solar altitude for comparative purposes.

Among the advantages of this method are: (1) occurrence of short-term variations of intensity caused by fluctuations in coil-to-contact-brush resistance and stepwise shorting of coils; (2) progressive reddening of the light at low intensities. The former simulates shading produced by varying cloud cover and micro-topographical features; the latter gives an effect similar to the progressive colour change of direct sunlight caused by scattering of short wavelengths at low solar altitudes.

After adapting the animal for 22 days to a 24-hr. bright-to-dim light-cycle (L : D 16 : 8), the effects of phase shifts were tested. Beginning of dusk was advanced 1, 2, 3 and 4 hr. on the first, third, fifth and seventh days, a cumulative shift of 10 hr. These alterations of régime were followed closely (Fig. 2, first 8 days). A 16-hr. periodicity (L : D 8 : 8) was then instituted. The new periodicity also was followed (Figs. 1*d* and 2). However, whereas the animal customarily ran throughout the entire nocturnal period on a 24-hr. day, in the course of the next 22 16-hr. cycles it failed to sustain continuous nocturnal running on several occasions, even when the relative length of the nocturnal period was decreased (Fig. 2, L : D 10 : 6).

After 22 16-hr. cycles, a constant nocturnal régime was initiated by presenting a dusk immediately following the last dawn. The animal responded with a 10-hr. phase-shift, commencing to run again and completing a second activity period. Although apparently returning to a circadian rhythm, it continued to show two closely spaced major activity periods in each subsequent cycle (Fig. 2, last 4 days).

The response to dawn (Fig. 1*c*) was practically identical on 16- and 24-hr. cycles—a peak of running and unerring cessation before 'daylight'. Dawn was a potent terminator of running; light following dawn was equally potent as an inhibitor (Fig. 1*d*). The ratio of wheel rotations per unit time from beginning of dusk to end of dawn, to those from end of dawn to beginning of dusk (D–L/L–D) was 1396/1 for 24-hr. cycles, 1161/1 for 16-hr. cycles. The sharpness of the 16-hr. periodicity is striking (Fig. 1*d*). Stepwise increments in revolutions during the hours following dusk primarily reflect more running, not faster speeds.

Fig. 2*e* shows a representative record of instantaneous speed and direction of running. The 'dawn response' involves a spurt of faster running, not simply more intense running. But a spurt of faster running also occurs during dusk. Thus, both twilight transitions appear to affect deer mice. Although dusk is sometimes 'ignored', the dawn changes are usually compelling—behaviour which is appropriate to nocturnal species. In this connexion, peaks of rodent activity also have been observed in the wild during dawn and dusk[7].

Dawn had a potent effect on even the most poorly synchronized subject. Fig. 1*b* shows the dawn and dusk responses of this animal (a mature male) to the same régime. It ran only 45 per cent as much during 24-hr. cycles (D–L/L–D = 63) and 37 per cent as much during 16-hr. cycles (D–L/L–D = 3·5) as did the female. Often it was not running at the beginning of dawn, so that its subsequent spurt of running was more accentuated.

These findings suggest the importance of using light régimes in the laboratory that are more nearly representative of natural changes than are simple on–off cycles.

New Records of *Gobius forsteri*

INCREASING use of the aqualung by zoologists has led to the exploration of sublittoral areas the topography of which had previously excluded investigation by the conventional methods of trawling and dredging. One of the more sensational discoveries on British coasts has been that of the leopard spotted goby by Mr. G. R. Forster of the Plymouth Laboratory. This was a species new to the British fauna, and regarded by Corbin[1] as also new to science, being described in *Nature* under the name of *Gobius forsteri* (Teleostei-Percomorphi). In addition to southern Cornwall and Devon, records were given for St. Helier (Channel Islands) and Santander (Spain). Recent work[2] has suggested that the goby may be identical with *Gobius thori* De Buen[3], a species founded on one specimen from the Aegean Sea collected as long ago as 1910. Further examples from the Mediterranean area are needed to settle this question, but in the meantime it is of interest to record *G. forsteri* from two new localities, extending the known northern limit of distribution by more than 250 miles. These are Dale, Pembrokeshire, and Port Erin, Isle of Man.

At the former, Prof. E. W. Knight-Jones, diving in August 1960, found that *G. forsteri* was "quite common immediately to the south of Dale Point and West Blockhouse Point, near the mouth of Milford Haven, in deep gullies just below the zone of *Laminaria hyperborea*". In the Irish Sea, the species was not revealed until July 11, 1961, when one of us (R. G. H.) discovered the goby on the inner side of a ruined breakwater which extends for some distance across the mouth of Port Erin Bay. At a depth of about 30 ft. (9·2 m), the fishes were seen in crevices of the concrete breakwater blocks or between these and a bottom of muddy sand, at the lower limit of the *Laminaria* zone. Since then, the species has been seen on the opposite side of the bay, below Bradda Head, and there is an unconfirmed record from Perwick Bay, Port St. Mary.

The finding of this hitherto unrecorded fish within a few hundred yards of the Marine Biological Station, Port Erin, directs attention to an ignorance of the bottom fauna of rocky inshore waters which only diving and, to some extent, trapping can remedy. These records provide another indication of how closely *G. forsteri* is tied to its own special habitat of rock crevices and gullies. In the course of field work on Manx gobies from 1958 to 1960, Port Erin Bay and the sea outside the ruined breakwater have been the scene of frequent trawling with a variety of gear—otter trawl, bottom young-fish trawl, and Agassiz trawl—all usually employed with a stramin cover on the cod end to retain small fishes. Within the angle of the breakwater, the bottom has been extensively *D*-netted by Naylor[4], and a fish trap was set in this area in late 1958. Apart from this recent work, the neighbourhood of Port Erin has been studied more or less intensively by marine zoologists since W. A. Herdman and the Liverpool Marine Biological Committee opened their first laboratory there in 1892. None of this work has ever suggested the presence of *G. forsteri* in the area, and the species even escaped notice during a submarine algal survey[5].

The extent to which this goby penetrates the Atlantic boreal region[6] is yet to be determined. Evidence from duration of breeding season is available only for captive specimens in the Plymouth Aquarium, where spawning took place during May–July[1]. This period is rather short for a lusitanian and possibly Mediterranean teleost[7], and suggests that the species may reach its northern limit at the British Isles like *Gobius cobitis* Pallas (= *G. capito* C. and V.)[8] and *G. paganellus* L.[9]. A shortening in duration of breeding season with approach to the northern boundary of the breeding range has been demonstrated in a number of other fishes with similar distribution, including the gobiids *G. paganellus* and *Pomatoschistus flavescens* (Fabr.)[10]. However, *G. niger* L. extends as far north as Trondheimfjord[11] in Norway, and *G. forsteri* could possibly follow suit.

The solution to this problem obviously lies in further exploration of sublittoral areas on rocky coasts of Scotland and Scandinavia. Since the fish in question is readily identified, a search of this type would provide an exercise of scientific interest for a group of amateur divers or local branches of the British Sub-Aqua Club. One of us (P. J. M.) would be pleased to give more details to anyone willing to help in such a project, or to identify any gobies collected by divers, and thanks Prof. E. W. Knight-Jones, Drs. Joanna M. Kain and N. S. Jones, and Mr. D. Eggleston for specimens and information concerning *G. forsteri*.

Dispersal of Coffee Rust *Hemileia vastatrix* B. et Br.

RAYNER[1] has recently stated that uredospores of *Hemileia vastatrix* can be dislodged from pustules by sudden mechanical shock. In this he is in agreement with Nutman, Roberts, and Bock[2], and with Bock[3].

The question is not, however, whether spores can be shaken into the air, but of their subsequent fate. Can such spores cause infection at a distance or not? In other words, is *H. vastatrix* air-borne as are the cereal rusts, or is it distributed over short distances only, by water-splash? Moreover, which of these methods of dispersal is effective in building up seasonal epiphytotics? Rayner[4–6] has supported the former view, and in particular has suggested that the winds of the south-west monsoon carried the disease from Africa (its country of origin) to Asia. Bock[3], on the other hand, using the rotating-rod spore traps of Harrington, Gill and Warr[7], has shown that under field conditions, at wind-speeds of up to 4·9 m.p.h. inside the plantation, spores dislodged by mechanical shock do not rise above the level of the pustules from which they are detached, but fall rapidly to the ground. The data published by Burdekin[8] support Bock's conclusions.

A characteristic of the air-borne rusts, as has been pointed out by Gaumann[9], is that a single spore can cause infection. We have transferred nearly 2,000 counted groups of uredospores of *H. vastatrix* to droplets of water on leaf-disks. Of a total of nearly one thousand 1-spore and 2-spore transfers less than 0·2 per cent resulted in infections, and even with the 10-spore and 20-spore groups only 1·1 per cent of infections were recorded. Groups of 150 spores, however, gave more than 90 per cent of infections. These results are in agreement with those of Bock[3], who, using different techniques, demonstrated that an average concentration of spores on the leaf surface of 15–30 spores per cm.^{2} is necessary for infection.

Bock[3] has also shown, on the basis of 450-hr. trapping in a heavily infected plantation, that if all the spores which became air-borne during a 24 hr. period were concentrated on the lower surfaces of the leaves, this would represent an average of only 0·12 spores per cm.^{2}, too low a number to cause infection. On the other hand, a single shower of 0·8 in. resulted in a concentration of 25 spores per cm.^{2}. He also found that a linear relationship held between the number of spores dispersed on the lower surfaces of leaves, and the amount of rainfall (in excess of 0·3 in.) causing the dispersal.

Rayner[1] has stated that the lesions, because they are confined to the lower surfaces of leaves, would be too infrequently hit by water-splash for this to be the predominant manner of dispersal. We have shown, by flash-photography, that upward splash is entirely adequate for this purpose. In one particular instance, when the leaf bearing the pustule was protected from drops falling from above, precipitation amounting to 0·6 in., completely removed all loose spores from a heavily-encrusted pustule by upward splash from neighbouring leaves alone. The concentration of the spore-suspension falling from the tips of leaves during a rain storm often very greatly exceeds that necessary for infection.

Additional evidence in favour of dispersal by water has been provided by Bock[10] in a study of the development of rust epiphytotics during which the lesions on more than 8,960,000 leaves were counted and recorded more than 5 rust cycles, or two and a half years. He concluded that his data were completely explicable if water-dispersal were effective, but not if spore movement were by air.

The long-range dispersal of *H. vastatrix* has been cited by Rayner[6] as evidence favouring dispersal by air, although Butler[11] considered that movement from Africa to Asia was probably by infected plant material. In fact Rayner[6] has himself given one instance of the introduction of the disease into the New World by this means: fortunately this was detected in time and suppressed. Coffee in South America is still free from the disease—a circumstance inexplicable if long-range dispersal by air were effective.

Full accounts of the work on inoculum-potential and splash-distribution of *H. vastatrix* will appear elsewhere.

Embedding Large Slices of Plant Tissue for Electron Microscopy

THE most suitable impregnating resins for ultra-thin sectioning of plant tissue penetrate very slowly to the centre of large masses of cells. This has restricted the range of problems which can be investigated. The following simple technique, an adaptation of that suggested by Luft[1], was evolved to embed and section successfully pieces of plant tissue, both meristematic and vacuolated, up to 1 mm.^{3}.

Shell 'Epikote Resin 812', which is slightly less viscous than Ciba 'Araldite resin *M*' but otherwise possesses all the virtues of the latter, was used exclusively. Luft's method was followed closely, and the most successful balance of hardeners for meristematic tissue was found to be four parts of the methyl nadic anhydride mixture to six parts of the dodecenyl succinic anhydride mixture. Equal parts of the two hardener mixtures are preferred for slightly harder tissue, for example, vacuolated cells of the root tip of broad bean.

The tissue is isolated, fixed and stained in the conventional way. Potassium permanganate, formaldehyde and osmium tetroxide were all used successfully as fixatives, and no differences in the penetration of the resin were noticed. The tissue is dehydrated through an ascending alcohol series and after the 100 per cent ethanol stage is given two ½-hr. washes in 100 per cent propylene oxide. The blocks of tissue are then transferred to a fresh 10 ml. of propylene oxide, and the complete resin mixture, plus accelerator, is added slowly in 1–2 ml. amounts. The mixture is swirled vigorously between each addition of the resin so that all the resin dissolves. The proportion of resin to solvent is built up slowly over a period of at least a week. The denser the tissue is, the longer this infiltration should be. Finally, the tissue blocks are removed from the resin/solvent mixture, drained on smooth filter paper and allowed to sink through freshly made and well-mixed resin in '00' gelatin capsules. No vacuum treatment is necessary. The blocks are then baked at 35° C. overnight. This lowers the viscosity of the resin, allows the tissue blocks to sink and bubbles to escape. After 12 hr. at this temperature the tissue blocks can be re-orientated and baked for a further two days at 45° C., after which they are ready for sectioning. Silver sections can be used unsupported on 100-mesh hexagonal support grids for low-magnification work and on 200-mesh or 400-mesh for high-magnification work. Millonig's[2] method of section staining to enhance the contrast of osmium tetroxide-fixed material was used successfully, but no section staining is necessary with potassium permanganate fixation.

ENTOMOLOGY

Sterilization of the Codling Moth by Gamma-Irradiation

Work is in progress in British Columbia to determine if the codling moth, *Carpocapsa* (= *Cydia*) *pomonella* (L.), can be eradicated by the sterile male technique, which was used so successfully against the screw-worm, *Callitroga hominivorax* (Cqrl.), in Curaçao[1].

When male pupæ, within 1 day of adult emergence, were exposed to 40,000 rads of γ-radiation, from a cobalt-60 source, dominant lethals were induced in about 99 per cent of the sperm without affecting adult emergence, mating, or adult longevity. Dominant lethality was also induced in 99 per cent of the sperm, without undesirable side effects, when 12–24-hr.-old male moths were subjected to the same dosage. Exposure of male pupæ or adults to higher dosages of radiation reduced the frequency of mating. Dominant lethals were induced in at least 96 per cent of the sperm when mature male larvæ, or eggs that had completed about two-thirds of their development, were subjected to 9,300 rads. However, many of the irradiated insects died before they reached the adult stage, and the frequency of mating was reduced. The female codling moth was sterilized by a lower dosage of γ-radiation than the male. This was true whether the insect was exposed in the egg, larval, pupal, or adult stage, though the difference was most noticeable following pupal irradiation. The female was also more easily killed by γ-radiation than the male, the difference being particularly marked in the egg stage. In general, radiosensitivity of both sexes decreased as development progressed from the egg to the adult stage.

Sperms from irradiated males competed poorly with those from normal males; mating of a single normal female with a single irradiated male (exposed as a pupa to 40,000 rads), either before or after a mating with a normal male, did not prevent the laying of eggs that were mostly viable.

When irradiated male moths (pupæ exposed to 30,000 rads; this dosage induces dominant lethality in about 90 per cent of the sperm) were caged with an equal number of normal female moths, the sex ratio of the adult offspring was approximately 9 males : 1 female. The female offspring were completely sterile, and the males were mostly so, for when they were mated with normal female moths, less than 2 per cent of the eggs laid were viable. However, when irradiated male moths were caged with normal male and female moths, in the proportion of 10 : 1 : 1, the sex ratio of the adult offspring was 1 : 1 and both sexes were mostly fertile.

In laboratory experiments in which (*a*) 50 irradiated males, (*b*) 50 irradiated males and 50 irradiated females, or (*c*) 50 irradiated females (both sexes exposed as pupæ to 30,000 rads), were added to cages containing 5 normal male and 5 normal female moths, the deposition of viable eggs was reduced 98 per cent in (*a*), 66 per cent in (*b*), and 60 per cent in (*c*).

In orchard experiments (cages over dwarf apple trees) in which both irradiated males and females (exposed as pupæ to 40,000 rads) were caged with normal male and female moths, in the proportion of (*a*) 10 : 10 : 1 : 1, and (*b*) 20 : 20 : 1 : 1, the number of adults in the F_1 generation in (*a*) remained about the same as the number of normal adults present in the parent generation, whereas the number of F_1 adults in (*b*) was reduced to one-sixth of the number of normal adults present in the parent generation. However, when irradiated males alone were caged with normal male and female moths, in the proportion of (*c*) 10 : 1 : 1, and (*d*) 20 : 1 : 1, the number of adults in the F_1 generation was reduced in (*c*) to about one-third, and in (*d*) to about one-tenth of the number of normal adults in the parent generation.

These results indicate that the sterile male technique may be a promising method for the control of the codling moth. The method will be tested in the field.

A Survey Method of Trypanosome Infections in *Glossina*

The incidence of trypanosome infections in wild populations of tsetse flies (*Glossina morsitans* West (Muscidae: Diptera)), varies from one locality to another, and seasonal changes also occur. The method hitherto used to determine infection-rates has been the dissection of samples of live flies as described by Lloyd and Johnson[1]. This has the disadvantage of requiring the establishment of a team of microscopists in the bush, so that examination of simultaneously collected samples over wide areas is difficult. The recognition of trypanosomes in the mouthparts of preserved wild *Glossina* is not possible because regurgitation of stomach contents, which may occur when the insect is placed alive in the preservative, renders many of them opaque.

Table 1. COMPARISON OF TRYPANOSOME INFECTION-RATES OBTAINED FROM PRESERVED HEADS AND BY DISSECTION OF LIVE *Glossina*

Area	Dissection of live flies		Preserved heads	
	No. examined	Infected (per cent)	No. examined	Infected (per cent)
A	250	10·8 ± 1·9	250	10·4 ± 1·9
B	359	18·4 ± 2·0	357	15·7 ± 1·9
C	132	26·5 ± 3·8	78	26·9 ± 5·0
	741	17·3 ± 1·4	685	15·0 ± 1·4

We have therefore developed a method in which Survey assistants are issued with small bottles containing methyl alcohol into which the heads of flies, severed with a small pair of scissors, are placed and then sent to the central laboratory for dissection and staining with Giemsa. There is no regurgitation, and trypanosomes can easily be seen and, in most cases, are identifiable (Figs. 1 and 2).

Flies must be lightly held before severing the head to avoid forcing gut contents into the mouthparts. It is also desirable to retain alive, in separate tubes, those flies captured while feeding, preserving the heads only when the mouthparts are free of blood. The method does not permit the recognition of immature infections of the gut nor, of course, of polymorphic trypanosomes in the salivary glands. However, infections of these types are comparatively rare, and for the purposes of investigations relating to the epidemiology of cattle trypanosomiasis the incidence of mature infections other than of *Trypanosoma congolense* and *T. vivax* is seldom important.

Preliminary tests were carried out in three widely separated areas in which flies were alternately either preserved as described or were dissected. The results are given in Table 1. In the live dissection figures infections of the gut only are omitted. There were 23 from all three areas, or 3·1 per cent.

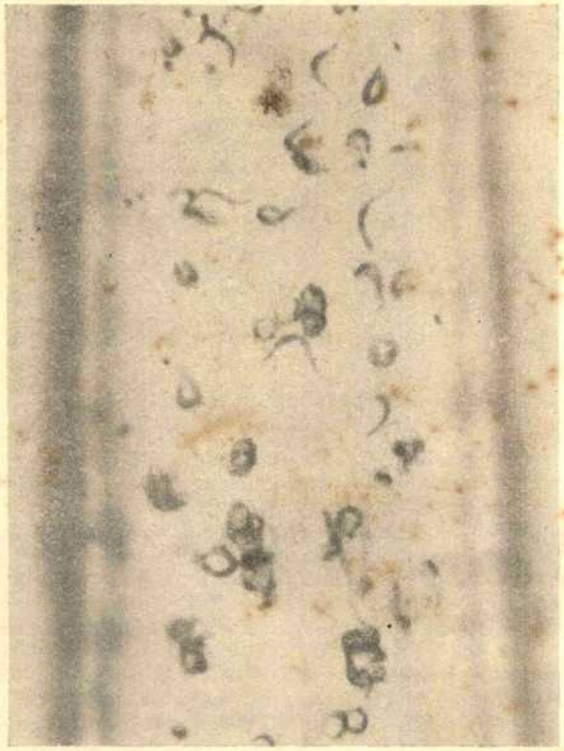

Fig. 1. Diffuse infection of *T. congolense* in labrum of *G. morsitans* preserved in the field. (× 1,200)

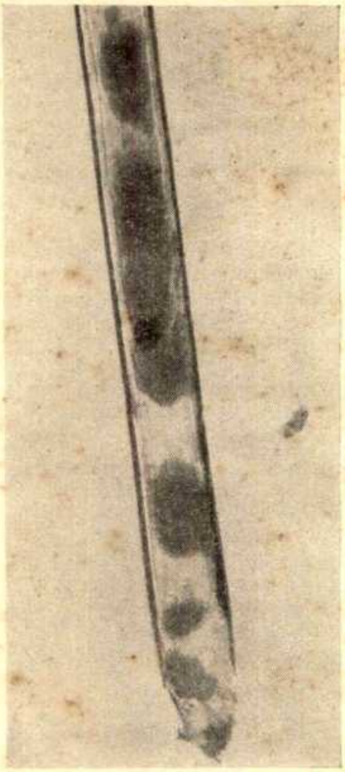

Fig. 2. Dense colonies of *T. congolense* near tip of labrum of *G. morsitans* preserved in the field. (× 180)

A feature of a trial examination of mouthparts of whole preserved flies was the difference in proportion of mouthparts with or without regurgitated blood in male and female flies captured off a bait ox. Of 556 males 40 per cent had regurgitated blood in the mouthparts, but of 150 females 70 per cent were obscured in this manner. This was to have been expected, if, as is generally accepted, male flies come to a bait in part under the influence of stimuli other than hunger, while females attack only to feed.

Flight of Grasshoppers in the Laboratory

OBSERVATIONS on mass flights of the migratory grasshopper, *Melanoplus bilituratus* (Walker) = (*M. mexicanus mexicanus* (Sauss.)), in 1938–40, indicated that large populations had moved 165–575 miles usually in a downwind direction[1]. During these prolonged flights the insects travelled 15–30 miles a day at an average speed of about 10–12 m.p.h. The wind during such flights was between 2 and 10 m.p.h.

The flight time of adults of *Camnula pellucida* (Scudder), *M. bilituratus* and *M. bivittatus* (Say) was measured in a laboratory wind tunnel by suspending them in an air stream on a pendulum-like suspension bar similar to that used by Krogh and Weis-Fogh[2]. The wind speed could be adjusted from 2·2 to 15·4 m.p.h. Flight time was taken as that interval during which the grasshoppers were flying into the wind in a normal flight posture[2] while keeping the suspension bar in a vertical position. Excessive changes in the wing-beat frequency or wing-beat amplitude, occurring at the beginning and at the end of a flight period, caused the suspension bar to deviate from the vertical position. Since changes in such flight characteristics are vital to 'lift'[3], these intervals of 'interrupted' flight were excluded from the data on duration of flight.

It was assumed that so long as the suspension bar remained in a vertical position the flying speed of the grasshopper was equal to the wind speed. In preliminary tests this was shown to be about 5 m.p.h. Air stream velocities greater than 8 m.p.h. interrupted flight and velocities less than 3 m.p.h. failed to maintain the insects in flight.

The duration of continuous flight of well-fed, 1- to 3-week old, laboratory-reared adults, under known conditions of temperature and humidity, is shown in Table 1.

Table 1

	Max. (min.)	Av. (min.)	Temp. (° F.)	R.H. (per cent)	No. of tests
C. pellucida, males	40	27	97–104	10–30	51
C. pellucida, females	180	158	97–104	10–30	48
M. bilituratus, males	163	36	90–106	10–30	36
M. bilituratus, females	134	50	90–106	10–30	42
M. bivittatus, males	40	17	96–105	10–30	45
M. bivittatus, females	70	43	96–105	10–30	51

The best flight was shown by sexually mature adults aged 7–20 days, excluding gravid females. Two- and three-day old *Melanoplus* adults showed a tendency to maintain sustained flight in only 4 out of 41 tests. They usually merely fluttered feebly or extended their tegmina in a 'planing' fashion and rarely assumed the proper flight position. Individuals older than three weeks would fly for a minute or two, flutter asynchronously, and then 'plane'. In more than 90 tests with month-old specimens of *M. bilituratus* and *M. bivittatus*, none would fly continuously for more than a minute. This would tend to substantiate field observations in which ". . . the more mature grasshoppers were continually dropping out (of a swarm) . . ."[1].

Prolonged flight of *C. pellucida* did not occur at temperatures below 95° F. The optimum temperature lay between 100° and 104° F. *M. bilituratus* flew at temperatures as low as 88° F.; but the best prolonged flights were made at about 96° F. *M. bivittatus* were reluctant to start flying. Often their flight was erratic, clumsy, or sporadic, but was maintained by some individuals at about 100° C. Such observations correspond very closely with observations made during natural flights in the field. Parker[4] and Parker *et al.*[1] recorded temperatures of 90°–98° F. during days of high flight activity of '*mexicanus*'. Furthermore, such flights ". . . do not depend upon high temperature alone but are greatly influenced by wind". This was also borne out in laboratory tests.

Increased humidity did not induce any change in the insects' ability to fly. At low humidities (approximately 10 per cent relative humidity) and high temperatures (about 110° F.) *M. bivittatus* became excessively active, ceased flying, kicked violently and went into heat torpor. Increasing the relative humidity to 50 per cent prevented hyperactivity and heat torpor, but it did not improve its flight capacity. The flight behaviour of *M. bilituratus* and *C. pellucida*, at temperatures of 110° F., was similar to that of *M. bivittatus*.

The present laboratory tests indicated that *C. pellucida* females could remain in flight for the longest period of time. They were followed closely by *M. bilituratus*. *C. pellucida* males and both sexes of *M. bivittatus* were relatively poor flyers, especially the latter, which may be regarded as being near sedentary insects. It was also shown that if grasshoppers flew for 3 hr. each day at a speed of 5 m.p.h. and assisted by a wind of some 5–8 m.p.h., they could readily travel distances of 30 miles. These observations point up the non-swarming behaviour of *M. bivittatus*, which is probably a result of the comparative shortness of the wings in relation to the body-weight. They also show the good flight potential of *C. pellucida*, even though this species has never been reported to migrate great distances.

MICROBIOLOGY

Chemotaxis in *Myxococcus*

We have been studying the formation of fruiting bodies by the myxobacterium *Myxococcus xanthus*. One area of concern was the mechanism by which vegetative rods accumulate to form the aggregates which later give rise to mature fruiting bodies. Bonner[1] has suggested that chemotaxis may be involved. Lev[2] and Jennings[3] have described a compound in mature fruiting bodies which can induce fruiting in cells growing on a medium in which fruiting does not ordinarily occur, but it is not clear that their substance attracts vegetative cells.

We have worked out a technique which gives fairly convincing evidence for chemotaxis in *Myxococcus*. It is similar in principle to methods[4] which have been used to detect chemotaxis in the slime amœbæ (*Acrasiales*), a group in which this phenomenon has been adequately dealt with in the literature[5].

Our method is as follows. A culture of strain *FB* of *Myxococcus xanthus* is grown in *C* broth (20 gm. of 'Difco Casitone', 1 gm. of magnesium sulphate, 1·36 gm. of potassium dihydrogen phosphate and 10 gm. of Merck soluble starch per litre of distilled water) with aeration at 30° C. until the concentration is about 3×10^8 cells/ml. About 0·01 ml. of the log phase culture is placed on the surface of a plate of *F* agar (0·8 gm. of 'Difco' nutrient broth powder, 3 gm. of sodium chloride and 15 gm. of 'Difco' powdered agar per litre). The plate is incubated at 30° C. for 24 hr. Then an autoclaved sheet of No. 300 *P. T.* cellulose dialysing membrane (Brosites Machine Corp., Inc., New York) is placed over the surface of the agar and smoothed with a glass rod. A second 0·01 ml. drop of log phase strain *FB* is pipetted on to the membrane above the original spot, and the plate is incubated for three days more.

Growth of the bacteria is more luxuriant below the membrane than above it, but the fruiting bodies which form below the membrane are distorted and flattened. Most of the fruiting bodies which form

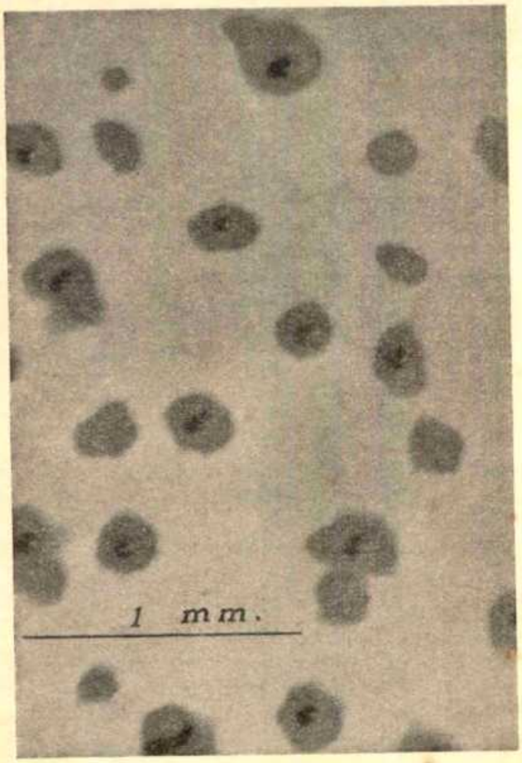

Fig. 1. Fruiting bodies of *Myxococcus xanthus* strain *FB* above and below a dialysing membrane. A drop of a 1:20 dilution of Loeffler's alkaline methylene blue stain was run over the membrane to stain the fruiting bodies lying on top

above the membrane lie directly over those below (Fig. 1). That this is not due to elasticotaxis[6] is suggested by control plates which have glass beads (of about the size of fruiting bodies) below the membrane and bacteria above it. There seems to be no relationship between the positions of the fruiting bodies which form on the membranes under these conditions and the glass beads below.

Our interpretation of these results is that centres of aggregation lying below the membrane excrete a compound capable of passing through the membrane and of initiating the formation of an aggregate (which later becomes a fruiting body) on top of the membrane. The movement of vegetative cells on top of the membrane is oriented towards points where this compound is most concentrated.

We thank Dr. M. Dworkin for a culture of strain *FB*. The senior author was assisted by training grant 2*E*–144, and the junior author was the recipient of research grant *E*–3221(*C*3), both from the U.S. Public Health Service.

Ions and the Germination of Spores of *Bacillus cereus T*

DETAILED experimental analysis of the two major types of aerobic bacterial spores, namely, strains of *Bacillus megaterium* which respond germinatively to the presence of glucose or an L-alanine–inosine mixture[1], have been completed[2,3]. Both organisms exhibited a non-specific requirement for ions, either inorganic or organic, for germination. In solutions of appropriate salts, the exogenous requirements for the above-mentioned organic compounds could be varied, and even eliminated altogether. The over-riding factor in the germination of these two types is ions. We proposed that many ions are intrinsically germinative for these organisms, that the organic adjuvants (glucose, L-alanine, inosine) are dependent on salts for maximal germinative powers, and that they augment the germinative capacity of ions[3]. This situation we call 'ionic germination'.

Ionic germination studies have now been extended to another species, *Bacillus cereus*, strain *T* (formerly *terminalis*), also one of the 'L-alanine–inosine' type. Methods of cultivation, production, and preparation of suspensions of spores, and the optical density method of measuring germination are those commonly used[2,4]. Verification of germination was obtained by microscopic determination of the loss of refractility, acquired darkening, stainability, and by the loss of heat resistance of the spores. Preliminary results indicated that suitably washed spores did not germinate when the L-alanine–inosine mixture was made up in deionized water, but did so promptly when the organic compounds were added to *tris* (10^{-1} *M*) or phosphate ($3 \cdot 3 \times 10^{-2}$ *M*) buffer. A 'titration' experiment in $3 \cdot 3 \times 10^{-2}$ *M* phosphate buffer revealed that a mixture containing as little as 10^{-5} *M* L-alanine and 2×10^{-4} *M* inosine elicited germination of the entire spore population (about 10^{8}/ml.) in 20 min. at 40° C. Table 1 shows that, in phosphate buffer, *B. cereus T* germinated rapidly and completely in the presence of inosine only, but not in the presence of L-alanine only. Germination in 10^{-1} *M tris* buffer was considerably inferior to that in phosphate buffer. Thus, L-alanine is unnecessary, and inosine is essential, in phosphate buffer. The germination obtained in deionized water by the higher concentrations of L-alanine and inosine combined we suspect is due, in part at least, to ionic impurities introduced with these organic compounds. High concentrations of L-alanine, for example, 5×10^{-2} *M*, elicited germination in phosphate buffer, but it was incomplete and clearly inferior to inosine at equivalent concentrations. (After these experiments were completed, there appeared a report[5] of the germination of a strain of *B. cereus* by a high concentration ($1 \cdot 7 \times 10^{-1}$ *M*) of L-alanine in *tris* buffer.) The by-passing of the L-alanine 'requirement' for germination in an appropriate ionic environment resembles the corresponding situation in *B. megaterium* Texas[2,3].

The phosphate buffer contained at least three ionic species, namely, Na^+, K^+, and $PO_4^{\equiv}$. Experiments appropriate for the objective revealed the unexpected fact that sodium ion is critical for the germination of this strain of *B. cereus*. An extension of the testing (Table 2) permits the following conclusions: (*a*) Significant germination did not occur in the absence of added Na^+. A possible exception was the weak activity of the chemically similar Li^+. (However, Na^+ as an impurity is a possibility.) (*b*) The germinative activity of Na^+ depends on the accompanying anions.

These may be inorganic or organic, and they are non-specific, but not all anions are compatible with Na^+ in germination. (*c*) In general, the dependence on the ionic environment is similar to that obtained with the strains of *B. megaterium*, especially the Texas strain[3]. However, important differences are noted for *B. cereus T*, for example, the inactivity of the alkaline earth chlorides, nitrate ion, ammonium salts, or the potassium salts of fluoride, fatty acids, and others. The most active compound tested was sodium acetate (4×10^{-2} *M*), which germinated the entire spore population of *B. cereus T* in less than 10 min. The germinatively active salts, even the most chemically dissimilar ones, by-passed the need for either L-alanine or inosine, but not both (Table 3).

Not enough evidence is at hand yet to gain an insight to the function of the ions in spore germination. However, ionic requirements for germination are exhibited by all the spores tested thus far, and their responses to various ions are different. Obviously, any theory relative to the mechanism of germination has to take into account this phenomenon, and in our hands data obtained on the role of organic adjuvants without due regard to an optimal ionic environment were misleading. Our working hypothesis is that various ions are the primary germinative agents, and non-ionic compounds, such as sugars, amino-acids, and ribosides, which are more or less interchangeable, augment the germinative activities of the ions. A more extended discussion is given elsewhere[3]. This work was supported in part by grants from the Office of Naval Research, the National Institutes of Health, and the National Science Foundation.

VIROLOGY

Effect of Œstrogenic Hormones on Agglutinability of Chicken Erythrocytes by Arthropod-borne Viruses

IN an earlier paper[1] from this laboratory it was shown that cock erythrocytes are agglutinated by diphasic tick-borne encephalitis virus, whereas hen erythrocytes usually are not agglutinated.

Further studies have revealed that this sex difference in the agglutinability of chicken erythrocytes is not limited to the tick-borne encephalitis virus but seems to be a phenomenon common to all arthropod-borne group *A* and *B* viruses. The difference can be demonstrated with sucrose-acetone extracted mouse brain antigens[2] as well as with tissue culture antigens prepared in an inhibitor-free maintenance medium[3]. When the agglutinability of erythrocyte samples was examined with these tissue culture hæmagglutinins at room temperature, the red

* Reciprocal of highest dilution showing hæmagglutination, per 0·5 ml.

blood cells of all the hens tested were found to be inagglutinable, whereas cells from different cocks were always agglutinated and to approximately the same titre (Table 1). If the mouse brain or tissue culture antigens are treated with protamine sulphate, however, such antigens are, for some as yet unknown reason, also capable of agglutinating hen erythrocytes to some extent, the sex difference then being less marked.

Since red blood cells of newly hatched chicks are equally agglutinable irrespective of sex, it is evident that females must lose the reactivity of their erythrocytes at some time in their lives. This time was found to coincide with the attainment of sexual maturity at the age of 4–5 months when the hens started to lay.

From the above observation it was inferred that female sex hormones may play some part in this disappearance of agglutinability. Experiments were therefore performed to test the effect of various sex hormones on the agglutinability of chicken erythrocytes. Cockerels weighing about 0·5 kgm. were given three intramuscular injections at 24-hr. intervals of one of the following hormones: œstradiol benzoate, 5 mgm.; diethylstilbœstrol, 5 mgm.; progesterone, 25 mgm.; testosterone propionate, 25 mgm.; each group consisting of three fowls. These amounts of the hormones were dissolved in 1 ml. of peanut oil. Erythrocyte samples were taken from a wing vein 1, 3, 5, 7, and 9 days after the last hormone injection. The agglutinability of the erythrocyte samples was determined with tissue culture antigens prepared from nine group *A* or *B* arbor viruses (Table 1). The tests were carried out at six different *p*H's ranging from 5·8 to 6·8 at room temperature according to the technique described by Clarke and Casals[2].

It appeared that neither progesterone nor testosterone propionate had any effect on the agglutinability of the erythrocytes. On the other hand, both œstradiol benzoate and diethylstilbœstrol resulted in complete or almost complete disappearance of the agglutinability. With the strongest hæmagglutinins, traces of hæmagglutination were sometimes seen. This change in agglutinability was transitory and lasted 5–7 days after hormone administration was discontinued, the agglutinability then gradually reappearing. With a single dose of 25 mgm. of œstradiol benzoate or diethylstilbœstrol, the same effect on agglutinability could be produced in adult cocks, too.

In adsorption experiments with tick-borne encephalitis virus carried out following methods described in an earlier paper[4], there was a clear correlation between agglutinability of the erythrocytes and their capacity for adsorption of the virus. Again, cells which were not agglutinable did not adsorb virus either.

It is known from the work of Entenman *et al.*[5] that the œstrogens produce a hyperlipæmia in the plasma of chickens, the levels of all the lipid classes of the plasma being increased. A possible explanation for the effect of œstrogenic hormones on agglutinability is that virus receptors on the surface of red cells may become coated with some substance from the hyperlipæmic plasma. Another possibility is that the œstrogens may reduce the number of arbor virus receptors on chicken erythrocytes. Investigations to ascertain the mechanism of the phenomenon described here are in progress.

In this connexion it is interesting that a similar sex difference in agglutinability was also observed with turkey erythrocytes during the period of egg-laying. Goose erythrocytes, on the other hand, which were introduced by Porterfield[6] for hæmagglutination studies with arbor viruses, do not exhibit this sex difference.

The hormone preparations used were supplied by Lääketehdas Orion Oy and Oy Medica Ab, Pharmaceutical Manufacturers, Helsinki. This work was aided by a grant from the Sigrid Jusélius Foundation.

Some Characteristics of a Virus occurring in Poplars

DURING the past few years the Plant Protection Service of the Netherlands and the Netherlands General Inspection Board of Arboriculture (N.A.K.B.) have paid much attention to a virus disease of poplars resembling Canadian poplar mosaic described by Atanasoff[1], and poplar mosaic mentioned by Klinkowski[2]. The N.A.K.B. tries to eliminate the disease by certifying only non-affected trees and by destroying affected stocks.

The disease is known to attack all commercial cultivars of the section Aigeiros Duby (*Populus canadensis* Moench). These are, arranged in decreasing order of conspicuousness of symptoms, *P. deltoides* Marsh and *P. canadensis* Moench cv. *robusta, heidemij, gelrica, serotina, marilandica*. Poplars of the section *Leucoides Spach* also show symptoms.

In June, light green spots emerging from the smaller veins of the spring leaves develop into distinct star-like patches. On *robusta* and *gelrica* in particular the spots soon become yellow. By late summer and autumn the symptoms have progressed as far as the older summer leaves. Seriously affected trees show symptoms extending far into the top leaves.

From fresh poplar leaves a virus was transmitted by the sap to various herbaceous hosts. Cowpea (*Vigna sinensis* Endl. var. Giant Black Eye) and *Petunia hybrida* Vilm. were among those found to be susceptible to the virus, cowpea in particular proving to be a good test plant. The inoculated primary leaves, after incubation for about 10 days, develop red local lesions which sometimes extend along the veins. After more than 20 days, systemic symptoms appear on the younger leaves, vein-clearing being followed by numerous red spots, especially near the veins.

On *Petunia hybrida* the symptoms are not very clear, semi-necrotic rings occasionally appearing in mature inoculated leaves about 25 days after inoculation. However, the virus could also be demonstrated to be present in inoculated leaves which had failed to develop symptoms.

Compared with other methods of mechanical transmission a modification of the leaf contact method[3] proved to be the most efficient. Poplar leaves were folded several times, cut with a blade to obtain an exposed surface, and dipped in a phosphate buffer solution (*p*H 7·5). Inoculation was then performed by wiping the exposed surfaces over the test leaves which had been dusted with 'Carborundum'. The inoculated leaves were washed immediately after inoculation.

Juice pressed from affected cowpea plants was diluted 1/10 in 0·01 *M* phosphate buffer *p*H 7, whereupon the temperature inactivation point and the dilution endpoint of this crude virus solution was determined[4]. No infectivity could be demonstrated after 10 min. heating at 54° C. nor after dilution to 1/10,000.

Virus preparations observed under the electron microscope revealed the presence of elongated rod-shaped particles. These uniform particles were found not only in a partly purified virus suspension derived from diseased poplar leaves but also in specimens prepared by the dip method[5] from poplar, cowpea and petunia leaves showing symptoms. Provisional measurements of 250 virus particles suggested an average length of about 735 mμ.

Other means are also being used in an attempt to identify the virus.

PSYCHOLOGY

Absolute Threshold for Electric Shock

For some time it has been suspected that the most relevant parameter when using electric shock as a stimulus is the applied wattage. Forbes and Bernstein[1], Gilmer[2], Hill *et al.*[3], Campbell and Teghtsoonian[4], Green[5], all found evidence to support this contention. Although constant current and constant voltage outputs have long been in use, a device capable of supplying a constant power output compensating for the changes in impedance found in any biological circuit has not hitherto been available.

To obtain a constant power output it is necessary to monitor continuously the instantaneous product of voltage and current, to compare this with a reference, and use the resultant error signal to control the output of the generator. This is achieved by continuously comparing the load current with a function proportional to the reciprocal of the load voltage. This function is derived by width-modulation, followed by integration and smoothing, of pulses generated by a phantastron triggered at 2·5 kc./sec. The error signal is arranged to control the generator output by way of a high-gain d.-c. amplifier. (The apparatus was designed by Mr. B. Corbett and supplied by Messrs. System Research Ltd.)

In the present experiment the three types of output, constant current, current voltage and constant power, were all used in conjunction with three sizes of electrode, 0·075, 0·15 and 0·3 in. diameter, giving nine conditions in all. On each trial a rectangular d.-c. stimulus of 1 sec. duration was applied to the ball of the thumb and index finger of the left hand. Thresholds were determined for all nine conditions using standard psycho-physical procedures.

A total of some 12,000 trials, including training series, were needed to obtain reliable thresholds. The experimenter acted as his own subject for this first experiment.

The results were quite clear cut. The threshold in terms of power remained close to 50 mW. regardless of the area of contact. The current threshold increased from 225 μamp. with the smallest electrodes to 458 μamp. with the largest electrodes, while the threshold in terms of voltage fell from 220 to 101 V. Current density, voltage density and all other indices also failed to provide a stable measure of the threshold.

Clearly, then, power is the single best measure of the shock threshold, since a 16-fold increase in the area of contact does not materially alter this index, but does affect other indices substantially and systematically.

The results of a second experiment make it necessary to qualify this general statement. A further three thresholds were determined for the three types of stimulus, using electrode jelly to improve contact with the medium-sized electrodes. Under these conditions the threshold dropped to 18 mW. This suggests that the crucial factor is the power dissipated in the subcutaneous tissues where the receptors actually lie. This view is supported by the casual observation that there would appear to be a simple, direct relationship between the thickness of a subject's skin and his threshold. A fine, delicate skin, such as many women possess, seems to go with a low threshold, while the man who works with his hands and has a coarse, heavy skin has a far higher threshold.

Since an experimenter being his own subject invites the classic bias of stimulus error, it was thought advisable to repeat the main part of the experiment with a completely naïve subject. The three types of stimulus were used with the largest and smallest pairs of electrodes, without electrode jelly.

Under constant power conditions the threshold was close to 32 mW. with both large and small electrodes. The current threshold increased substantially with the larger electrodes, while the voltage threshold dropped proportionally even more. This result therefore confirms the main finding that under constant power conditions the threshold in mW. is independent of the area of contact.

From a practical point of view two conclusions appear to be worth considering.

(1) As a negative reinforcer, where the experimental animals run over a grid, it is obviously of little use to control either the voltage or the current, as this leaves the wattage to vary with the area of contact. In these circumstances it would therefore pay to standardize shock as a negative reinforcer in terms of wattage. Since also the stimulus is felt only on

the make and break there is a strong argument in favour of using a.c. rather than d.c. stimulation. This would make it impossible for the animal to control the frequency of the shock by freezing on the grid.

(2) As an agent in shock 'therapy' the implications are more serious. The occasional unfortunate demise of a patient who is receiving the 'therapy' suggests that there are times when the stimulus may have exceeded its intended effect. If the wattage were controlled rather than the voltage or current it is possible that some of these mishaps might be avoided.

Effect of Strain and Group Size on the Response of Mice to 'Seconal' Anæsthesia

The uniformity of first crosses of inbred strains as compared with the parental stocks has now been demonstrated on a number of occasions and the literature on the subject has been extensively reviewed by Lerner[1] and by Biggers, McLaren and Michie[2]. The work of Michie and McLaren[3,4] is of particular interest here for, as well as demonstrating the effect of heterosis on variation, they used as their metameter barbiturate sleeping time in mice. The work reported here was an investigation of the interaction between this genetic influence on variation and an aspect of the social environment, group size.

Indications that the numbers of animals caged together before an experiment influence variation have been provided almost entirely by the work of Chance. He showed, for example, that in gonadotrophin assays in rats the lowest variance was recorded in animals maintained in groups of two before the experiment and that solitary animals were most variable[5]. Chance also found in a preliminary survey that mice kept six in a cage were more variable than mice two per cage as judged by their response to 'Nembutal'.

The experiments to be described here were carried out as follows: Inbred mice of the *CE* and *CBA* strains were supplied to us when they were approximately five weeks old. After arrival they were kept in groups of 30–50 for one week to allow acclimatization and were then set up in the experimental groups of 1, 2 and 8 per cage. They were housed under reversed lighting conditions and at constant temperature. The animals were anæsthetized three days after setting up the experiment and again a week later; thus in part 1 of the tests the animals had been in their number groups for three days and in part 2 for ten days. The anæsthetic used was quinalbarbitone sodium ('Seconal'), a solution of which was prepared by grinding up proprietary tablets in distilled water. The injection route was intraperitoneal and the dose was graded for body-weight in order to give a mean anæsthetic time of approximately 20 min. For the purpose of the experiment a mouse was assumed to be anæsthetized if it failed to give a righting reflex when placed on its back. Two mouse rolling machines were constructed so that 24 animals could be examined at one time. The animals were examined at 2-min. intervals from the time of injection until, on recovery, they gave a righting reflex on three successive trials. After this they were removed from the machine.

The results are shown in Table 1: as each strain was tested twice, the figure given is the weighted mean of two within day, within strain, within number group variances. Michie and McLaren used a logarithmic transformation on their anæsthetic times, but such a treatment was not consistent with the observed distribution of our data and therefore the actual anæsthetic times in minutes were used to calculate the variances shown.

Table 1

Strain	Part 1			Part 2		
	No. per cage					
	1	2	8	1	2	8
	Variance					
CE	143	101	185	248	76	186
CBA	620	398	448	297	83	420
CBA♂ × *CE*♀F_1	52	50	130	78	68	88
CE♂ × *CBA*♀F_1	93	91	119	74	77	203

Three points emerge from these results. First, that there is an effect ascribable to genetic homeostasis; it is clear that the variance of the F_1 hybrids is considerably less than that of the parental stocks (cf. Michie and McLaren[4]). Secondly, the strains themselves are different in their response, the *CBA* strain being more variable than the *CE* strain. The *CE* × *CBA* hybrid is more variable than the reciprocal cross and shows, as does the maternal strain, a high variation in groups of eight animals that have been together for ten days. This would indicate that some maternal effect is involved. Thirdly, the 2-per-cage group is less variable than are the solitary animals or groups of 8-per-cage. This effect is most marked at ten days and in the pure lines.

It has frequently been observed[6,7] that isolated mice become aggressive and the high variation shown by this number group may be connected with the behavioural disturbance involved in isolation. Grant and Chance[8] have shown that rank orders are only demonstrable in male laboratory rats when the numbers caged together are less than six. Uhrich[9] showed rank orders in groups of laboratory mice (3–6 per cage) and if the same numerical limits apply to this species as to the rat it is possible that the low variation shown by the 2-per-cage group as compared with the 8-per-cage group is a reflexion of the stable social situation of the former. If so, this effect, which reduces the variation in the response as much as does the heterozygosity of the F_1 hybrid, might be called by parallel nomenclature 'social homeostasis'.

I thank the Universities Federation for Animal Welfare for the junior research fellowship which enabled me to undertake this work and for financial assistance.

FORTHCOMING EVENTS

Monday, July 2—Friday, July 13

Imperial College of Science and Technology, Department of Chemical Engineering and Chemical Technology (at Imperial College, London, S.W.7)—Summer School in "Health Physics (Radiation Protection)".

Monday, July 2—Thursday, July 5

Second Congress of the International Federation of Societies of Cosmetic Chemists (at the School of Pharmacy, 29–39 Brunswick Square, London, W.C.1).

Tuesday, July 3

Royal Society of Medicine (at 1 Wimpole Street, London, W.1), at 5.30 p.m.—Annual Meeting.

Wednesday, July 4

Institution of Electrical Engineers, Utilization Section (at Savoy Place, London, W.C.2), at 9.30 a.m.—Symposium on "A.C. Railway Electrification".

Thursday, July 5—Friday, July 6

Institute of Physics and the Physical Society, Spectroscopy Group (in collaboration with the British Non-Ferrous Metals Research Association and the British Iron and Steel Research Association, at the Spa Hotel, Buxton, Derbyshire)—Symposium on "Spectroscopy in the Metallurgical Industry".

Monday, July 9—Thursday, July 12

British Institution of Radio Engineers; Institute of Physics and the Physical Society; and the University of Birmingham (in the Electrical Engineering Department, The University, Birmingham)—Symposium on "Sonar Systems".

APPOINTMENTS VACANT

Applications are invited for the following appointments on or before the dates mentioned:

Assistant Lecturer in Biochemistry—The Registrar, University College of Wales, Aberystwyth (July 5).

Assistant Lecturer (with a degree in a biological subject) in Zoology, to teach biology and human anatomy and physiology to "O" level and zoology to "A" level and degree level—The Principal, Wigan and District Mining and Technical College, Wigan (July 5).

Lecturer (with experience in the use of digital computers and in numerical analysis) in the Computing Laboratory—The Secretary of University Court, The University, Glasgow (July 6).

Assistant Lecturer, Grade B (graduate, preferably with experience in teaching, research or industry) in Chemistry—The Clerk to the Governors, Mid-Essex Technical College and School of Art, Market Road, Chelmsford, Essex (July 7).

Lecturer or Assistant Lecturer in Radioastronomy—The Registrar, The University, Manchester 13 (July 7).

Lecturer (with a good honours degree in pharmacy) in Pharmacy—The Registrar, The University, Manchester 13 (July 7).

Assistant Lecturer or Lecturer (honours graduate in either oceanography, physics or mathematics, and willing to spend several weeks each year at sea) in the Department of Oceanography—The Registrar, The University, Liverpool, quoting Ref. No. CV/101/N (July 9).

Lecturer or Assistant Lecturer in Numerical Analysis in the Department of Applied Mathematics—The Registrar, The University, Liverpool, quoting Ref. No. CV/112/T (July 9).

Lecturer or Assistant Lecturer in Biological Chemistry—The Registrar, The University, Manchester 13 (July 12).

Lecturer or Assistant Lecturer (man or woman graduate) in the Department of Chemistry—The Secretary, Bedford College (University of London), Regent's Park, London, N.W.1 (July 12).

Lecturer (Grade II) in Veterinary Pathology in the Clinical Laboratory of the Veterinary Medicine Department at Langford (Bristol 13 miles)—The Registrar and Secretary, The University, Bristol (July 13).

Assistant Lecturer (to teach through the medium of Welsh) in the Department of Philosophy; and an Assistant Lecturer in Psychology—The Registrar, University College of Wales, Aberystwyth (July 14).

Lecturer or Assistant Lecturer in Physics—The Registrar, The University, Sheffield (July 14).

Research Assistant (graduate in chemistry or geology) in Geology, to assist Dr. C. S. Exley in spectrographic work—The Professor of Geology, The University, Keele, Staffs (July 14).

Professor of Electronic Computation and Director of the Digital Computing Laboratory, School of Electrical Engineering, University of New South Wales—The Agent-General for New South Wales, 56–57 Strand, London, W.C.2; and the Appointments Section, The University of New South Wales, Box 1, Post Office, Kensington, New South Wales, Australia (July 20).

Assistant Lecturer (with a degree in chemistry, agricultural chemistry or agriculture with a strong interest in chemistry) in Agricultural Chemistry—The Principal, Seale-Hayne Agricultural College, Newton Abbot, Devon (July 21).

Cytologist (honours graduate in botany or agricultural botany), for work involving some general routine examination of grasses, cereals and potatoes, but original research would be encouraged, particularly in connexion with the genecological studies of hill land species now in progress—The Secretary, Scottish Plant Breeding Station, Pentlandfield, Roslin, Midlothian (July 21).

Head (electrical engineer of high academic distinction, experience of research and teaching to Dip.Tech. or final degree standard, and preferably industrial experience) of the Electrical Engineering Department (Grade IV), Brighton College of Technology—The Director of Education, Brighton Education Committee, 54 Old Steine, Brighton, Sussex (July 23).

Chair of Agricultural Biology; and Chair of Agricultural Economics in the University College, Ibadan, Nigeria—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (July 25).

Senior Lecturer in Chemistry at the Royal College, Nairobi—The Secretary, Inter-University Council for Higher Education Overseas, 29 Woburn Square, London, W.C.1 (July 28).

Graduate Metallurgist, for fundamental research on deformation and fatigue in metals—The Registrar, The College of Aeronautics, Cranfield, Bletchley, Bucks.

Laboratory Technician (Physics) (preferably with electronics experience), for work on a D.S.I.R. supported project dealing with extreme infra-red spectroscopy—The Registrar (PT), Queen Mary College (University of London), Mile End Road, London, E.1.

Phillips Petroleum Fellow in Polymer Science, to work in the general field of the polymerization of cyclic ethers—Prof. Geoffrey Gee, Department of Chemistry, The University, Manchester 13.

Research Assistant in Organic Chemistry, to work on some aspects of the chemistry of nucleic acids and their derivatives under the supervision of Dr. G. Shaw—The Registrar, Bradford Institute of Technology, Bradford 7.

Senior or Chief Technician (graduate or experienced technician with a special interest in training junior staff, advising research students and maintaining and devising apparatus) in the Department of Zoology—The Assistant Bursar, The University, Reading, Berks.
